**ROBERT D. BALLARD**

ENCYCLOPEDIA OF

# VOLCANOES

According to Greek Mythology, the giant Typhon is buried under Etna volcano. Whenever the giant stirs, the volcano erupts violently. Eighteenth century print. (See *The History of Volcanology*, p. 15.)

# ENCYCLOPEDIA OF VOLCANOES

Editor-in-Chief

**HARALDUR SIGURDSSON**

ARTICLE INDEX	XI	MELTING THE MANTLE	55
CONTRIBUTORS	XIII	<i>Paul D. Asimow</i>	
FOREWORD	XIX	MIGRATION OF MELT	69
<i>Robert D. Ballard</i>		<i>Martha J. Daines</i>	
PREFACE	XXI	PLATE TECTONICS AND VOLCANISM	89
<i>The Editors</i>		<i>Michael R. Perfit and Jon P. Davidson</i>	
GUIDE TO THE ENCYCLOPEDIA	XXIII	COMPOSITION OF MAGMAS	115
INTRODUCTION	1	<i>Nick Rogers and Chris Hawkesworth</i>	
<i>Haraldur Sigurdsson</i>			
THE HISTORY OF VOLCANOLOGY	15	ORIGIN OF MAGMAS	133
<i>Haraldur Sigurdsson</i>		<i>Timothy L. Grove</i>	
		VOLATILES IN MAGMAS	149
		<i>Paul Wallace and Alfred T. Anderson, Jr.</i>	
<hr/> PART I			
ORIGIN AND TRANSPORT OF MAGMA		PHYSICAL PROPERTIES OF MAGMAS	171
		<i>Frank J. Spera</i>	
MANTLE OF THE EARTH	41	MAGMA CHAMBERS	191
<i>Raymond Jeanloz</i>		<i>Bruce D. Marsh</i>	

RATES OF MAGMA ASCENT <i>Malcolm J. Rutherford and James E. Gardner</i>	207	BASALTIC VOLCANIC FIELDS <i>Charles B. Connor and F. Michael Conway</i>	331
PLUMBING SYSTEMS <i>Charles R. Carrigan</i>	219	FLOOD BASALT PROVINCES <i>Peter R. Hooper</i>	345
MAGMA ASCENT AT SHALLOW LEVELS <i>Claude Jaupart</i>	237	SUBMARINE LAVAS AND HYALOCLASTITE <i>Rodey Batiza and James D. L. White</i>	361
		SEAMOUNTS AND ISLAND BUILDING <i>Ralf Schmidt and Hans-Ulrich Schmincke</i>	383
		SUBGLACIAL ERUPTIONS <i>John L. Smellie</i>	403
<hr/>			
<b>PART II</b> <b>ERUPTION</b>			
EARTH'S VOLCANOES AND ERUPTIONS: AN OVERVIEW <i>Tom Simkin and Lee Siebert</i>	249	<hr/>	
SIZES OF VOLCANIC ERUPTIONS <i>David M. Pyle</i>	263	<b>PART IV</b> <b>EXPLOSIVE VOLCANISM</b>	
VOLCANIC EPISODES AND RATES OF VOLCANISM <i>Haraldur Sigurdsson</i>	271	MAGMATIC FRAGMENTATION <i>K. V. Cashman, B. Sturtevant, P. Papale, and O. Navon</i>	421
		PHREATOMAGMATIC FRAGMENTATION <i>Meghan Morrissey, Bernd Zimanowski, Kenneth Wobletz, and Ralf Buettner</i>	431
<hr/>			
<b>PART III</b> <b>EFFUSIVE VOLCANISM</b>			
BASALTIC VOLCANOES AND VOLCANIC SYSTEMS <i>George P. L. Walker</i>	283	HAWAIIAN AND STROMBOLIAN ERUPTIONS <i>S. Vergniolle and M. Mangan</i>	447
LAVA FLOWS AND FLOW FIELDS <i>Christopher R. J. Kilburn</i>	291	VULCANIAN ERUPTIONS <i>Meghan M. Morrissey and Larry G. Mastin</i>	463
LAVA DOMES AND COULEES <i>Jonathan H. Fink and Steven W. Anderson</i>	307	PLINIAN AND SUBPLINIAN ERUPTIONS <i>Raffaello Cioni, Paola Marianelli, Roberto Santacroce and Alessandro Sbrana</i>	477
LAVA FOUNTAINS AND THEIR PRODUCTS <i>John A. Wolff and Janet M. Sumner</i>	321	SURTSEYAN AND RELATED PHREATOMAGMATIC ERUPTIONS <i>James D. L. White and Bruce Houghton</i>	495
		PHREATOPLINIAN ERUPTIONS <i>B. F. Houghton, C. J. N. Wilson, R. T. Smith, and J. S. Gilbert</i>	513

VOLCANIC PLUMES <i>Steven Carey and Marcus Bursik</i>	527	VOLCANISM ON VENUS <i>L. S. Crumpler and Jayne C. Aubelle</i>	727
PYROCLAST TRANSPORT AND DEPOSITION <i>Colin J. N. Wilson and Bruce F. Houghton</i>	545	VOLCANISM ON MARS <i>James R. Zimbelman</i>	771
PYROCLASTIC FALL DEPOSITS <i>B. F. Houghton, C. J. N. Wilson, and D. M. Pyle</i>	555	CRYOVOLCANISM IN THE OUTER SOLAR SYSTEM <i>Paul Geissler</i>	785
PYROCLASTIC SURGES AND BLASTS <i>Greg A. Valentine and Richard V. Fisher</i>	571		
IGNIMBRITES AND BLOCK-AND-ASH FLOW DEPOSITS <i>A. Freundt, C. J. N. Wilson, and S. N. Carey</i>	581	<hr/>	
LAHARS <i>James W. Vallance</i>	601	PART VI	
DEBRIS AVALANCHES <i>Tadahide Uti, Shinji Takarada, and Mitsuhiko Yoshimoto</i>	617	VOLCANIC INTERACTIONS	
VOLCANICLASTIC SEDIMENTATION AROUND ISLAND ARCS <i>Steven Carey</i>	627	VOLCANIC GASES	803
CALDERAS <i>Peter W. Lipman</i>	643	<i>Pierre Delmelle and John Stix</i>	
COMPOSITE VOLCANOES <i>Jon Davidson and Shan De Silva</i>	663	GEOTHERMAL SYSTEMS	817
SCORIA CONES AND TUFF RINGS <i>Dirk Vespermann and Hans-Ulrich Schmincke</i>	683	<i>Fraser Goff and Cathy J. Janik</i>	
		SURFACE MANIFESTATIONS OF GEOTHERMAL SYSTEMS WITH VOLCANIC HEAT SOURCES	835
		<i>Manfred P. Hochstein and Patrick R. L. Browne</i>	
		DEEP OCEAN HYDROTHERMAL VENTS	857
		<i>David A. Butterfield</i>	
		VOLCANIC LAKES	877
		<i>Pierre Delmelle and Alain Bernard</i>	
		MINERAL DEPOSITS ASSOCIATED WITH VOLCANISM	897
		<i>Noel C. White and Richard J. Herrington</i>	

---

PART V  
EXTRATERRESTRIAL VOLCANISM

VOLCANISM ON THE MOON <i>Paul D. Spudis</i>	697
VOLCANISM ON IO <i>Rosalyn Lopes-Gautier</i>	709

---

PART VII  
VOLCANIC HAZARDS

VOLCANIC ASH HAZARDS TO AVIATION <i>T. P. Miller and T. J. Casadevall</i>	915
---	-----

VOLCANIC AEROSOL AND GLOBAL ATMOSPHERIC EFFECTS <i>Michael J. Mills</i>	931	GROUND DEFORMATION, GRAVITY, AND MAGNETICS <i>John B. Murray, Hazel Rymer, and Corinne A. Locke</i>	1121
HAZARDS FROM PYROCLASTIC FLOWS AND SURGES <i>Setsuya Nakada</i>	945	GAS, PLUME, AND THERMAL MONITORING <i>John Stix and Hélène Gaonac'h</i>	1141
LAVA FLOW HAZARDS <i>Donald W. Peterson and Robert I. Tilling</i>	957	SYNTHESIS OF VOLCANO MONITORING <i>Stephen R. McNutt, Hazel Rymer, and John Stix</i>	1165
THE HAZARD FROM LAHARS AND JÖKULHLAUPS <i>Kelvin S. Rodolfo</i>	973	VOLCANO WARNINGS <i>Christopher G. Newhall</i>	1185
HAZARDS OF VOLCANIC GASES <i>Glyn Williams-Jones and Hazel Rymer</i>	997	VOLCANIC CRISES MANAGEMENT <i>Servando De La Crùz-Reyna, Roberto Meli P., and Roberto Quaas W.</i>	1199
VOLCANIC TSUNAMIS <i>James E. Beget</i>	1005	VOLCANIC HAZARDS AND RISK MANAGEMENT <i>Russell Blong</i>	1215
VOLCANIC SEISMICITY <i>Stephen R. McNutt</i>	1015	RISK EDUCATION AND INTERVENTION <i>David Johnston and Kevin Ronan</i>	1229
IMPACTS OF ERUPTIONS ON HUMAN HEALTH <i>Peter J. Baxter</i>	1035	<hr/>	
VOLCANIC CONTRIBUTIONS TO THE CARBON AND SULFUR GEOCHEMICAL CYCLES AND GLOBAL CHANGE <i>Michael A. Arthur</i>	1045	<b>PART IX</b>	
THE ECOLOGY OF VOLCANOES: RECOVERY AND REASSEMBLY OF LIVING COMMUNITIES <i>Ian W. B. Thornton</i>	1057	ECONOMIC BENEFITS AND CULTURAL ASPECTS OF VOLCANISM	
VOLCANISM AND BIOTIC EXTINCTIONS <i>Michael R. Rampino and Stephen Self</i>	1083	EXPLOITATION OF GEOTHERMAL RESOURCES <i>Stefán Arnórsson</i>	1243
<hr/>		VOLCANIC SOILS <i>Chien-Lu Ping</i>	1259
<b>PART VIII</b>		VOLCANIC MATERIALS IN COMMERCE AND INDUSTRY <i>Jonathan Dehn and Stephen R. McNutt</i>	1271
ERUPTION RESPONSE AND MITIGATION		VOLCANOES AND TOURISM <i>Haraldur Sigurdsson and Rosaly Lopes-Gautier</i>	1283
SEISMIC MONITORING <i>Stephen R. McNutt</i>	1095

## FOREWORD

If one could drain the world's oceans and remove their sediment cover, one would quickly realize that the majority of the Earth's surface is covered with lava flows. Although the human race has lived in close contact with volcanic activity since our early origins in the African Rift Valley, only recently have we begun to comprehend how volcanically active our planet really is. Even more recently, exploration of our solar system shows us that volcanism has played and continues to play an important role in the early genesis and subsequent evolution of both the planets and the moons within our solar system and beyond.

Given our growing awareness of the importance of volcanism to the past, present, and future history of Earth and its celestial partners, the publication of the *Encyclopedia of Volcanoes* is clearly needed and appropriate at this time. Thanks to the efforts of Editor-in-Chief Dr. Haraldur Sigurdsson and his highly qualified Associate Editors and contributing authors, the *Encyclopedia of Volcanoes* is drawn from a vast and enlarging data base.

I was first introduced to volcanoes by Dr. Sigurdsson in the early 1970s. At the time, I was preparing for the first manned exploration of the Mid-Ocean Ridge during Project FAMOUS. This was a critical time in the earth sciences when our community sought to better

understand this mighty undersea mountain range and the important role its volcanic and tectonic processes played in the then newly evolving concept of plate tectonics and seafloor spreading.

I vividly remember traveling with Haraldur to his native country of Iceland, which sits astride the Ridge. There we scaled one volcano after another, including Surtsey, Eldfell, and Krafla. That introduction to terrestrial volcanism prepared me for the many years I would spend investigating undersea volcanic processes.

Those efforts eventually led to the discovery of hydrothermal vents in 1977 and the exotic life forms that live on the internal energy of the Earth through a process we now know as chemosynthesis. That effort was followed in 1979 with our discovery of high-temperature "black smokers" and a clearer understanding of the chemistry of the world's oceans.

Since that time the study of volcanism has expanded rapidly, branching out to embrace many fields of research. As a result, the study of volcanism is no longer an isolated field of research but one closely linked to other disciplines and areas of research including the chemistry of the world's oceans and atmosphere, the creation of important mineral assemblages, the role volcanism has played in the origin of life as well as its

negative impact upon biological evolution, and most recently its impact upon mankind itself.

The *Encyclopedia of Volcanoes* has been an immense undertaking involving the collective efforts of over 100 international experts on the subject, resulting in a 1000-page volume broken down into 82 chapters.

Clearly, this volume is the most comprehensive presentation on this subject, a work important to those in

the field as well as to others seeking a broader understanding of this subject.

## PREFACE

The *Encyclopedia of Volcanoes* is a complete reference guide, providing a comprehensive view of volcanism on the Earth and on the other planets of the Solar System that have exhibited volcanic activity. It is the first attempt to gather in one place such a vast store of knowledge on volcanic phenomena.

The volume addresses all aspects of volcanism, ranging from the generation of magma, its transport and migration, eruption, and formation of volcanic deposits. It also addresses volcanic hazards, their mitigation, the monitoring of volcanic activity, and economic aspects and, for the first time, analyzes several specific cultural aspects of volcanic activity, including the impact of volcanic activity on archaeology, literature, art, and film. To compose a single volume that is a complete reference for such a far-ranging phenomenon is indeed a daunting task.

---

### ARRANGEMENT OF CONTENT

When the editors began to develop the fundamental structure of this Encyclopedia, we were faced with two choices: either constructing a dictionary-like volume composed of defined terms, arranged in alphabetical order, or following a thematic approach, where the multitude of volcanic processes are defined, described, and elaborated in a series of chapters. We have adopted the latter approach in this volume.

To provide our readers with the best possible treatment of volcanic processes, we have adopted the

time-honored custom of Denis Diderot and Jean D'Alembert of recruiting the leading experts in each branch of volcanology and related fields to author the chapters that lie outside the expertise of the editors. When Diderot and D'Alembert began to compile information for their monumental 21-volume *Encyclopédie* (1751-1765), they went to the carpenters, the masons, the embroiderers, and the other experts for help with the specific terms and concepts, in order to get all the technical details right. Thus they secured an article for the *Encyclopédie*, penned by the pioneer field volcanologist Nicholas Desmarest (1725-1815), on the volcanic origin of columnar basalt. Similarly, the editors of the *Encyclopedia of Volcanoes* have recruited the recognized authorities in each field or speciality of volcanology to contribute chapters to this volume. Thus this volume is the product of over 100 volcanologists, petrologists, and other scientists who have specialized knowledge about volcanoes and related processes.

---

### SECTIONAL PLAN

In this volume, the principal aspects of volcanic activity are dealt with in 82 chapters, divided between nine major parts. An introduction to each part written by the editors is provided to give a general perspective of the topics and processes contained in that part. Each chapter cov-

ers one fundamental volcanic process in depth and stands alone as a comprehensive overview of the phenomenon in question. Nevertheless, the sequence of major parts and their chapters is intended to be directional and evolutionary, as far as possible, following magma from its place of deep origin to the surface of the Earth.

Thus in the first part, the volume commences with 12 chapters on the principal source regions of magmas, the mantle of the Earth, melting processes, magma generation, and transport and geochemical evolution of magmas, as they rise into the Earth's crust. The second part addresses the fundamental aspects of distribution of volcanism in space and time and the range in the scale of volcanic eruptions, in terms of magnitude and intensity. In the three subsequent parts, chapters address the various styles of eruption of magmas, namely, effusive (lavas) versus explosive, and the multitude of types of volcanic deposits that result.

Part V provides comprehensive overviews of volcanic activity on other members of the Solar System, namely, on the Moon, Io, Mars, and Venus and the unusual cryovolcanism on the Galilean satellites of Jupiter. Extraterrestrial volcanology is probably the area of volcanologic research that will experience the greatest growth in the future, as space exploration continues to provide new discoveries in other worlds. In Part VI the interactions of volcanism with hydrosphere and atmosphere are discussed, as well as formation of those mineral deposits that owe their origin to volcanic processes. The impact of volcanoes on society is explored in Part VII, where the various types of volcanic hazards are discussed. Volcano monitoring is treated in Part VIII, along with the mitigating measures that have been developed to counteract volcanic disasters. In the final section of the Encyclopedia, a variety of economic benefits accruing from volcanism are described, and the volume closes with four chapters on the cultural aspects of volcanism and its impact on archaeology, art, literature, and film.

---

#### CONVENTIONS OF STYLE

In this volume, we have adopted the convention of using lowercase in the spelling of those adjectives that describe volcanic processes, such as surtseyan and plinian.

As this volume is intended for the general reader, such distracting paraphernalia as references or footnotes have been dispensed with as much as possible. Instead, a section of Further Readings, containing a list of half a dozen or more major texts on the subject matter, is

provided at the end of each chapter for those interested in the chief sources.

---

#### APPENDIXES

Two appendixes are included in the volume. Appendix 1 consists of a series of tables that give common scientific and mathematical units and conversion factors. It also provides a variety of numerical data on the Earth.

Appendix 2 is a table of active volcanoes on Earth, as compiled by Tom Simkin and Lee Siebert of the Smithsonian Institution. A listing containing all the volcanoes on Earth, with data on their eruptions, is beyond the feasibility of this work, as this list alone would equal this volume in length. The editors have therefore opted to list only historically active volcanoes, i.e., the volcanoes whose eruptions have been witnessed and documented, totaling 550 in number. The oldest eruption in this list is therefore the plinian eruption of Vesuvius in Italy on 24 August in 79 A.D. This selection of the historical period is admittedly somewhat arbitrary, as the "historical period" varies greatly in length from place to place on Earth. In Europe and Japan the historical record of volcanism extends back over one thousand years, whereas in New Zealand and North and South America, for example, it is merely a matter of a few centuries, because written records in these regions begin generally with European settlement.

In Appendix 2 the historically active volcanoes are listed in alphabetical order, and their locations are given in terms of longitude and latitude. The tabulation also includes all of their historic eruptions.

---

#### ACKNOWLEDGMENTS

The number of people who have assisted the authors and editors in the creation of this volume is literally in the hundreds. A list of those we especially thank is given in the Acknowledgments section at the end of the volume.

We single out here, however, the following staff members at Academic Press for their outstanding work: the project's sponsoring editor, Frank Cynar, who bears the responsibility for recruiting the editors of this volume; the project manager, Cathleen Ryan; and the production editor, Jacqueline Garrett.

THE EDITORS

---

## GUIDE TO THE ENCYCLOPEDIA

The *Encyclopedia of Volcanoes* is a complete reference guide to this subject, including studies of the origin and transport of magma, of eruptions, and of effusive volcanism and explosive volcanism. Other sections of the work discuss extraterrestrial volcanism, volcano interactions, volcanic hazards, eruption response and mitigation, and economic and cultural aspects of volcanism. Each article in the Encyclopedia provides a scholarly overview of the selected topic to inform a broad spectrum of readers, from researchers to the interested general public.

In order that you, the reader, will derive the maximum benefit from the *Encyclopedia of Volcanoes*, we have provided this Guide. It explains how the book is organized and how information can be located.

---

### ORGANIZATION

The *Encyclopedia of Volcanoes* consists of 82 individual articles arranged in a thematic manner; that is, the placement of a given article is based on its content and not on its alphabetical wording. Articles on related topics are placed together in sequence.

Each article is a full-length treatment of the subject at hand. Thus the Encyclopedia's format will allow its

readers to choose their own method for referring to the work. Those who wish specific information on limited topics can consult the A-to-Z Article Index (see p. xi) and then proceed to the desired topic from there. On the other hand, readers who wish to obtain a full overview of a larger subject can read the entire series of articles on this subject from beginning to end; e.g., Eruptions. In fact, one can even read the entire Encyclopedia in sequence, in the manner of a textbook (or a novel), to obtain the ideal view of the complete subject of volcanoes.

---

### ARTICLE FORMAT

Each article in the *Encyclopedia of Volcanoes* begins at the top of a right-hand page, so that it may be quickly located. The author's name and affiliation are displayed at the beginning of the article. The text of the article is organized according to a standard format, as follows:

- Outline
- Glossary
- Defining Statement
- Body of the Article
- Cross-References
- Bibliography

---

## OUTLINE

Each article in the Encyclopedia begins with an outline that indicates the general content of the article. This outline serves two functions. First, it provides a brief preview of the text, so that the reader can get a sense of what is contained there without having to leaf through all the pages. Second, it serves to highlight important subtopics that will be discussed in the article. For example, the article “Volcanic Plumes” begins with the subtopic “Generation of Volcanic Plumes.”

The outline is intended as an overview and thus it lists only the major headings of the article. In addition, extensive second-level and third-level headings will be found within the article.

---

## GLOSSARY

The Glossary contains vocabulary terms that are important to an understanding of the article and that may be unfamiliar to the reader. Each term is defined in the context of the particular article in which it is used. Thus the same term may appear as a Glossary entry in two or more articles, with the details of the definition varying slightly from one article to another. The Encyclopedia includes approximately 500 glossary entries.

The following examples are glossary entries that appear with the article “Flood Basalt Provinces.”

**hotspot** An area in the Earth’s upper mantle that is hotter than the ambient temperature.

**picrite** A volcanic rock with a large proportion of the magnesium-rich mineral olivine.

---

## DEFINING STATEMENT

The text of each article in the Encyclopedia begins with a single introductory paragraph that defines the topic under discussion and summarizes the content of the article. It thus serves the purpose of a brief abstract of the article. For example, the article “Pyroclastic Surges and Blasts” begins with the following defining statement:

The recognition that volcanic explosions could produce density-driven currents that flow rapidly away from the vent, devastating the landscape and leaving thin pyroclastic deposits and ash dunes, was an important step towards our current understanding of volcanic systems. Deposits left by these pyroclastic surges are a key in interpreting the eruptive history of a volcano and in predicting the hazards a volcano might pose for the future.

---

## CROSS-REFERENCES

Articles in the Encyclopedia contain references to other articles. These cross-references appear at the end of the text for the article. They indicate related articles that can be consulted for further information on the same topic, or for information on a related topic. For example, the article “History of Volcanology” has cross-references to “Archaeology and Volcanism,” “Earth’s Volcanoes and Eruptions: An Overview,” “Mantle of the Earth,” “Origin of Magmas,” “Plate Tectonics and Volcanism,” “Volcanoes in Art,” and “Volcanoes in Literature and Film.”

---

## FURTHER READING

The Further Reading section appears as the last element in each article. This section lists other sources outside the Encyclopedia that will aid the reader in locating more information on the topic at hand.

The entries in this section are for the benefit of the reader, to provide references for further research or browsing on the given topic. Thus they consist of a limited number of entries. They are not intended to represent a complete listing of all the materials consulted by the author or authors in preparing the article. The Further Reading section is in effect an extension of the article itself, and it represents the author’s choice as to the best sources available for additional information.

---

## INDEX

The Subject Index for the *Encyclopedia of Volcanoes* contains more than 3800 entries, arranged alphabetically. Reference to the general coverage of a topic appears as a marginal entry, such as an entire section of an article devoted to the topic. References to more specific aspects of the topic then appear below this in an indented list.

---

## ENCYCLOPEDIA WEBSITE

The *Encyclopedia of Volcanoes* maintains its own editorial Website on the Internet at:

<http://www.apnet.com/volcano/>

This site provides complete information about the contents of the Encyclopedia. For information about other current Academic Press reference works, such as the *Encyclopedia of the Solar System*, go to:

## GLOSSARY

**convection** The process by which the Earth's mantle loses heat, producing currents of solid but deformable rock that rise toward the surface and contribute to plate motion.

**eclogite** A rock type common in the Earth's mantle, with the same chemical composition as basalt, but with a mineral assemblage that is stable at high pressure.

**intensity** The rate of flow of magma out of a volcano during eruption, expressed as mass eruption rate (MER) in kilograms per second (kg/s).

**magnitude** The size of a volcanic eruption, expressed as the volume of material erupted, usually in cubic kilometers ( $\text{km}^3$ ).

**peridotite** The principal rock that forms the Earth's upper mantle, consisting mainly of the mineral olivine, with lesser amounts of pyroxene, garnet, and/or spinel. It is

the source of basaltic magmas, which are formed from peridotite by partial melting.

**photodissociation** Chemical reactions that occur in the atmosphere, due to ultraviolet radiation.

**proterozoic eon** The period in Earth's history that began 2.5 billion years ago and ended 0.57 billion years ago.

**pyroclasts** Fragmentary material ejected during a volcanic eruption, including pumice, ash, and rock fragments.

**radionuclides** Chemical elements that undergo spontaneous and time-dependent decay, resulting in the formation of other elements and the release of radioactive energy in the form of heat.

**stromatolites** The earliest calcium carbonate-secreting organisms on Earth, first appearing during the Proterozoic. Their activity contributed to drawing down carbon dioxide from the atmosphere and fixing it in limestone and other sedimentary rocks, contributing to changing atmospheric chemistry and climate.

**subduction** The process of sinking of crustal plates into the Earth's mantle. Subduction causes magma generation and results in buildup of island arcs above subduction zones.

**volatiles** Those chemical compounds or elements contained in magmas that are generally released as gases to the atmosphere during a volcanic eruption. They include water, carbon dioxide, and sulfur dioxide. They are generally dissolved in the magma prior to eruption or when the magma is under high pressure, but exsolve during ascent of the magma to the surface.

**volcanic aerosol** Tiny particles of sulfuric acid droplets, formed by reactions between volcanic sulfur dioxide gas and water vapor in the stratosphere. The resulting aerosol dust veil has important effects on backscattering and absorption of solar radiation and leads to a net surface cooling on the Earth, with possible climate change.

---

## I. THE MELT OF THE EARTH

Volcanic eruptions are the most awesome and powerful display of nature's force. The idea that terra firma may explode under our feet and bombard us with glowing hot ejecta seems almost incomprehensible. Every year about 50 volcanoes throughout the world are active above sea level, threatening the lives and property of millions of people. A single eruption can claim thousands of lives in an instant. For example, in the 1902 eruption of Mont Pelée on the Caribbean island of Martinique, a flow of hot ash and gases overwhelmed the city of St. Pierre, killing all but one of its 28,000 inhabitants. More recently, a mudflow triggered by the 1985 eruption of the volcano Nevado del Ruiz in Colombia killed nearly all of the 25,000 inhabitants of the town of Armero.

The relationship between people and volcanoes is as old as the human race. Our earliest ancestors evolved in the volcanic region of the East African Rift, where their activities and remains are preserved by volcanic deposits, such as the stunning 3.7-million-year-old *Australopithecus* hominid footprints crisscrossing a volcanic ash deposit at Laetoli. In fact, the wealth of information we now have on early hominid evolution has only been made possible because of the rapid burial and excellent preservation of their remains in volcanic deposits. Is it a mere sport of nature that humans evolved in a volcanic region, or was this African volcanic environment especially favorable to human evolution? Was it the abundant game and fertility of the volcanic plains, with their rich soils? We shall probably never know the answer, but humans quickly learned to make use of volcanic rocks in toolmaking and captured fire from volcanoes, to open up the realms of the dark and the cold for further expansion of the race.

When humans first sought explanations for volcanic phenomena, they linked these violent processes to mythology and religion. But with the rise of Western philosophy and learning, Greek scholars in the third century before Christ began the search for the actual physical causes of volcanism, as outlined in Chapter 2.

The Greeks speculated that eruptions were the result of the escape of highly compressed air and gases inside the Earth, but later the Romans proposed that volcanoes were natural furnaces in which combustion of sulfur, bitumen, and coal took place. This search for the actual causes of volcanism on Earth and other planets has continued to our day, but we now have many of the answers.

Volcanology is the study of the origin and ascent of magma through the planet's mantle and crust and its eruption at the surface. Volcanology deals with the physical and chemical evolution of magmas, their transport and eruption, and the formation of volcanic deposits at the planetary surface. Some volcanic processes constitute a major natural hazard, whereas others are highly beneficial to society. Thus, the study of volcanism has far-ranging significance for society. For most people, volcanology conjures up a picture of an erupting volcano. Volcanoes and their eruptions, however, are merely the surface manifestation of the magmatic processes operating at depth in the Earth, and thus the study of the volcanism is inevitably highly interdisciplinary, most closely linked to geophysics, petrology, and geochemistry.

In this volume, we examine volcanology in the widest sense, covering not only the traditional aspects of the generation of magmas (traditionally the domain of petrology and geochemistry) and their transport and eruption (the field of traditional volcanology), but also the multitude of effects that volcanism has on the environment and on our society and culture. Volcanism is the best way to probe the interior of Earth. Adopting an anthropomorphic view, we could regard magma as the sweat of the Earth, resulting from the labors of moving the great crustal plates around on the planet's surface and maintaining the Earth's mantle well stirred. The analogy is not that far fetched, because magma and volcanism in general are also a means of heat loss for the Earth. For the Earth scientist, these fluids emerging from the Earth carry valuable clues about the internal constitution of our planet. Just as the medical doctor analyzes the various fluids of the human body, the geochemist samples and analyzes the magmatic liquids that issue from Earth's volcanoes.

For the human race, the Earth is a blessed planet, because of its position in the solar system and because of its physical dimensions and vigorous dynamic internal processes, among which volcanism plays a fundamental role. Our Earth is just sufficiently far away from the Sun to benefit from its heat, but not so close as to lose its crucial oceans by rapid evaporation or its precious water by photodissociation at the top of the atmosphere

and subsequent escape to space. The Earth is cool enough that liquid water stays on its surface—but not so cool that all water freezes. Earth's gravity is sufficiently high to exceed the escape velocity of water and carbon dioxide molecules, allowing it to retain a unique atmospheric composition, with enough carbon dioxide to create a comfortable greenhouse and to provide the building blocks for life, as well as to shield us against harmful solar ultraviolet radiation. Earth's internal heat reservoir is not so hot that it makes life unbearable because of continuous volcanic eruptions, but is sufficient to drive mantle convection and plate tectonics. The volcanism resulting from plate tectonics continuously recycles volatile elements such as water, carbon dioxide, and sulfur between the inner Earth and its surface reservoirs: the oceans and atmosphere. It is a very ancient cycle. In the distant history of the primitive Earth, the original atmosphere and oceans probably resulted from the early degassing of the interior of the globe, largely through volcanic activity.

Volcanism is flux of energy and matter. It is an expression of the storehouse of Earth's inner energy, derived in part from cooling of an originally hot planet and in part from heat resulting from the radioactive decay of naturally occurring uranium, potassium, thorium, and other radionuclides present deep in the Earth. Thus, volcanic eruptions are the surface expression of these deep Earth processes. When viewed on a geologic time-scale, the motions of the inner Earth are veritable storms raging within the planet, with thunderheads rising up through the mantle to form plumes that break the surface as great volcanic hot spots. Other internal storms also lead to convective rollover of the mantle, pulling and pushing along the great crustal plates at the surface, resulting in volcanic activity where plates converge or are pulled apart. When we compare Earth to the other planets in the solar system, we may wonder why our home planet is so prone to volcanic eruptions. The logical question is, however, why does the Earth have such vigorous plate tectonics, the driving force of volcanism?

---

## II. VOLCANISM AND PLATE TECTONICS

Earth may be unique among the planets in the solar system in that its outer rigid skin—the crust and lithosphere—is continuously being destroyed and regenerated. It has active plate tectonics, where the heat and

smoke of volcanism rise from the two main battlefields between the plates: the rifts or ocean ridges and the subduction zones. The most important consequence of plate tectonics, discussed in Chapter 6, is geologic recycling of materials, turning the Earth into an immense chemical factory where volcanism plays a crucial role. As great crustal plates are pulled apart in the ocean basins, the solid but mobile Earth's mantle below the rift responds to the decrease in overburden and rises upward to fill in the rift. When the rising peridotite mantle experiences a decrease in pressure, it spontaneously undergoes melting, without addition of heat. The reader who does not have a background in petrology or volcanology should pause at this point and ponder the last sentence, for here lies the key to an understanding of the vast majority of volcanic processes: decompression melting, as described further in Chapter 4. It may be difficult at first to comprehend that rock may melt, without addition of heat, simply because the pressure acting on it decreases, but this is the most common melting process in the Earth. The idea that melting could occur simply as a result of the decrease of pressure (decompression melting) dates back to the beginning of the 19th century, but it was not generally accepted by geologists until the latter part of the 20th century. Early volcanologists knew that the Earth's interior was hot but solid, and from the basic principles of thermodynamics that were developed in the 1830s, they could theorize that melting would occur if pressure decreased, that is, if the mantle rock were brought upward to a region of shallower depth in the Earth. It was only with the advent of the theory of plate tectonics that a mechanism for vertical motion leading to decompression was discovered.

The interstitial melt that forms during decompression, behaving rather like the water that seeps between the sand grains on the beach, forms no more than a few percent of the rising mantle during melting. But the new basaltic magma is less dense and rises faster than the mantle. It collects into pockets that form magma reservoirs, eventually pushing its way upward into the rift in the midocean ridge, to erupt as lava from fissures on the ocean floor. Thus, volcanism is continuously adding new mantle-derived volcanic crust to the plate margins, temporarily welding together the rifted plates, until they break again in another eruption (Fig. 1).

But why are the plates moving apart? Are they being pushed or are they sliding “downhill” because of the elevated position of the midocean ridge? Are they being dragged along by the convection of the underlying mantle? Or are they pulled along by the subduction of the old, cold, and therefore dense leading edge of the plate

into the mantle? To comprehend the fundamental underlying causes of volcanism in island arcs and midocean ridges, we need to answer this important question. Empirical evidence shows that the plates today are moving primarily because of the force we call *slab pull*. The plates that are moving fastest are all attached to long and very active subduction zones. Once the cold leading edge of the plate enters the mantle, its fate is sealed: It will subduct. Solid-state phase transitions occur in the minerals making up the plate, converting low-pressure minerals into a much more dense high-pressure assemblage, thus increasing the bulk density of the plate to a point where it exceeds the density of the upper mantle and spontaneously sinks, dragging along with it the attached plate at the surface.

How was this cycle of plate tectonics started, or has it always operated on Earth? We do not yet know the answer, but its operation goes back at least to the Proterozoic eon (0.57–2.5 billion years ago). One fascinating idea is that subduction was literally initiated by biological processes on Earth. When the stromatolites, the first calcium carbonate-secreting organisms, began to flourish in the Earth's oceans, they mined the abundant CO<sub>2</sub> from the planet's atmosphere and fixed it into dense rock: limestone. In the process, they and other carbonate-fixing organisms gave off the oxygen that created for us an atmosphere that is fit to breathe. When the great masses of dense limestone rock first accumulated around the continental margins late in the Proterozoic, they may have downwarped the underlying oceanic crust to such an extent that the high pressure resulted in conversion of low-pressure basaltic crust to its high-pressure form of eclogite. With a density greater than that of the upper mantle, the eclogite crust would sink into the mantle and pull along with it the attached crustal

FIGURE 1 Most of Earth's volcanism occurs at the junctions of the dozen or so plates that make up the exterior shell of the Earth. Midocean ridge volcanism occurs at the boundaries where plates are pulling apart. Arc volcanism occurs where plates are converging, above the subduction zones. Below the plates resides the asthenosphere, the part of the Earth's mantle from which most magmas originate. (After Allegre, 1992.)

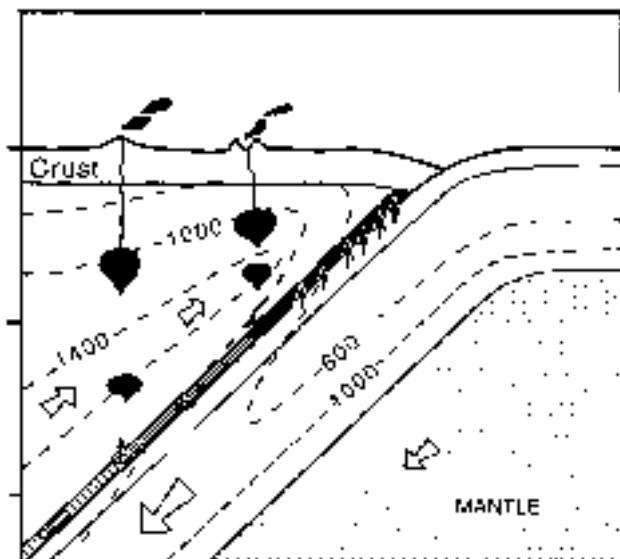

FIGURE 2 Arc volcanism above a subduction zone. The descent of the cold subducting plate causes upwelling of hotter mantle below the volcanic arc. Furthermore, volatile components, such as water, are released from the subducting plate to the overlying mantle wedge, promoting melting of the mantle and formation of magmas that feed the arc volcanoes above. The dashed lines are isotherms of temperature distribution in the mantle and subducting plate (in degrees centigrade).

plate, initiating subduction and setting in motion the first plate tectonic cycle (Fig. 2).

### III. THE MIDOCEAN RIDGE

A remarkable discovery made only 35 years ago was that the vast majority of volcanism on Earth—perhaps more than 80%—occurs at depths beneath the ocean waves. Although we had an inkling of the importance of the global midocean ridge system, its importance was only revealed in the 1960s with the exploration of the ocean floor and establishment of a global seismic network. We cannot generally witness this type of volcanic activity on the ocean floor, but in certain regions, such as Iceland, the midocean ridge literally grows out of the ocean or is exposed on land. In November 1963, as I tossed about in the frigid and turbulent waters south of Iceland, I had the privilege of witnessing the result of the rifting of the Mid-Atlantic Ridge and the growth of the volcanic island of Surtsey.

Normally, the basaltic eruptions on the ridge are effusive and create pillow lava flows on the ocean floor. At

these depths in the ocean the pressure is so high that seawater does not boil explosively even in contact with the red-hot lava. On the other hand, when the underwater volcano grows and reaches shallow levels, the style of activity changes dramatically, as we observed when Surtsey emerged. Violent explosions sent showers of black ash, lapilli, and muddy steam over our boat, as the hot magma flashed the seawater to superheated steam in shallow water. The steam explosions literally tore apart the molten lava and generated a type of eruption that we now know as *surtseyan*.

Hydrothermal activity is an important consequence of volcanic activity at the midocean ridge, and this process has made its imprint on the chemical composition of the oceans. The injection of magma into the fractured volcanic crust at the midocean ridge sets in motion a vigorous hydrothermal system. In a way, this system is rather like the radiator on the front of the great magma engine. It circulates cold seawater from the ocean down through the fractured crust, where it encounters hot volcanic or intrusive rocks at depth, in proximity to young dikes or even close to the magma reservoir. Here the water is heated. It exchanges chemicals with the rocks, leaving some chemicals from seawater behind and picking up others from the rock that is hydrothermally altered in the process. The heated seawater transports metal-rich solutions toward the surface.

Volcanism on the midocean ridge has a profound impact on the chemistry of the oceans. The hydrothermal circulation process is so forceful at the midocean ridges that the entire mass of the world's ocean is recycled through the hot volcanic crust at a rate of about  $1.5 \times 10^{14}$  kg/year. This rate is sufficient to cycle the entire ocean through the midocean ridge about once in 5 million years. This huge flux of seawater through the oceanic crust has greatly influenced the chemical composition of the oceans through time, resulting in addition and removal of certain chemicals from seawater. This process leads, for example, to the addition of calcium, potassium, and lithium to seawater, from magmas and rocks at the ocean ridges, and the removal of, for example, magnesium from seawater into the oceanic crust. The discovery of midocean ridge hydrothermal activity has explained several puzzles regarding the "sources" and "sinks" of several chemical components in the ocean geochemical cycle. Thus, the midocean ridges are major sinks for magnesium and sulfate and an important source of calcium and manganese.

Hydrothermal fluids also transport metals in solution toward the surface. Upon emerging onto the ocean floor, the solutions cool and precipitate metals, leading to the formation of iron-manganese-rich sediments at

the midocean ridge. Locally, the hydrothermal solutions emerge through vents on the ocean floor at very high temperature (350°C). These solutions carry high concentrations of metals and precipitate sulfides, sulfates, and oxides around the vent, to form chimneys up to 10 m high that belch out hot solutions. The solutions precipitate various minerals as they emerge into the ocean, forming black smokers. These solutions are very rich in silica, hydrogen sulfide, manganese, carbon dioxide, hydrogen, and methane, as well as potassium, calcium, lithium, rubidium, and barium. Minerals precipitated on the ocean floor by this process include pyrite ( $\text{FeS}_2$ ), chalcopyrite ( $\text{CuFeS}_2$ ), and sphalerite ( $\text{ZnS}$ ). The high concentrations of hydrogen sulfide in these vents support a unique biological assemblage, including sulfide-oxidizing bacteria, which form the basis of a food chain.

#### IV. THE SUBDUCTION FACTORY

The vast majority of land or island volcanoes on Earth are in volcanic arcs above subduction zones. Although they represent only about 10–20% of the volcanism on Earth, the arc volcanoes are most important in terms of their impact on our society. Because they are subaerial and vent directly into the atmosphere, their eruptions can affect our atmosphere. Furthermore, the regions around arc volcanoes are often densely populated and thus may be regions of high risk.

Whatever mechanism may have initiated it, subduction is a dominant component in the great geologic machine that processes and recycles the Earth's oceanic crust and upper mantle. Although the 100-km-thick subducting plate is composed primarily of oceanic crust and upper mantle rocks, it also contains a sliver of sediment at its upper surface and water, carbon dioxide, and other volatile elements bound in clays and other hydrous minerals. In this fashion, the volatile elements are returned to the Earth's mantle from whence they came originally, when they were emitted as volcanic gases in eruptions during the degassing of the early Earth.

Water may also facilitate plate motion, lower mantle strength and viscosity, and play a crucial role in lubricating the subduction zone, because the presence of water in the subduction zone environment promotes the formation of structurally weak hydrous silicate minerals that results in rocks of low strength (Fig. 3). Similarly, water, even in trace amounts, promotes partial melting by lowering the beginning of melting of mantle rocks.

**FIGURE 3** The solidus defines the location of the beginning of melting in the Earth's mantle. The figure shows the effects of pressure and volatiles (water and carbon dioxide) on the configuration of the solidus of peridotite, the dominant rock type in the upper mantle. Right-hand vertical scale is depth below the surface; left-hand scale is in units of pressure (GPa). The four solidi shown are the “dry” solidus (neither  $\text{H}_2\text{O}$  nor  $\text{CO}_2$  present), the  $\text{CO}_2$ -saturated solidus, the  $\text{H}_2\text{O}$ -saturated solidus, and (intermediate and unlabeled) the  $\text{H}_2\text{O}$ -undersaturated solidus (water is present, but only in sufficient amount to form hydrous minerals). The presence of either  $\text{H}_2\text{O}$  or  $\text{CO}_2$  has a dramatic effect of lowering the beginning of melting of the mantle. Under most Earth conditions, melting is likely to begin in the depth range of several tens of kilometers.

When this occurs in the upper mantle at the base of the lithosphere (the low-velocity layer), plate motion is facilitated. Further, subducted water decreases mantle density in the wedge below the volcanic arc, promoting melting and buoyant upwelling of partially molten mantle material and thus promoting volcanism at the surface.

The presence of water in the magma further sets the chemical evolution of the magma on an entirely different course from “dry” magmas, leading to the silica enrichment typical of magmas in volcanic arcs above subduction zones, as discussed in Chapters 7 and 8. Without the subduction of water, the majority of volcanism on Earth would be submarine, of the type we observe on the midocean ridge: eruption of basaltic magmas of relatively narrow compositional range, releasing dominantly carbon dioxide and sulfur dioxide gases to the ocean, but without emission to the atmosphere. In this subduction-free world, only a small fraction of volcanism would release volcanic gases directly to the atmosphere, that is, the hot spot volcanism of the type we see in Iceland and Hawaii today.

One of the interesting paradoxes of the Earth is that subduction occurs because the leading edge of the plate is cold and dense enough to sink, yet in this apparently frigid environment, volcanism is a characteristic feature. How is it that magma generation occurs in the subduction zone, in response to the descent of the cold plate? The explanation for this paradox is twofold. On one hand, the water introduced into the mantle wedge above the subduction zone lowers the melting point of mantle rock (peridotite), facilitating magma generation and volcanism at the surface (Fig. 3). In addition, the descent of the plate stirs up the mantle, bringing upward a current of warmer mantle material from the depth, again facilitating melting by decompression and resulting in magma generation.

It has been suggested that the island arcs above subduction zones are the “kitchen” where continental crust is made. The process of magmatic differentiation or geochemical evolution of magmas beneath the volcanic arcs results in the formation of relatively high-silica andesitic or rhyolitic magmas that solidify as low-density rocks, as described in Chapter 8. In the “kitchen,” the high-silica magmas may be regarded as the cream that evolves from the primary basaltic magma and rises to the top. The high-silica rocks are too light to subduct, and they accumulate in the arc environment, typically at continental margins. The process by which arc volcanics and associated intrusive rocks accumulate is referred to as *continental accretion* and may be the principal mechanism for continental growth. In this manner, the subduction zone acts as a giant still, melting the mantle and separating the continent-forming material out of the melts, adding it to the continents and leaving behind a depleted upper mantle. Thus, the great subduction zone still treats chemical elements in two ways. Some are continuously recycled, namely, the volatile components, such as water and carbon dioxide, whereas others are largely retained in the arc crust.

To what extent is the water, which drives explosive volcanism in arcs, derived from the subduction of the oceans? If the recycling is working, then we should find geochemical evidence of subducted material in the magmas erupted from island arc volcanoes. One of the spectacular success stories of geochemistry is its role in providing proof of the recycling of certain trace chemical components. The discovery came with the detection of the isotope  $\text{Be}^{10}$  in arc volcanics. This relatively short-lived isotope (half-life about 1.5 million years) is derived solely from reactions in the atmosphere, and it accumulates in marine sediments that may be subducted. The fact that  $\text{Be}^{10}$  is present in some arc magmas in measurable amounts is proof that relatively young oceanic sedi-

ments or fluids must have been subducted and become incorporated in the magma sources underneath the volcanic arcs. Although it is likely that oceanic sediments and related fluids contribute only 1–2% of the magma (the rest is mantle contribution), their chemical imprint is clear and the consequences are evident in the explosive character of these water-rich magmas.

---

## V. VOLCANOES ON HOT SPOTS

The plate tectonic revolution of the 1960s did not explain the origin of a number of the better known volcanoes on Earth, particularly the volcanic islands like Hawaii, the Galapagos, and Iceland. In many cases they show no direct relation to plate boundaries and thus do not fit into the paradigm of plate tectonics. They are volcanic, however, and have a high eruption rate, which has earned them the name *hot spots*. Perhaps the most insidious hot spot is the Yellowstone volcanic field in the United States, a hot spot located in the center of a continental plate. Its prehistoric giant explosive eruptions include some of the largest known on Earth, but because of the long dormant periods, it is a potential continent-wide or even global volcanic threat that we often overlook.

Unusual geochemical signatures in the basaltic hot spot lavas, described in Chapters 7 and 8, suggest a magma source deeper in the mantle than the midocean ridge source or a source that has not been tapped before by earlier magma extraction. This has led to the idea that hot spot volcanoes are supplied by deep mantle plumes, focused mushroom-like currents of solid but hot rock, rising from either the lower mantle or even from the boundary layer between the mantle and the core of the Earth. This is a radical idea, but if correct, it could mean that volcanoes such as Kilauea in Hawaii bring a signature to the surface from rocks that originally were near the core of the Earth, some 2900 km below the volcanoes.

An alternative model for the origin of hot spot magmas brings us back to subduction. It is likely that great masses of ancient subducted masses of lithosphere reside within the deep mantle. Here the subducted slab of cold lithosphere eventually warms up and its density becomes equal to or even less dense than the surrounding mantle, causing its rise toward the surface as a plume of rock. Nearing the surface, the hot material undergoes decompression melting and magma generation. Again, geochemical evidence from volcanics in some hot spots

supports the idea that subducted slabs may be the fuel for mantle plumes and at least some hot spot magmas.

---

## VI. VOLCANISM ON OTHER WORLDS

Those who expected that volcanism on other planets of the solar system would be similar to that on Earth were in for a series of big surprises when exploration of the planets began in earnest. Early ideas on extraterrestrial volcanism were largely directed toward the Moon, where craters were seen to be abundant. In 1665 Robert Hooke first proposed the presence of volcanoes on the Moon, but he had observed the lunar craters telescopically. In the 18th century, Pierre Laplace proposed that meteorites were volcanic material ejected from the Moon. Volcanism on the Moon did not seem such a bad idea at the time, considering its cratered and pock-marked visage. In 1785, however, Immanuel Kant pointed out that most lunar craters were much larger than any volcanic features known on Earth, and Kant proved to be correct in his assessment that the lunar craters are not of volcanic origin; we now know that most are the products of meteorite bombardment. Exploration of the lunar surface during the Apollo program revealed vast areas or “oceans” of volcanic rocks, known as Maria, but they turned out to be extremely old, mostly on the order of 3.7 billion years (Chapter 45).

One of the major surprises—and a disappointment to volcanologists—has been that most of the planets are volcanically “dead.” That disappointment was, however, compensated by the discovery of spectacular volcanism on Io, where sulfur-rich magma fountains are ejected to heights of hundreds of kilometers (Chapter 46). But Io has more surprises. Its volcanism is most likely not the result of internal thermal energy, as on Earth, but rather due to the tidal energy transferred from the gravitational pull of the giant parent planet Jupiter, causing the interior of Io to heat up. We will no doubt have many similar volcanic surprises awaiting us when we explore other strange worlds in the future.

---

## VII. VOLCANIC PROCESSES

A bewildering variety of volcanic processes occur at the surface during an eruption, and the list of the volcanic rock types and types of volcanic deposits is seemingly

endless. Fortunately, as volcanology has progressed in the latter half of the 20th century from a descriptive endeavor to a truly interdisciplinary science, we have discovered the major factors that control eruption processes and account for the diversity of the products, as described in parts II, III, and IV of this volume. Although each eruption is unique, and each volcano seems to have its distinct “personality,” several fundamental parameters dictate the style of eruption (Table I).

By far the most important parameter is the mass eruption rate (eruption intensity), which depends on the rate of supply of magma during eruption. The observed range in mass eruption rates on Earth is huge, more than at least three orders of magnitude, and extending beyond  $10^9$  kg/s. It is beyond our comprehension to visualize 1 million tons of red-hot molten rock jetting out of the crater of a volcano every second—not for a few seconds, but for hours or days, such as occurs during large ignimbrite-forming eruptions. We are accustomed to referring to such events as “explosions,” but that is somewhat of a misnomer, because they are not instantaneous bursts, but rather sustained emissions of magma and gases; only the onset is really explosive. The mass eruption rate is truly a measure of eruption intensity, because it controls the height of the eruption column in explosive events and the length of lava flows in effusive eruptions.

As shown in Fig. 4, eruption intensity shows a good correlation with the total mass or volume of magma erupted (magnitude). Although we may intuitively expect that the largest magma bodies within the Earth result in the highest magnitude (largest volume) eruptions, but why they should also be the highest intensity events is not immediately obvious. The flow rate is, of course, a function of the magma pressure and the diameter of the conduit. The explanation may lie in the time it takes for the volcano to widen its conduit by erosion

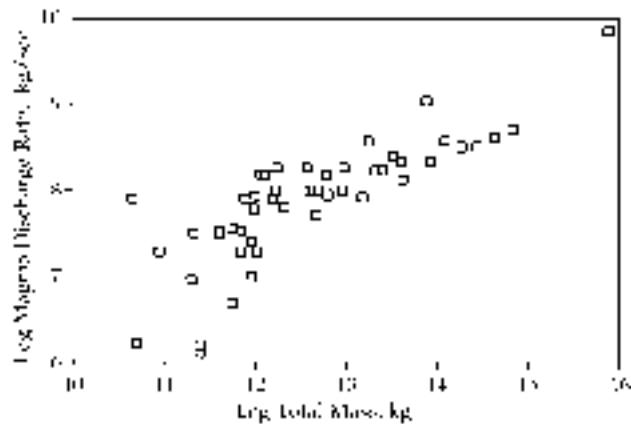

FIGURE 4 The figure shows the range in volcanic intensity and magnitude for a number of eruptions on Earth, shown as log units. The magma discharge rate (intensity) during a volcanic eruption can range from  $10^6$  to  $10^{10}$  kg/s in the most violent events. The total erupted mass (magnitude) can range to more than  $10^{15}$  kg, equivalent to a magma volume of several thousand cubic kilometers.

during eruption and allow more magma to pass to the surface. In most major explosive eruptions, the intensity increases with time during the event, and it is most logical to assume that this is simply due to gradual widening of the conduit as it is eroded by the passage of hot magma and the explosive blast of rock, ash, and pumice fragments.

During an explosive eruption, as mass eruption rate increases, so does the height of the eruption column, attaining more than 40 km in the Earth’s atmosphere for the largest eruptions. Although this correlation is in part related to increase in the height of the jet of magma and pyroclasts emerging from the vent, it is really more influenced by the thermal energy from the eruption,

TABLE I Some Factors That Influence Volcanic Processes

Factor	Typical range	Comments
Magma temperature	800–1250°C	Influences magma viscosity and affects energy available for eruption plume rise.
Magmatic water	0.1–6 wt% H <sub>2</sub> O	Controls magma fragmentation through the vesiculation process.
Magma viscosity	$10^2$ – $10^{10}$ poise	Determines flow properties of magmas, vesiculation, bubble growth; controls the rise and escape of bubbles out of magmas.
Mass eruption rate	$10^6$ – $>10^9$ kg/s	The rate of flow of magma out of the vent is single most important factor.
External water	0.01–0.5 vol. fract.	The fraction of external water that mixes with magma in the conduit or vent.
Crystal content	0–50%	Affects bulk viscosity and thus rheology of magma.

available to drive a convective plume. In fact, most of the eruption column above a volcano is a thermal plume, where heat is transferred from the hot pyroclasts to the surrounding air, which in turn convects vigorously, mixes with the ash and other pyroclasts, and drives the plume sky-high.

Paradoxically, however, when the mass eruption rate reaches a critical value, the eruption column ceases to rise; in fact, the column begins to collapse. The process of column collapse generates the most destructive phase of volcanic eruptions and produces pyroclastic flows and surges: hot ground-hugging cloudlike density currents of ash, pumice, volcanic gases, and heated entrained air.

It seems at first paradoxical that the column should collapse with increasing mass eruption rate, but the explanation lies in the efficiency of mixing of air with the mixture of pyroclasts erupting from the vent. Under conditions of moderate mass eruption rate, the erupting mixture entrains and mixes with a large volume of air, which is heated, becomes buoyant, and contributes to the rapid rise of the eruption column. As the mass eruption rate increases, however, pyroclasts in the interior of the column become isolated from the atmosphere and have less opportunity to mix with air. Consequently, the entraining of air is no longer contributing to the buoyancy of the column; it becomes denser and collapses as a fountain of hot ash, gases, and pumice, to generate a density current.

The second factor that influences volcanic processes, listed in Table I, is the concentration of magmatic water. Water is almost absent in the basaltic magmas erupted on the midocean ridge, but occurs in concentrations of up to 6% in the high-silica magmas of island arcs (Chapter 9). The role of water is twofold, both as the agent that causes vesiculation and fragmentation of magmas and as an important component in accelerating the magma and pyroclasts out of the vent. It is the presence or amount of water in the magma that primarily determines the division between effusive and explosive eruptions, but only a little water goes a long way. With a few percent of water dissolved under high pressure at depth, the magma begins to grow steam bubbles as it rises to the surface. The solubility of water decreases rapidly with decreasing pressure, and the volume fraction of the exsolving steam grows fast. If the bubbles are unable to rise and escape from the magmatic liquid, they will continue to expand until they burst and tear apart the magma into pyroclasts of ash and pumice. As the exsolution and volume expansion of water occur in the conduit of the volcano, this will result in a great

volume increase of the erupting magma mixture, propelling it out of the vent.

Magma viscosity is another important factor affecting flow properties of magmas and determining the ability of steam bubbles to rise and escape out of the magma. Viscosity is influenced by temperature, magma composition, and crystal content. In high-temperature and low-silica basaltic magmas, the viscosity is so low that gas bubbles can generally rise in the magma, whereas in high-silica low-temperature magmas, the high viscosity inhibits bubble rise; they move passively with the magma in the conduit, up toward the vent (Chapter 14).

All of the factors just mentioned are internal to magma or the volcanic system, but a number of external parameters can also influence the volcanic process. The most important of these factors is external water. Magmas rising through the crust and to the Earth's surface have a high probability of encountering water, either in the form of oceans, lakes, glaciers, or as water-rich rock formations. We saw earlier, in connection with the 1963 Surtsey eruption, that the interaction of external water and magma is relatively passive when it occurs in regions of high hydrostatic pressure, such as in the deep ocean, but violent explosions will, on the other hand, occur in shallow water. Similarly, magma rising through highly porous and water-logged rocks at shallow levels in the crust can result in explosive eruption because of the conversion of water to steam in contact with the magma. Thus even "dry" basaltic magmas, virtually devoid of magmatic water, can erupt with explosive violence if external water is at hand.

---

## VIII. THE IMPACT OF VOLCANISM

As emphasized earlier, volcanism is the surface manifestation of deep Earth processes, and eruptions are merely the smoke rising from the "subduction factory" or the midocean ridge "kitchen." In the greater scheme of things, volcanic activity is thus a part of a geodynamic system that is essential for maintaining a balanced environment for life on Earth. On a local scale, however, both hazards and benefits are associated with volcanoes, as discussed in Chapters 56 to 67 and 76 to 82, respectively.

Despite their awe-inspiring, spectacular, and even deadly fireworks, volcanic eruptions have not been nature's most deadly hazard in living memory. The principal volcanic disasters since 1700 have taken a total of 260,000 lives, which pales in comparison with the death

toll from earthquakes and tropical storms. The deadliest disaster known was probably the 1556 Huahsien earthquake in China, which killed more than 820,000 people. In 1976 the magnitude 7.8 Tangshan earthquake, also in China, killed more than 240,000 people. The worst hurricane in history occurred in 1970 in the Ganges Delta in Bangladesh, with a loss of 500,000 lives. Yet living with a dormant or active volcano, looming large above village or town, is a visible and permanent threat and qualitatively different from the transient threat of a hurricane or a sudden earthquake.

When we view volcanic hazards, however, we must take the long view and keep in mind that the historical period is too short to display the full range of the magnitude and intensity of volcanic eruptions that the Earth can muster. Even in the 6000-year life span of our civilization, we have been spared a mega-eruption of the type that can occur. We are all familiar with the concept of the storm of the century—an event so large that it occurs only very rarely—but the probability of its recurrence increase with time. Similarly, high-magnitude and high-intensity volcanic eruptions are low-probability events, but they will recur in the future. In our limited human experience, we have the eruption of the type that occurs once in 100 years, such as Krakatau in 1883, or the eruption that occurs once in 1000 years, which must be regarded as the Tambora eruption of 1815. What about the 10,000 or 100,000 or every million years eruption? The Toba eruption on Sumatra, about 75,000 years ago, is probably at the upper limit of eruptions that can occur on the Earth, emitting 2000 km<sup>3</sup> of magma. That there is an upper limit on the magnitude of eruptions is itself an interesting concept, but most likely any larger magma chamber cannot be contained in the Earth's crust and will spontaneously erupt. Because the Toba event occurred in the far distant past, our information of its environmental impact is still blurred, but a cataclysmic event of this type would have a catastrophic impact on global society today, as discussed in Chapter 67. When we take the geologic perspective of time and volcanism, we are therefore reminded of the chilling words of the American historian Will Durant: "Civilization exists by geologic consent, subject to change without notice." The Tambora eruption on the island of Sumbawa in Indonesia in 1815 gives an inkling of what may happen in such a volcanic event.

The regional impact of the 1815 Tambora eruption in the East Indies has been dimmed by the passage of time, and only incomplete counts exist, but they indicate a natural disaster of enormous gravity for the Indonesian people. The disaster struck both on the island of Sum-

bawa, where Tambora is located, and on the neighboring islands of Lombok, Flores, South Sulawesi, and Bali. Even Java was not spared. During the climax of the explosive eruption on April 10, 1815, hot pyroclastic flows swept down all flanks of the volcano and wiped out the feudal kingdoms of Tambora on the north side and Sanggar on the east side of the mountain. In the Kingdom of Tambora, the loss of life was so complete that it extinguished the Tambora language, probably the easternmost Austro-Asiatic language at the time, with more than 10,000 people killed outright in the pyroclastic flows. The blanket of ash fallout on Sumbawa also destroyed all the crops, resulting in a famine immediately after the eruption. It was accompanied by a variety of diseases, and clean water was not to be had anywhere. For some reason, the island's climate changed, becoming so hot and dry that crops would not grow—probably because of the destruction of the vegetation and higher runoff. An additional 38,000 people died of starvation and disease, having lost 75% of their livestock, and 36,000 fled the island. It took the island at least one century to recover from this ecological and human disaster.

The effects of the Tambora eruption were not, however, restricted to Sumbawa. The ash fall was principally to the west. In Lombok and Bali, the ash was so thick that many people were killed immediately as the roofs of their homes collapsed under the weight of huge quantities of ash. Even on these distant islands the toll from famine and disease brought about by the eruption was severe. On Lombok, estimates of the death toll ranged between 44,000 and 100,000 and on Bali at least 25,000. The depth of famine and disease was so great that it even claimed lives among the Balinese royalty. A conservative number of dead in the East Indies from the Tambora 1815 eruption is at least 117,000.

News of this distant eruption in Indonesia did not reach the Western world for some time, but unusual atmospheric phenomena and climate deterioration set in during 1816—"the year without summer." As detailed in Chapter 57, Tambora-size (ca. 100 km<sup>3</sup> of magma) explosive volcanic eruptions emit large quantities of sulfur dioxide gas into the stratosphere, where it is converted into a sulfuric acid aerosol dust veil that encircles the Earth. The aerosol has the effect of reducing solar heat reaching the surface of the planet, leading to global cooling. Strange atmospheric phenomena had been observed in Europe before the summer of 1816. In May 1815 the sunsets in England were exceptionally colorful, and by September the sky seemed to be on fire every evening. But the spectacular skies brought bad weather the following year, and the year 1816 is the

worst on record in Europe, with the mean temperature about 3°C below average across the entire continent from Britain in the north to Tunisia in the south. In England the summer was miserable, with the mean temperature for June the lowest on record, or 12.9°C. In France it was so cold that the wine harvest was later than at any time since record keeping began—delayed until November in those districts where the grapes were not already frozen on the vine. In Germany crops failed, a situation exacerbated by the war with Napoleon, and famine and price inflation were widespread. Conditions in Germany became so intolerable that people in many districts rioted and set off in search of better living conditions, starting the great migration from northern Europe east to Russia and west to America. The severe weather in fact led to crop failure of all the major crops in Europe and a doubling of the price of wheat from 1815 to 1817. When we consider that in the early part of the 19th century agriculture was the mainstay of society, it is clear that the climate change had a strong impact on the economy of the Western world.

In North America the year 1816 was also unusually cold and dry, especially in New England and, as mentioned, is known in annals as “the year without summer.” In early May, most farmers had planted their corn, the main crop at that time. But by mid-May the weather deteriorated, with severe frost that froze the fields as far south as New Jersey. As late as mid-June frosts also plagued New England, New Jersey, and New York. Then a great drought began, stunting or destroying the few remaining crops. In early July frost again swept over New England, from Maine to Connecticut, and again in late August in Maine, Vermont, and south to Massachusetts. By the end of September a final frost destroyed the few crops that had survived the frigid summer. These crop failures, in both Europe and North America, have rightfully been called “the last great subsistence crisis of the Western world.” The growing season, of course, was much shorter than normal. In New England the average growing season is about 120 to 160 days, but in 1816 it was only 70 days in Maine, 75 in New Hampshire, and 80 in Massachusetts—a reduction of 40–50% (Fig. 5). Many farmers suffered such heavy losses that they abandoned their farms and migrated to the western territories.

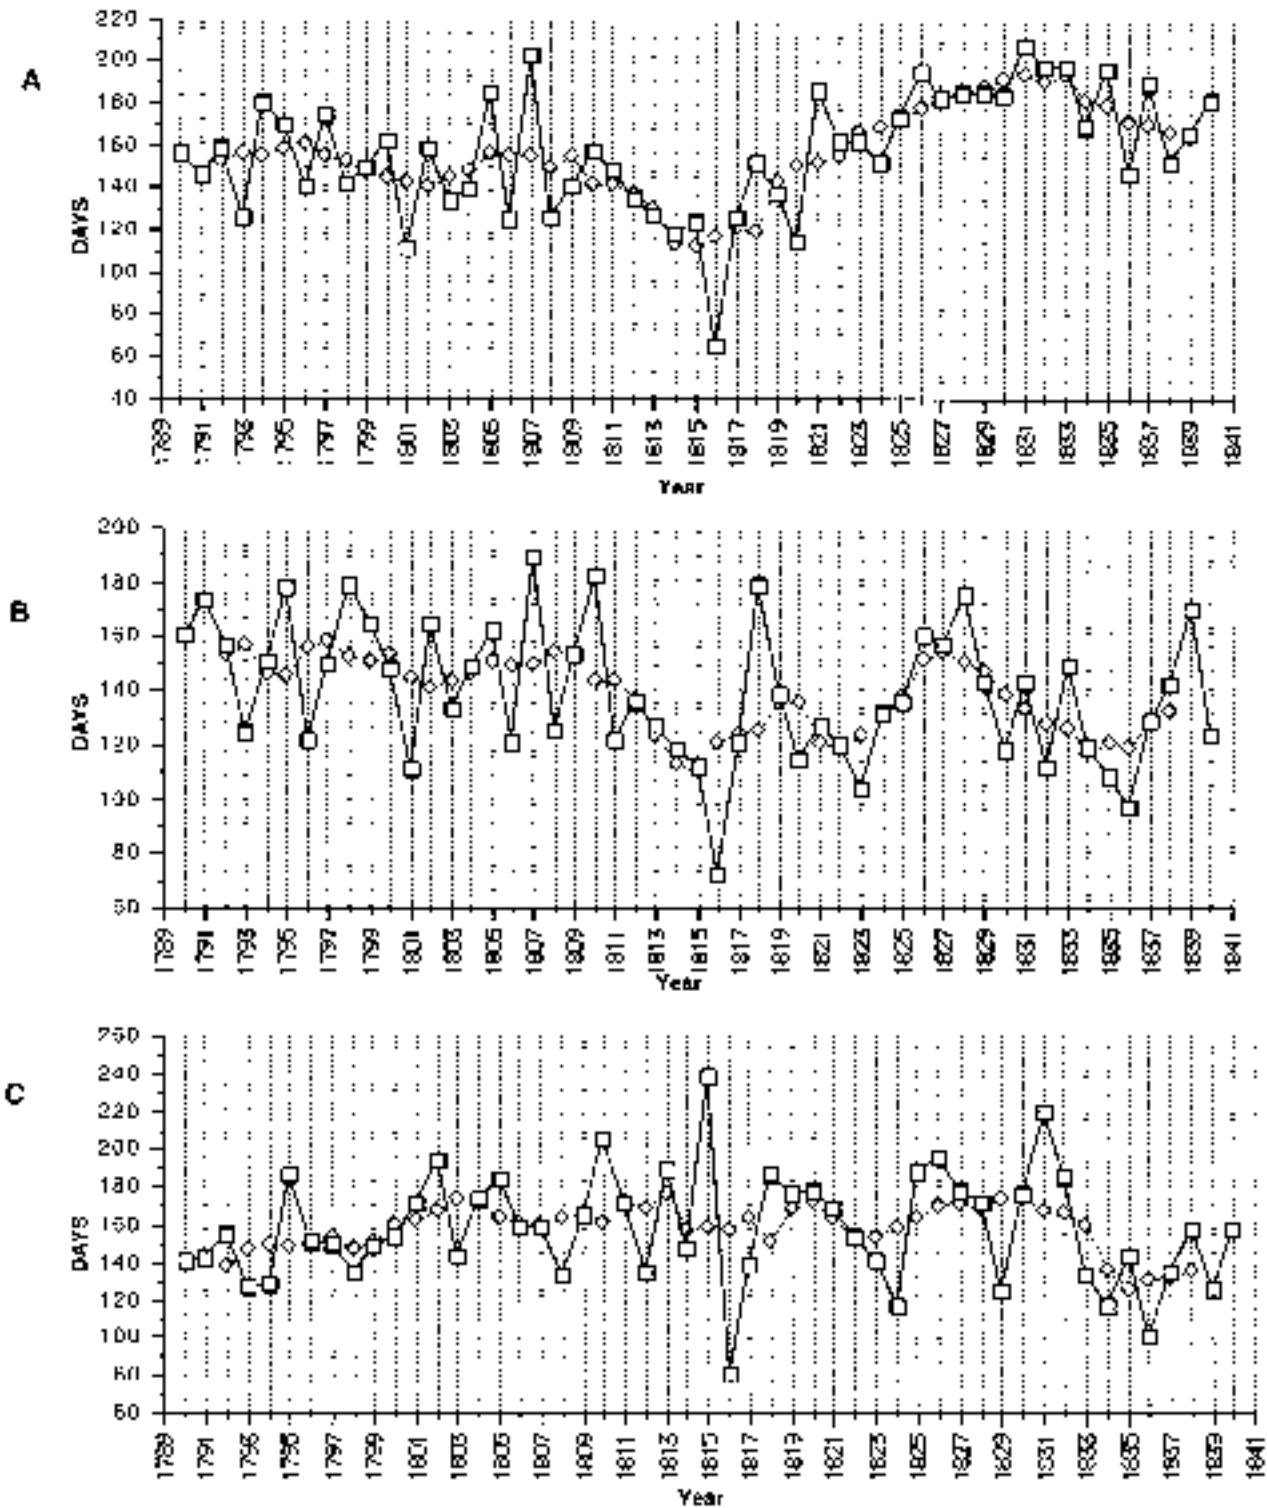

The abnormal climate conditions in 1816 have frequently been proposed as an important factor in the first worldwide cholera epidemic. The bad weather also caused a series of crop failures in India, and as a consequence a cholera epidemic broke out in Bengal. It was spread further afield by British soldiers, to Afghanistan,

Nepal, and Indonesia in 1820. A second epidemic broke out in India in 1826 and spread to Europe in 1831 and North America in 1832. It is likely that the severe climate conditions (abnormal weather, crop failures, subsequent famine, and reduced resistance to disease) brought about by Tambora may have played a role in the origin of a new and aggressive form of cholera that first did its deadly work in Bengal in 1817.

The global climate impact of large eruptions is a major reason that an understanding of volcanic phenomena is important for society today. A Tambora-size eruption in the 21st century will have much more profound effects on humans living on an overcrowded Earth, where natural resources are strained to the limit. The effects of a Toba-size eruption (ca. 2000 km<sup>3</sup>) in the future are incalculable, but it will occur—we hope not in our lifetime.

For the most part, humans not only have learned to live with the slumbering volcanic giant, but have managed to extract a variety of economic benefits from the material and energy resources that lie at the roots of volcanoes. The precious diamond is merely carbon that has been crystallized under the high pressure (equivalent to the weight of the Eiffel tower resting on a 10-cm plate) and the high temperature in the Earth’s mantle. Diamonds are brought up to the surface in volcanic pipes, such as the famous diamond pipes of Kimberley in South Africa. Even the carbon in precious diamond may be of mundane origin, reminding us of the steady recycling of material in Earth’s kitchen. Thus isotopic analyses show that the carbon in at least some diamonds is probably derived from marine sediments that were subducted into the mantle early in Earth’s history. As described in Chapter 55, a wealth of mineral deposits is also associated with the roots of volcanoes, where hydrothermal activity has led to concentration of metals.

One of the more promising benefits from volcanic activity is the harnessing of geothermal energy. The Earth’s crust and lithosphere are in reality a boundary layer between the hot mantle and the hydrosphere and atmosphere. In volcanic regions the heat flux across this boundary layer is very large, and it can be tapped effectively by drilling. For example, about 85% of all homes in Iceland are heated with geothermal water, making Icelanders the largest users of geothermal energy per capita in the world (24,000 kWh per capita). It is estimated that the use of geothermal energy alone is saving imported oil costs of about \$560 per year per person (Chapter 76). With the modern technology of deep drilling, the exploitation of this cheap and clean energy resource from the interior of the Earth does not

**FIGURE 5** Volcanic eruptions can change the climate. The great Tambora volcanic eruption in Indonesia in 1815 led to a short-term global climate change that dramatically shortened the growing season in New England the following year. The sulfur dioxide gas emitted by the volcano produced a veil of sulfuric acid aerosol in the stratosphere worldwide, decreasing the amount of solar radiation reaching the Earth's surface, causing global cooling. The figure shows the length of the growing season on an annual basis (dots) from 1789 to 1841 and the 5-year running average (solid line). Growing season in the states of (A) Maine, (B) New Hampshire, and (C) Massachusetts. The shortest growing season on record was in the year following the Tambora eruption. (Reproduced from *The Year Without a Summer? World Climate in 1816*, published by the Canada Museum of Nature, Ottawa, 1992.)

have to be restricted to active volcanic regions such as Iceland, Italy, and New Zealand, but may be one of the major global sources of energy of the future.

## GLOSSARY

**decompression melting** The melting that occurs when some portion of the Earth's mantle undergoes a decrease in pressure, such as due to convective rise or upwelling of mantle peridotite beneath midocean ridges and volcanic arcs. The upwelling results in melting, because the melting point (beginning of melting) of peridotite occurs at a lower temperature with decreasing pressure.

**eclogite** An igneous rock with a mineralogy characterized by high-pressure minerals, but whose chemical composition corresponds to that of basalt.

**exothermic reaction** A chemical reaction that produces heat. The early chemists proposed that exothermic chemical reactions deep within the Earth, such as reactions between sulfur and iron, or oxidation of the alkali metals could be the cause of heat and volcanic activity.

**neptunists** The group of 18th-century geologists who believed that basalt and similar rocks were not of volcanic origin, but had formed by precipitation from a primordial ocean.

**obsidian** High-silica volcanic glass, generally black or dark gray in color, with the chemical composition of rhyolite.

**palagonite** A claylike mineral produced by the hydration of basaltic volcanic glass.

**peridotite** An ultramafic (high-magnesia, low-silica) igneous rock, whose mineralogy is dominated by olivine and pyroxene. Peridotite is the principal rock type of the Earth's upper mantle and the most likely source rock for basalt by partial melting.

**plutonists** The group of 18th-century geologists who believed that basalt and related rocks were produced by solidification from magma or silicate melt.

**sideromelan** Basaltic volcanic glass, which produces palagonite upon hydration.

**xenoliths** Rock fragments originating in the deep Earth (primarily the mantle), brought to the surface by volcanic eruptions.

---

## I. INTRODUCTION

This chapter is on the history of ideas about the generation of magma within the Earth—the root cause of all volcanic phenomena. It is a process that results in the transport of material and heat from depth to the surface of our planet. It would seem logical that the history of ideas on melting in the earth would be synonymous with the history of “classical” volcanology. This is not the case, however, because up to the mid-1970s volcanology was essentially a descriptive endeavor, devoted primarily to the geomorphology of volcanic landforms, geography of volcanic regions, and the chronology of eruptions. Until recently, volcanologists have shown little insight as to the physical processes of volcanic action and often ignored the causes of the melting processes that lead to the formation of magma. Volcanology thus became a descriptive field, lacking rigor, and on the fringes of science. It is now timely to redefine modern volcanology as the science that deals with the generation of magma, its transport, and the shallow-level or surface processes that result from its intrusion and eruption. Modern volcanology is, however, highly interdisciplinary and draws widely from diverse geoscience subspecialties.

The processes that bring about melting in the Earth had been discovered by physicists in the mid-19th century, but due to the bifurcation of scientific fields, volcanologists were on the whole ignorant of these findings of the early natural philosophers or geophysicists and continued to pursue a descriptive approach to surface features without acquiring an understanding of the fundamental processes at work deep in the Earth. Table I lists some of the principal historical advances made in the study of volcanism up to the 20th century.

---

## II. THE BEGINNINGS

In prehistoric times, opportunities to “discover” fire and to observe heat abounded in the natural world. Lightning strikes ignited fires in the primeval forest or on arid, grassy plains. Volcanic eruptions and lava flows threw forth showers of glowing sparks and incandescent heat. Most likely these were the sources our early ancestors borrowed from, carefully nurturing the fires they kindled, for their sources were only fickle and local. With fire at their command, humans could venture into new realms of cold and dark—into polar terrain and mountain caves.

Our knowledge of human precursors and early humans is intimately linked with volcanic eruptions (see Chapter 80). It is because of the excellent preservation of fossils in volcanic deposits that paleoanthropologists have begun to unravel the mystery of human origins. Most of the oldest remains of early man come from volcanic regions in Africa and Indonesia, and the association of volcanic activity with these fossils is no mere coincidence. The most logical explanation for their relative abundance and good preservation in such environments is that the bones were rapidly covered by volcanic deposits. Just as the Roman cities of Pompeii and Herculaneum were instantly buried by the eruption of Vesuvius in 79 A.D. and preserved virtually intact to our day, so have earlier volcanic deposits sealed in the remains and fragile artifacts of our more distant ancestors, preserving them for millions of years. The stunning discovery of 3.7-million-year-old *Australopithecus* hominid footprints crisscrossing a volcanic ash deposit at Laetoli in the East African Rift is a graphic testament of the power of preservation by volcanic ash fall. Volcanic deposits also contain minerals that can conveniently be dated by measuring the decay of radioactive isotopes of potassium and argon, a method that has enabled the dating of fossil remains of the oldest human, *Homo habilis*, at Olduvai as 1.75 million years old. A similar setting in the African rift at Hadar in Ethiopia has yielded fossils of the possible human precursor, *Australopithecus afarensis*, permitting its dating at 3.5 million years. Volcanic stone is the earliest known material used in the creation of tools by genus *Homo*. The earliest stone artifacts are about 2.5 million years old, implements made from lava, found on the shore of Lake Turkana in east Africa. Following their humble beginnings as toolmakers with the fashioning of these crude “cores,” early humans gradually improved the techniques of working stone into flakes, choppers, hand axes, cleavers, and, finally, delicate obsidian stone blades in the upper Paleolithic.

More mundane materials such as pumice and volcanic ash have been used for nearly 3000 years in making cement. A mixture of volcanic ash and lime produces a very durable and water-resistant hydraulic cement. Volcanoes were also a principal source of sulfur. Early on people realized that sulfur burns with a strange and sputtering flame, giving off an evil-smelling and choking vapor. Probably the first uses for sulfur were to kill insects and to bleach wool, feathers, and fur. Homer knew of its fumigation property, and praised the “pest-averting sulfur” and Ulysses called out: “Quickly, bring fire that I may burn sulfur, the cure of all ills.” Over the centuries the burning of a sulfur candle was a house-

TABLE I The Evolution of Ideas about Volcanic Activity

Scientist	Year	Discovery or hypothesis
Anaxagoras	5th cent. B.C.	Eruptions caused by great winds inside the Earth
Seneca	65 A.D.	Combustion as a source of heat in Earth
Pliny the Elder	79 A.D.	First scientific expedition to study an eruption
Pliny the Younger	79 A.D.	First volcanic eyewitness account, Vesuvius eruption
Snorri Godi	1000 A.D.	Basaltic rock in Iceland recognized as of lava flow origin
Liberti Fromondi	1627	Explosive eruptions compared to combustion of gunpowder
Edward Jorden	1632	"Fermentation" chemical reactions of sulfur generate terrestrial heat
René Descartes	1650	Incandescent Earth core as source of volcanic heat
Athanasius Kircher	1665	First global map of the distribution of volcanoes on Earth
Francesco d'Arezzo	1670	First experiments with molten rocks; melts Etna lava
J.-E. Guettard	1751	Identifies rocks at Volvic in Auvergne, France, as lava
Pierre Grignon	1761	Extracts crystals from glass slags; products of glass furnaces compared to products of volcanoes
Nicholas Desmarest	1763	Prismatic basalt columns in Clermont of volcanic origin
William Hamilton	1776	Pioneer in field volcanology; recognizes dikes and magmatic veins
Ben Franklin	1783	Volcanic eruptions have atmospheric effects and can cool Earth
James Hutton	1785	Recognizes intrusions of magma into the crust of the Earth
James Hall	1790	Melting and crystallization experiments on basalt
D. Dolomieu	1790	Some sediments are stratified and consolidated volcanic ash
Leopold von Buch	1799	Minerals in lavas formed by crystallization from magma
Lazzaro Spallanzani	1794	Earliest chemical analysis of volcanic rocks
John Playfair	1802	Water vapor is the dominant magmatic gas; causes explosions
Robert Kennedy	1805	Speculates that change in pressure affects melting of rocks
Humphry Davy	1808	First complete chemical analysis of basalts
Pierre Cordier	1815	Exothermic reactions of alkalis provide volcanic heat
A. von Humboldt	1822	Identifies and analyzes the mineral components of lavas
George P. Scrope	1825	Linear arrangement of volcanoes related to deep-seated tectonics
Charles Darwin	1835	Decompression melting can produce magma in Earth's interior
S.-D. Poisson	1835	Chemical differentiation produces variety of magma types
Gustav Bischof	1837	Crystal settling is the agent of magmatic differentiation
William Hopkins	1839	Recognizes that the high pressure in the deep Earth would lead to solidification of rock at higher temperature
Robert Bunsen	1851	Demonstrates experimentally that the transformation from solid rock to magma results in increase in volume
S. Waltershausen	1853	Decompression melting as a process in generation of magmas
Robert Mallet	1858	Magma mixing produces intermediate magma types; recognizes that magmas are solutions
Osmond Fisher	1881	Water vapor expansion causes magma fragmentation and pyroclastic; recognizes importance of submarine volcanic rock formations
John Judd	1881	Map of global distribution of earthquakes and volcanoes
Carl Barus	1893	Proposes convection currents within the Earth
Alfred Lacroix	1902	Volcanic recycling of water from volcanoes to atmosphere, to oceans, and back to magma through solid Earth
Frank Perret	1906	First to determine the melting curve of basalt as a function of pressure
Alfred Wegener	1912	Documentation of the eruption of Montagne Pelée
Arthur Holmes	1915	Pioneer in application of technology to study of volcanic phenomena
Arthur Holmes	1916	Theory of continental drift
Arthur Holmes	1928	Calculates a temperature profile for the Earth based on radioactive generation of heat
Norman L. Bowen	1928	Basaltic magma generated by partial melting of peridotite
		Decompression melting and magma generation by mantle convection
		Fractional crystallization theory developed to explain magma range

cleaning ritual following a case of contagious disease in the home. Sulfur features in Egyptian prescriptions of the 16th-century B.C., and Pliny the Elder describes its medicinal, industrial, and artisan uses in his *Historia Naturalis* (77 A.D.). The Romans also found a new application in warfare for the sulfur they mined in Sicily. By mixing it with tar, rosin, and bitumen, they produced the first incendiary weapon.

*[A] volcano is not made on purpose to frighten superstitious people into fits of piety and devotion; nor to overwhelm devoted cities with destruction; a volcano should be considered as a spiracle to the subterranean furnace, in order to prevent the unnecessary elevation of land, and fatal effects of earthquakes; and we may rest assured that they, in general, wisely answer the end of their intention, without being in themselves an end, for which nature has exerted such amazing power and excellent contrivance.*

### III. THE LEGENDS AND HELL

Volcanic eruptions (Table II), the most spectacular and awe-inspiring of natural phenomena, have throughout history inspired religious worship and led to the creation of myths (Chapter 80). Even in the 20th century, these responses can be observed when a volcano erupts. James Hutton, regarded by many as the father of geology, was in 1788 the first to attempt to explode the myth associated with volcanic eruptions. In Hutton's view,

Primitive people the world over have long believed that volcanoes were inhabited by deities or demons that were highly temperamental, dangerous, and unpredictable. To appease the capricious gods, humans have for centuries made the ultimate sacrifice. Thus the Mayans, Aztecs, and Incas offered humans to their volcanoes. Nicaraguans long believed that their dangerous volcano Coseguina would stay quiet only if a child were thrown into the crater every 25 years. Similarly, young women were thrown into the crater of Masaya volcano in Nicaragua to appease the fire. Until recently, people on Java

TABLE II Historic Eruptions

Eruption	Significance
Thera (Santorini), 1650 B.C.	One of the largest explosive eruptions on Earth; may have contributed to the decline of Minoan civilization
Vesuvius, A.D. 79	First major historical eruption to occur within range of major cities; first eruption to be documented by an eyewitness
Etna, 1669	Major lava flow event with widespread destruction in Catania from lavas
Lakagigar, 1783	Largest lava flow eruption on Earth; catastrophic impact on Iceland population from haze produced by volcanic gas emission
Asama, 1783	Local devastation from pyroclastic flows; country-wide impact in Japan from climate effects
Tambora, 1815	Largest historic volcanic eruption on Earth; highest eruption column (43 km); global sulfuric acid aerosol causes global climate change; largest known death toll of over 92,000 people
Krakatau, 1883	First large eruption of the modern age; severe impact and death toll from tidal waves (tsunami)
Mount Pelée, 1902	The classic example of a small eruption causing severe loss of life; the beginning of the study of pyroclastic flow and surge processes
Paricutin, 1943	The birth and growth of a new volcano observed
Bezymianny, 1956	One of the highest known eruption columns in a historic event (42 km)
Surtsey, 1963	Best evidence of magma–water interaction during explosive eruption
Mount St. Helens, 1980	First major eruption to be monitored intensively with modern technology
El Chichón, 1982	Most widespread pyroclastic surges from a historic explosive event
Nevado del Ruiz, 1985	Another example of a small eruption causing severe loss of life; tragic example of lack of hazard mitigation measures
Pinatubo, 1991	Largest eruption of the 20th century; major societal impact in Philippines; important global atmospheric effects

sacrificed humans on Bromo volcano, and still throw live chickens into the crater once a year. People living near the feared volcanoes of Nyamuragira and Nyaragongo in central Africa annually sacrificed 10 of their finest warriors to the cruel volcano god Nyudadagora. To those who were skeptical of such rites and pointed out that earlier sacrifices had failed to prevent or stop an eruption, the believers have countered with the argument that things would have been much worse without the sacrifice.

The Aztec people named the volcanoes surrounding the Valley of Mexico after their gods. Popocatepetl and Iztaccihuatl, lying to the east of the valley, were worshiped as deities, linked to a beautiful love story. When Popocatepetl ("Smoking Mountain") returned victorious from war to claim his beloved, his enemies sent word ahead that he had been killed, and princess Iztacchihuatl ("Sleeping Woman") died of grief. Popocatepetl then built two great mountains. On one he placed the body of Iztaccihuatl; on the other he stands eternally, holding her funeral torch.

Volcanic eruptions featured high in Greek mythology, which abounds with allusions to volcanoes, associating them with such gods as Pluto, Persephone, Vulcan, and the fearsome Typhon. The idea that volcanic activity represents the stirrings of the Titans, giants imprisoned in the Earth, goes back to the classical time of the Greeks. The mythical association of volcanic eruptions with battles between the Olympian gods and the Titans is very likely to date back to Preclassical antiquity. The Greeks saw the Titans as huge man-creatures, born of the Earth to attack the gods. Confined under various volcanic regions, their appearance on the land or in the air seemed the logical precursor to a volcanic eruption. The most awe-inspiring of all the Greek monsters was Typhon. The firstborn of Gaia (Mother Earth) and Zeus, he was the largest monster that ever lived. His arms, when spread out, reached a hundred leagues, fire flashed from his eyes, and flaming rocks hurtled from his mouth. Even the gods of Olympus fled in terror at his sight. Typhon rebelled against the gods and even opposed Zeus, who then hurled Mount Etna at him, trapping the frightful creature under the mountain. When Typhon was thus imprisoned under Etna, a hundred dragon's heads sprang from his shoulders, with eyes that erupted flames, a black tongue and a terrible voice. Each time Typhon stirs or rolls over in his prison, Etna growls, and the Earth quakes, with eruptions and veils of smoke covering the sky (Fig. 1).

The Hades of the Greeks and Romans made an easy transformation into the Hell of the early Christians, described in the Bible as a place with an eternal fire that

shall never be quenched. St. Augustine spoke of Hell as containing a lake of fire and brimstone. By the Middle Ages, Hell had taken on great importance, with most scholars convinced that it was a real and fiery place. One place most often cited as the gateway to Hell was Mount Etna volcano in Sicily, and "sailing to Sicily" became a euphemism for going to Hell.

#### IV. WIND IN THE EARTH

The earliest known ideas on the cause of volcanic eruptions date to the Greek natural philosophers of the fifth-century B.C. Anaxagoras proposed that eruptions were caused by great winds stored inside the Earth. When these winds were forced through narrow passages or emerged from openings in the Earth's crust, the friction between the compressed air and the surrounding rocks generated great heat, leading to melting of the rocks and the formation of magma. To anyone who has observed an explosive volcanic eruption, this is a perfectly logical idea, one that in fact was taken up by Aristotle and passed on by scholars until the Middle Ages.

Aristotle (384–322 B.C.) discussed the origin of earthquakes, attributing the same or similar origin for volcanic eruptions. "The Earth," he wrote in the *Meteorologica*, possesses "its own internal fire," which generates wind inside the Earth by acting on trapped air and moisture, leading to earthquakes and volcanic eruptions. He even makes a comparison with human anatomy in discussing the effect of the "internal wind": "For we must suppose that the wind in the earth has effects similar to those of the wind in our bodies whose force when it is pent up inside us can cause tremors and throbings." Aristotle thought that the heat associated with volcanic eruptions was generated by friction produced when the wind moved rapidly through restrictions within the Earth. "The fire within the Earth can only be due to the air becoming inflamed by the shock, when it is violently separated into the minutest fragments. What takes place in the Lipari Isles affords an additional proof that the winds circulate underneath the Earth."

The identification of volcanic activity with "wind and fire" by the early Greeks follows logically from actual observations of a volcanic eruption. The most striking phenomena are first the explosive uprush of hot gases or "wind" from the Earth through the crater; then the incandescent red-hot glow of molten rock, giving the appearance of fire. It was on the basis of these phenom-

FIGURE 1 According to Greek mythology, the giant Typhon is buried under Etna volcano, and whenever the giant stirs, the volcano erupts violently. (Eighteenth-century print.)

ena that Aristotle postulated a vast store of pent-up wind within the Earth, which generated friction and high heat and found its escape in volcanoes. After all, the Platonic view was that heat is a kind of motion. Aristotle's concept of volcanism is thus firmly rooted in his ideas about the capacity of motion to generate heat as stated in his *Meteorologica*: "We see that motion can rarefy and inflame air, so that, for example, objects in motion are often found to melt." This theory, which dates in fact to his predecessors, Anaxagoras, Plato, and Democritus, was remarkably long lived and had adherents well into the 16th century.

#### V. INTERNAL COMBUSTION

Initially the Roman philosophers adopted the Greek view of the causes of volcanic eruptions, but eventually they proposed another explanation, one more in keeping with the practical Roman mind. Lucius Annaeus Seneca (2 B.C.–A.D. 65) wrote on volcanism in his work on natural philosophy, *Questiones Naturales*. He attributed volcanic eruptions in part to the movement of winds within the Earth, struggling to break out to the surface, thus in part following Aristotle. But his most notable and

truly original contribution to theories of volcanism is his proposal that the heat liberated from volcanoes is derived from the combustion of sulfur and other flammable substances within the Earth—an idea that was to have many adherents into and even beyond the Middle Ages. His claim was that there were great stores of sulfur and other combustible substances in cavities within the Earth, and that when the great subterranean wind rushed through these regions, frictional heating would set these fuels on fire. It is in his discussion of hot springs and thermal waters that Seneca first makes reference to sulfur and other combustible materials as a potential heat source, proposing that “water contracts heat by issuing from or passing through ground charged with sulfur.” He then extends this process to explain the blasts from a volcanic eruption in his work *Questiones Naturales*:

*We must recognise, therefore, that from these subterranean clouds blasts of wind are raised in the dark, what time they have gathered strength sufficient to remove the obstacles presented by the earth, or can seize upon some open path for their exit, and from this cavernous retreat can escape toward the abodes of men. Now it is obvious that underground there are large quantities of sulfur and other substances no less inflammable. When the air in search of path of escape works its tortuous way through ground of this nature, it necessarily kindles fire by the mere friction. By and by, as the flames spread more widely, any sluggish air there may be is also rarefied and set in motion; a way of escape is sought with a great roaring of violence.*

Seneca's ideas were long lived and formed the basis of the interpretation of the causes of volcanic eruptions throughout the Middle Ages and even well into the 18th century.

Other significant writing on volcanism in the Roman world is found in poetry. The Latin poem *Aetna*, written between A.D. 63 and 79, is of considerable importance in the history of volcanological thought; its likely author is Lucilius Junior. The poet maintained that the Earth is not solid, but has numerous caverns and passages. Heat, he argues, is more intense and powerful when in action in a confined space within the Earth, with the bellows-like action of winds in subterranean furnaces giving rise to volcanoes. In his view, the flames of Etna were fueled by a combustible substance, such as liquid sulfur, oily bitumen, or alum.

Philostratus the Elder (ca. A.D. 190) also discusses subterranean passages in the Earth, with fires breaking out through volcanoes: “If one wishes to speculate about such matters, the island of Sicily provides natural bitumen and sulfur, and when these are mixed by the sea,

the island is fanned into flame by many winds, drawing from the sea that which sets the fuel aflame.”

The eruption of Vesuvius in 79 A.D. marks a watershed in the study of volcanism. When he observed the eruption from Misenum, at a distance of 30km, Pliny the Elder set out on the first expedition devoted to the study of a volcanic process; he died in the attempt. His nephew Pliny the Younger stayed at home, where he had a spectacular view of the eruption, and wrote the first eyewitness account of the phenomenon, a classic description in the volcanological literature (Fig. 2).

## VI. EXOTHERMIC CHEMICAL REACTIONS

Study of the Earth, like many scholarly activities, suffered a setback with the growth of the new Christian religion; and the only role of volcanoes in this new world order was to serve as a reminder of the hellfires burning below. This irrational attitude toward science continued well beyond the Middle Ages. Even by the 18th century, most writers on the philosophy of nature still considered that God created the Earth as a habitat for humans, that it had undergone certain stages of evolution since, and that it would ultimately be transformed or destroyed by Him. This was still manifest in the writings of John Wesley (1703–1791), the founder of Methodism, who taught that before sin entered the world, there were no earthquakes or volcanoes. These convulsions of the Earth were simply the “effect of that curse which was brought upon the earth by the original transgression.”

The Early Middle Ages of Western Europe coincided with a remarkable growth of learning in Asiatic countries, which were in their prime from A.D. 800 to 1100. Contrary to the Christian philosophy, the Koran encouraged the Islamic scholar to practice the mastery of *taffakur*, or the study of nature. Unlike most learned Europeans, who saw nature as a vivid illustration of the moral purposes of God, the Arabs sought knowledge that would give them power over nature. They were the first alchemists; and one element that figured prominently in their studies was sulfur, which was in part mined from volcanoes. Their discovery that sulfur could also give off heat in chemical reactions was to generate the idea that volcanic action was also fueled by sulfur in the Earth.

The early chemists dealt a death blow to the theory of internal combustion as the source of subterranean fires. In his work on *Discourse of Naturall Bathes and*

**FIGURE 2** During the A.D. 79 eruption, Pliny the Younger remained at home in Misenum to do his homework, while his uncle set out on a research and rescue mission toward the volcano, where he perished. (From a painting by Angelica Kauffmann, 1785. Oil on canvas, The Art Museum, Princeton University.)

*Minerall Waters* (1632), Edward Jorden (1632) rejected the notion that the Earth is a hollow and fiery furnace with a universal fire fueled by combustible coal, bitumen, or sulfur. He pointed out the fundamental problem regarding the internal fire: It would require a tremendous amount of air to keep it burning. Any flame that is confined without access of abundant air would soon be put out, because “fuliginous vapours … choake it if there were not vent for them into the ayre.” Such abundance of air could not reach the deeper portions of the Earth to fan the central fire. Instead, Jorden proposed that volcanic regions are underlain at only a shallow depth by “fermenting” material. As a source of the heat, he sought an explanation in the process of chemical reactions as a basis for a new system of the Earth. “Fermentation” or chemical reaction could take place in the presence of water, which was clearly abundant deep in the Earth’s crust, whereas combustion could not proceed in the presence of water. Although his reasoning logically should have ended the hypothesis of combustion as the heat source in the Earth, the idea persisted well into the late 18th century.

Another pioneer chemist was Robert Hooke (1635–1703), who began his career as Robert Boyle’s laboratory assistant in Oxford. Hooke was one of the first to make a clear distinction between heat, fire, and flame, and, together with Boyle, to study the various phenomena of heat. He developed a “nitro-aerial” theory of combus-

tion, in which thunder and lightning were likened to the flashing and explosion of gunpowder, during the combustion of sulfur and nitre. These ideas are reminiscent of the work of Liberti Fromondi in the *Meteorologorum* (1627), in which the explosive power of earthquakes and volcanic eruptions was compared to the effect of gunpowder. Volcanic activity Hooke attributed to “the general congregation of sulfurous, subterraneous vapors.” In his work on *Lectures and Discourses of Earthquakes and Subterraneous Eruptions* (1668), Hooke also claimed that geologic activity was on the wane, and that subterranean fuel had been more plentiful in the past history of the Earth, when eruptions and earthquakes were apparently more severe: “That the subterraneous fuels do also waste and decay, is as evident from the extinction and ceasing of several vulcans that have heretofore raged.” This concept of a finite supply of “subterraneous fuels” was widely accepted and was endorsed by Lord Kelvin in 1889.

Isaac Newton (1642–1727) concerned himself with the process of volcanism, but his ideas on the causes of this phenomenon were derived from his contemporary alchemists and early chemists. His ideas on the causes of “burning mountains” are clearly a direct outcome of his secret work on alchemy. In Newton’s chemical experiments, he had observed the evolution of heat, or exothermic reactions, when certain substances were mixed together, such as “when aqua fortis, or spirit of

vitriol, poured upon filings of iron dissolves the filings with great heat and ebullition." With some other sulfurous mixtures "the liquors grew so very hot on mixing as presently to send up a burning flame," and "the *pulvis fulminans*, composed of sulphur, niter, and salt of tartar, goes off with a more sudden and violent explosion than gunpowder." By 1692 Newton had formulated opinions about the origin of heat in the Earth and its intensity, and compared it to the irradiance received by the Earth from the sun: "I consider that our earth is much more heated in its bowels below the upper crust by subterraneous fermentations of mineral bodies than by the sun." In an experiment described in his work *Opticks*, Newton tested his fermentation hypothesis and drew his conclusion on the causes of volcanism:

*And even the gross body of sulphur powdered, and with an equal weight of iron filings and a little water made into a paste, acts upon the iron, and in five or six hours grows too hot to be touched and emits a flame. And by these experiments compared with the great quantity of sulphur with which the earth abounds, and the warmth of the interior parts of the earth and hot springs and burning mountains, and with damps, mineral coruscations, earthquakes, hot suffocating exhalations, hurricanes, and spouts, we may learn that sulphureous steams abound in the bowels of the earth and ferment with minerals, and sometimes take fire with a sudden coruscation and explosion, and if pent up in subterraneous caverns burst the caverns with a great shaking of the earth as in springing of a mine.*

A new and influential hypothesis on exothermic chemical reactions as a driving force of volcanism was developed with the discovery of the alkali metals by Humphry Davy. The new chemical theory did not call for a fluid interior, a vast storehouse of sulfur, or an internal fire in the Earth, and was consistent with the prevailing idea that volcanic activity in the Earth was progressively decreasing. Davy had a great interest in geology, eventually founding in 1807 the Geological Society of London. That year he was able to isolate by electrolysis for the first time the metals of the alkaline earths—potassium and sodium and later calcium, strontium, magnesium and barium. The high heat liberated upon the oxidation or "burning" of these metals upon reacting with water, with spectacular flames and explosions, so impressed Davy that it led him to propose a new hypothesis for volcanism in 1808. After his famous chemical discoveries, Davy was convinced that the heat given off during oxidation of the alkalies and the alkaline earths was the source of heat for volcanic action, suppos-

ing the existence of large quantities of the metallic alkaline earths within the Earth under volcanic regions.

One of the fiercest critics of Davy's theory about volcanic heat was Gustav Bischof in Germany. The arrangement of volcanoes in great continent-wide lines on the Earth's surface was taken by Bischof as a clear indication of a deep-seated origin of volcanic action, ruling out any superficial source within the crust. Davy had maintained that air could circulate through the Earth via volcanic craters and thus participate in heat-giving oxidation reactions. But the French chemist L. J. Gay-Lussac had shown by logic that it was impossible for atmospheric air to enter deep into volcanoes, because the pressure of the high-density magmatic liquid is acting outward. Air could not possibly flow into the volcanic system and fuel the oxidizing reactions against such a steep pressure gradient.

Charles Lyell in the *Principles of Geology* (1830) considered the possible role of oxidation of the alkalis and alkaline earths as a chemical heat source, following Davy's ideas closely:

*Instead of an original central heat, we may, perhaps, refer the heat of the interior to chemical changes constantly going on in the earth's crust; for the general effect of chemical combination is, the evolution of heat and electricity, which, in their turn, become sources of new chemical changes. It has been suggested, that the metals of the earths and alkalis may exist in an unoxidized state in the subterranean regions, and that the occasional contact of water with these metals must produce intense heat. The hydrogen, evolved during the process of saturation, may, on coming afterwards in contact with the heated metallic oxides, reduce them again to metals; and this circle of action may be one of the principal means by which internal heat, and the stability of the volcanic energy, are preserved.*

Even near the end of the 19th century the chemical theory was still alive.

Despite the many objections, the chemical theory of volcanism was surprisingly long lived and continued to be entertained by prominent scientists well into the middle of the 20th century. Arthur L. Day was the last of the proponents of the chemical theory, when he proposed in 1925 that chemical reaction between gases plays a leading part in generating volcanic heat. In his view, various gases from different sources in the Earth meet within the crust, and their reactions lead to local fusion and generation of magma. This idea was particularly appealing to Harold Jeffreys, a leading geophysicist in the early 20th century. He considered vulcanism as "local and occasional, not perpetual and world-wide." In account-

ing for the “local and occasional” eruptions, Jeffreys appealed to Day’s chemical theory of heat generation and melting in the Earth.

## VII. THE COOLING STAR

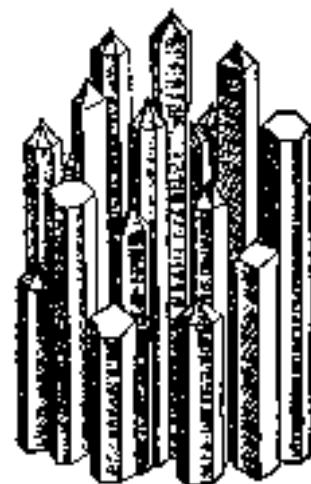

During the latter part of the 17th century, several philosophers adopted the view that volcanism was due to original or primordial heat in the Earth. The first of these was the French mathematician René Descartes (1596–1650), whose works were to have a profound influence on thinking about the origin of the Earth. The solar system originated, he proposed, as a series of “vortices,” with the Earth first appearing as a star, “differing from the sun only in being smaller,” and collecting dense and dark matter by gravitational attraction and losing energy as matter falls into place by gaseous condensation. He divided the Earth into three regions: a core consisting of incandescent matter, like that of the Sun; a middle region of opaque solid material (formerly liquid but now cooled); and an outermost region, the solid crust. All of these layers had been arranged in this concentric fashion by virtue of their density. In this scheme, he maintained, there was enough primordial heat remaining to supply any volcano. Descartes’s ideas influenced Baron von Leibniz (1646–1716), a German mathematician who proposed that the Earth must have existed originally in a state of fusion, and had thus acquired its spherical form and concentric shell structure, with denser metals concentrated in the center. Lacking an independent source of heat, the planet had cooled by simple conduction over geologic time, forming a stony and irregular crust. The hypothesis of Descartes that the Earth contained a vast store of primordial internal heat was of fundamental significance in evolution of geophysics and volcanology.

## VIII. PLUTONISTS VICTORIOUS OVER THE NEPTUNISTS

Some rocks, which were later found to be of volcanic origin, were thought by the medieval philosophers to have originated by precipitation from water. Thus the Swiss philosopher Konrad Gesner (1516–1565) was convinced that the perfectly symmetrical and hexagonal basalt columns of many lava flows had precipitated as

giant crystals from a primordial ocean (Fig. 3). Two centuries later, Richard Pococke still claimed that the columns of the Giant’s Causeway, those huge six-sided pillars of basalt that rise from the sea in Northern Ireland, were formed by precipitation from an aqueous medium. The concept of a crystallization form for these highly ordered rock structures is not surprising, considering their regular shape: The pillars of the Giant’s Causeway resemble in many respects giant crystals that might have precipitated out of ocean waters. The debate on volcanic versus aqueous origin of basalt was to become one of the fiercest controversies in the history of Earth science.

The idea of precipitation of rocks from a great ocean had strong theological origins in the legend of the Great Deluge. The leading figure of the Neptunist school was Abraham Gottlob Werner (1749–1817). Among his students were the most famous geologists of his day, including Alexander von Humboldt, Leopold von Buch, Georges Cuvier, Johann Wolfgang Goethe, Jean François d’Aubuisson, and Robert Jameson. Werner considered volcanoes of minor importance, as accidental and relatively recent or postaqueous phenomena on the Earth. They owed their existence, he claimed, to the action of fire (much as the medieval philosophers had proposed), activated by the ignition of coal deposits or other flammable materials in the Earth: “Most if not all volcanoes arise from the combustion of underground seams of coal.” To support this notion, he proposed

**FIGURE 3** In the late 16th century, Konrad Gesner drew hexagonal basalt columns of lava flows with terminations as crystals, because he believed that they had precipitated as giant crystals from a primordial ocean—in keeping with the Neptunist view of the aqueous origin of basalt.

that deposits of coal or other combustible materials were invariably present in the vicinity of volcanoes.

By the first half of the 18th century, chemists were familiar with the formation of crystals in the laboratory as a product of precipitation from an aqueous solution. Because Werner and his followers had recognized that basalt was a crystalline rock, it was perhaps not unnatural that they also deduced its origin as a precipitate from an aqueous solution. It was not until after the middle of the 18th century that the idea slowly began to spread that crystallization could also occur as a result of the removal of heat from a silicate melt. In 1761 Pierre Clement Grignon complained that chemists overemphasized aqueous systems, pointing out, after he managed to extract crystals from glass slags, that the products of glass furnaces compared to the products of volcanoes. The idea that magma was a solution that could produce crystals was beginning to emerge, and a group of geologists embraced the view that basalt owes its origin to solidification of magma. The adherents of this theory became known as the Plutonists. A profound difference between the Neptunist and Plutonist theories related to the quantity and role of heat in the planet's interior. The Neptunists saw a negligible role for heat as a geologic agent and considered volcanoes to be a minor phenomena related to shallow-level processes. The Plutonists, on the other hand, saw heat as the fundamental driving force, pointing out the abundance of volcanoes, basalts, and granite as evidence of melting of rocks at high temperature within the Earth. By the early 19th century, the Neptunist theory had become severely weakened and was encountering increasing opposition, especially when it was shown that the silicate minerals that compose crystalline rocks such as basalt and granite are insoluble in aqueous solutions at normal temperature.

## IX. THE FIRST FIELD VOLCANOLOGISTS

Most of the early ideas about heat in the Earth were based on "armchair geology," speculation based on little or no field observation. In the 18th century, the approach to the study of the origin of the Earth gradually evolved from pure speculation to a search for answers in rock formations exposed at the surface and in mine shafts. It was the labors of certain men, including those connected with the great mining industry in southern Germany, that brought about the revolution in the study of the Earth and the invention of field geology. A great

leap in volcanology was made when geologists were able to identify ancient rocks as of volcanic origin, in regions far removed from active volcanism. This breakthrough occurred in the middle of the 18th century in France.

In 1751 Jean-Etienne Guettard (1715–1786) and his friend de Malesherbes made a journey through the Auvergne region, where they noticed some very unusual, black, and porous stones in mile posts, and Guettard immediately suspected that they were lava rock. They then visited Volvic, where Guettard noted dipping layers of the rock with scoriaceous upper and lower surfaces and other unmistakable signs of volcanic activity. He concluded that the stones were indeed from a large lava flow. When they came to the area of Puy de Dome, Guettard recognized that basaltic rock of the hardened lava had flowed from an ancient crater in the cone-shaped hill above (Fig. 4).

The geologist who first demonstrated the volcanic origin of basalt was Nicholas Desmarest (1725–1815). In 1763 he found prismatic basalt forming hexagonal columns in southwest Clermont. Tracing the rocks to their source, he found similar columns standing vertically in the cliff above, grading upward into the scoriaceous top of the lava flow. His simple observation of the association of columnar basalt as a component of a lava flow stands as a major advance in science (Fig. 5). Although Desmarest had demonstrated unequivocally the volcanic origin of basalt, the debate between the Vulcanists and Neptunists continued to rage into the 19th century. His theory of basalt as lava was bitterly opposed by many.

Among the pioneers in field volcanology was William Hamilton, who resided in Naples for several decades and had ample opportunity to study Vesuvius. Among his many observations were precise drawings he made of the changing outline of the volcano during the eruption of 1767 (Fig. 6). Hamilton was also fortunate to be resident in Naples when the early discoveries and excavations were being made in Herculaneum and Pompeii, findings that brought to light the destructive power of the A.D. 79 Vesuvius eruption (Fig. 7).

---

## X. EXPERIMENTS OF THE PLUTONISTS

The undisputed leader of the Plutonists was the Scottish geologist James Hutton (1726–1797). He demonstrated the phenomenon of intrusion of magma into layered

FIGURE 4 The pioneer geologists Nicholas Desmarest and Jean-Etienne Guettard identified ancient rocks in central France as volcanic in origin, although they were far removed from active volcanoes. This 17th-century print shows hexagonal columnar basalts in the Auvergne region, where Desmarest demonstrated their volcanic origin.

strata, and proposed that this molten rock originated in the highly heated interior of the deep Earth. Hutton devoted much energy to field work, examining geologic strata in Scotland, England, and France.

Hutton was an intensely religious man and argued that the Earth's processes followed a divine plan. Thus, volcanoes existed both as safety valves for the release of excess heat from within the Earth, and as a global force, because their expansive and uplifting power was needed to raise the surface of the Earth and contribute to the soils, so that plants and animals might flourish. Hutton thus saw volcanism as a means towards the realization of a higher purpose in the natural order of things.

Hutton and his followers had observed layers in the Earth's crust that, while they resembled basalt in mineralogical and other properties, were sandwiched between layers of sedimentary rock. They recognized that these rocks, which they referred to by the common mining term *whinstone*, were not volcanic but of igneous origin,

and had been forcefully intruded between the sedimentary layers. Furthermore, they concluded that these rocks had solidified from magma.

Many of Hutton's opponents had maintained that the melting and solidification of crystalline rocks, such as granite or gabbro, would only yield an amorphous, glassy mass upon cooling, as observed in glass-making furnaces, and therefore the process could not produce basalt, whinstone, or other volcanic rocks. This objection to the Huttonian theory was tackled experimentally by the Scottish geologist and chemist Sir James Hall (1761–1832). To test Hutton's claim that rocks such as whinstone or basalt were derived from magma, Hall set out to do experiments on melting and cooling of basalts. First Hall melted the lava and basalt specimens, and then he converted the melted rock to glass by quenching. Next Hall remelted the crystal-free glass and allowed the melts to cool slowly. In so doing he produced crystalline or partly crystalline rocks, rough and stony in texture, which resembled the original rock samples. These

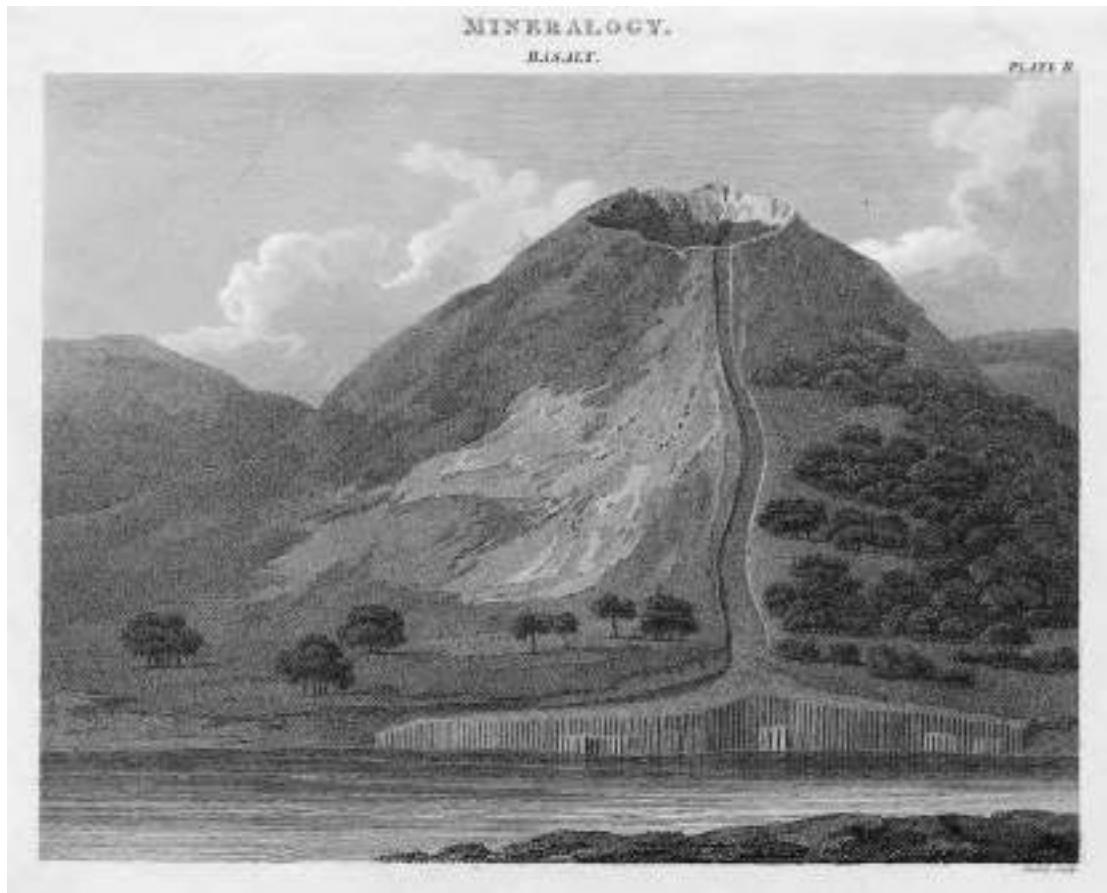

FIGURE 5 When the volcanic origin of columnar basalt was accepted, the early volcanologists quickly showed that it occurred as lava flows, and was connected to volcanic vents, as shown in this 18th-century engraving.

rocks, he showed, had melting and crystallization features exactly the same as those of basalts.

Demonstrating that melts of basaltic rocks precipitate silicate crystals upon cooling was of fundamental importance in establishing the volcanic theory on the origin of basalt. But if basalt rock was merely a product of solidification from a high-temperature silicate melt, then the experimental fusion and recrystallization of the rock should not affect its chemical composition. To test this, Hall submitted specimens of the products of his melting experiments to Robert Kennedy for chemical analysis in 1805, who found that their composition was essentially the same as the original rocks. Hall's demonstration, which was of fundamental importance in establishing the volcanic theory for the origin of basalt, dealt a final blow to the Neptunist theory of an aqueous origin for basalt, granite, and other rocks of igneous origin. Although Hall was a pioneer in experimental work on high-temperature and high-pressure experimental pe-

trology, he was not the first to conduct experiments with molten rocks. The first melting experiments on basalts were done by the Italian scholar Francesco d'Arezzo in 1670, who fused Etna's lavas.

#### XI. A SOLID EARTH

Most geologists studying volcanic activity in the early and mid-19th century continued to envisage a planet with a solid crust and a largely molten interior, influenced by the ideas of Descartes. Heat within the Earth was considered a residue of the central, primitive heat held by the Earth at the time of its formation, a supply that had been diminishing over geologic time. The idea of a central, primitive heat was developed primarily from the observation of increasing temperature with depth

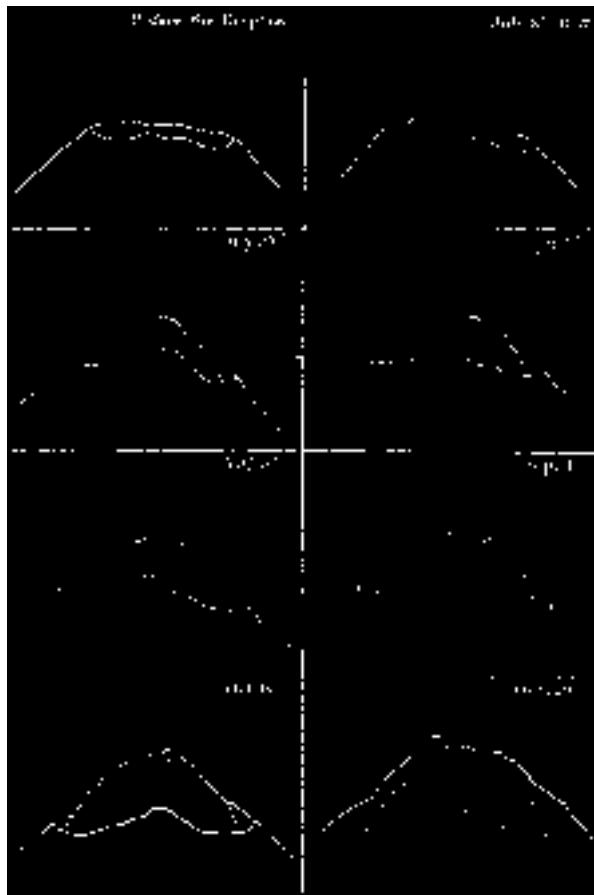

FIGURE 6 William Hamilton made some of the first quantitative measurements of volcanic morphology, when he carefully traced the changing outline of the summit of Vesuvius during the 1767 eruption.

in the Earth, based on measurements in mines and drill holes. Such observations led to the theory that the Earth began as a molten sphere, and has been cooling ever since. But if the interior of the globe were molten, it should yield to the gravitational attraction of the Sun and the Moon, and there would be little or no relative movement of the Earth's surface and the ocean's, that is, no sea tide. The response of the Earth to tidal forces, then, became a critical test for the molten Earth hypothesis. The French physicist Andre-Marie Ampere (1833) was the first to point out that observations of tidal action did not support the hypothesis of a fluid interior.

From 1839 to 1842 William Hopkins analyzed the effects of the Moon and the Sun on the rotation axis of the Earth. He concluded that the outer rigid crust must be at least 1500 km in thickness: "We are necessarily led, therefore, to the conclusion that the fluid matter

of actual volcanoes exists in subterranean reservoirs of limited extent, forming subterranean *lakes*, and not a subterranean ocean." Hopkins's studies were continued by his student, William Thomson (Lord Kelvin), who showed, on the basis of the effects on the Earth of gravitational attraction of the Sun and the Moon, that the Earth was essentially rigid and that the ideas of James Dwight Dana of "an undercrust fire-sea" were untenable. Geologists were now in a great quandry: There was no evidence for a large body of magma within the Earth, yet there was a requirement for supplying magma to countless volcanoes throughout the history of the planet. How can you derive magma from the interior of a solid planet?

The Earth's structure at the turn of the century was regarded as a series of concentric, solid shells or layers, with an outermost 30- to 40-km-thick, low-density layer of granitic crust (sial) making up the continents. This was underlain by a very thick layer (sima or the mantle) of high-density, ultrabasic rock with the composition of peridotite, and finally by the central core. Those who were searching for a molten region in the Earth as a source of magmas were now faced with a geophysical picture of a largely solid interior. A magma source in the molten core seemed impossible, at a depth of more than 2900 km below the surface.

## XII. DECOMPRESSION MELTING

The discovery that the Earth beneath the crust was essentially solid completely eliminated the "undercrust fire-sea" that Dana and others had proposed as a source of the magmas that feed Earth's volcanoes. Scholars, now faced with the task of showing how hot magma could be derived from within a solid Earth, found in the science of thermodynamics a partial solution to the problem. In the early years of the 18th century, it had been appreciated that pressure influences the temperature at which substances will undergo a change of phase—such as from a liquid to a gas, or from a solid to a liquid. The possible effects of pressure on melting of rocks in the Earth had been qualitatively appreciated very early on in the development of geologic thought. Perhaps the earliest recognition of this fundamental effect was made in 1802 by John Playfair. He pointed out that just as a change in pressure affects the boiling point of water, so would melting in the Earth be influenced by the great pressure exerted by the overlying rocks.

**FIGURE 7** An 18th-century engraving showing the excavations of the Roman city of Herculaneum, buried by the A.D. 79 eruption of Vesuvius. Although the impact of the excavations was primarily on archaeology and art history, it was also a forceful reminder of the total destructive force of a volcanic eruption for visiting scholars like Johann Wolfgang Goethe and William Hamilton.

The next to address the importance of pressure in volcanic systems was George Poulett Scrope. By 1825 in his work *Considerations on Volcanos*, Scrope had realized the effect of pressure on the solubility of water in magmas, and was one of the first to point out that decrease of pressure on a water-rich magma could explain volcanic explosions due to the release of dissolved water. He also argued that a change of pressure could either lead to melting or crystallization of magma, without change in temperature:

*Having thus far considered the effect of an increase of temperature, or a diminution of pressure, on a mass of lava under such circumstances, let us examine what will follow from the reverse; namely, an increase of pressure, or a diminution of temperature. Upon the solid lava, it is clear, no corresponding change will be produced; but every diminution of temperature, or increase of pressure, on a mass, or a part of the mass, liquified in the manner stated above, must occasion the condensation of a part of the vapour which produces its liquidity, and so far tend to effect its reconsolidation.*

Simeon-Denis Poisson had proposed in 1835 that the excessively high pressure in the deep interior of the Earth would lead to solidification of rock material at much higher temperatures than at the low pressures near the surface.

While Playfair and Scrope were struggling with a qualitative approach to the question of the effect of pressure on melting, a more elegant and quantitative approach was being developed in France and Germany, marking the birth of thermodynamics. From the work of Sadi Carnot, Rudolph Clausius, and Benoit-Pierre-Emile Clapeyron came the Clausius-Clapeyron equation, which quantifies the relationship between temperature, volume and pressure of a substance:

$$\frac{dT}{dP} = \frac{T\Delta V}{\Delta H}.$$

Consider two phases of the same chemical substance, for example, a liquid and solid (magma and rock), in equilibrium with one another at temperature  $T$  and pressure  $P$ . By supplying heat slowly to the system, one phase changes reversibly into another to bring about melting, with the system remaining at equilibrium. In the equation, the fraction  $dT/dP$  represents the rate of variation of the melting point  $T$  with change in pressure  $P$ . The value  $\Delta V$  represents the volume change on melting and is generally positive (i.e., the specific volume of the solid is smaller than the volume of the corresponding liquid), while the value  $\Delta H$  is the entropy change. The equation expresses the variation of pressure and temperature for a system in equilibrium. The magnitude and sign of the slope of the melting curve,  $dT/dP$  reflects

the magnitude and sign of the volume change,  $\Delta V$ , of the substance in question upon solidification or freezing.

It was shown early in the 18th century, in melting and crystallization experiments, that the specific volume of a volcanic rock such as basalt is lower than that of the corresponding magma. Many of the geologists who studied columnar basalt correctly interpreted its structure as evidence of contraction of magma upon cooling and solidifying to rock. During cooling and solidification, the material shrank in volume, forming roughly hexagonal columns separated by a pattern of contraction joints. Thus it was clear that the term  $\Delta V$  in the Clausius-Clapeyron equation was positive, and consequently, the equation predicts that the pressure-temperature melting curve ( $dT/dP$ ) of the source rock of basaltic magma has a positive slope in the Earth, that is, the temperature of melting increases with pressure. This interpretation of columnar basalt was consistent with the experimental results of the German chemist Gustav Bischof in 1837, who carried out one of the first measurements on the volume change of basalt and other volcanic rocks upon fusion and showed that rocks contract upon solidification from magma. He concluded that a melt of granite rock contracted about 25% upon solidification, trachyte about 18%, and a basaltic melt 11%.

Another German chemist, Robert Wilhelm Eberhard Bunsen, was one of the first to experiment on the relation between pressure and melting point of substances. The laboratory facilities available in Bunsen's time (1850) permitted only modest pressures to be achieved, roughly the equivalent of the pressure at a depth of 1 mile in the ocean. He therefore performed his experiments on materials with a relatively low melting point, such as ambergris and paraffin, and extrapolated these results to the high pressures and temperatures prevailing deep in the Earth. His work showed that a pressure increase of only 100 atm increased the melting point of these substances by several degrees centigrade. At about the same time (1851), William Hopkins began to experiment with James Joule, Lord Kelvin, and William Fairbairn, on the effects of pressure on the solidification of the Earth's interior. A large lever apparatus generated pressure up to 5400 atm, equivalent to the pressure at approximately 15-km depth in the Earth. Initially the experiments were on substances with low melting point, such as beeswax and spermaceti, and they essentially confirmed the work of Bunsen.

These pioneers had established that a solid hot substance such as rock at depth in the Earth could spontaneously begin to melt if the pressure is decreased, without the addition of heat. They had finally found the secret of the generation of magmas in a solid Earth: decom-

pression melting. But the solution of one problem led to the creation of another, even more daunting problem: What is the mechanism that brings about decompression? Some ingenious proposals were put forth to solve this problem. Thus in 1878 the American geologist Clarence King, realizing that local relief of pressure leads to melting in the Earth, suggested that the pressure release could occur with the erosion and removal of overlying crustal rocks: "So that the isolated lakes of fused matter which seem to be necessary to fulfill the known geological conditions may be the direct result of erosion." This seemed perfectly logical at the time, but if true, the rate of erosion of a given area must occur at a higher rate than that of heat conduction from the rising hot rock. Geologic evidence did not support this theory on two counts. First, many mountainous regions, where erosion is highest, show no signs of volcanism; and second, the rate of pressure relief due to erosion is so slow that heat lost through conduction would prevent melting at depth.

As director of the U.S. Geological Survey, King fostered the fundamental experiments of Carl Barus on rocks at high pressure. Barus determined the volume change and latent heat of basalt upon melting. He concluded that the term  $dT/dp$  in the Clausius-Clapeyron equation was equivalent to 0.025 for basalt, that is, the melting point increases at a rate of  $2.5^{\circ}\text{C}$  for every 100-atm increase in pressure. In 1893 Carl Barus was also the first to determine the melting curve of basalt as a function of pressure, which enabled King to propose a geothermal gradient for the Earth (Fig. 8).

In 1909 the British geologist Alfred Harker summed up his opinion on magma generation in *The Natural History of Igneous Rocks*: "We must seek the immediate cause of igneous action, not in the generation of heat, but chiefly in *relief of pressure* in certain deep-seated parts of the crust where solid and molten rock are approximately in thermal equilibrium. We are thus led by an independent line of reasoning to the principle already enunciated, which connects igneous action primarily with crustal stresses, and so secondarily with crust-movements." Furthermore, "at a sufficient depth, such conditions of temperature prevail that solid and liquid rock are in approximate thermal equilibrium. Any local relief of pressure within that region, connected with a redistribution of stress in the crust, must then give rise to melting." These statements were an incisive expression of the fundamental principle of melting, but what was still lacking was the mechanism that brought about the relief of pressure.

Not all geologists were ready to embrace this as a solution to the origin of magma, because a viable geo-

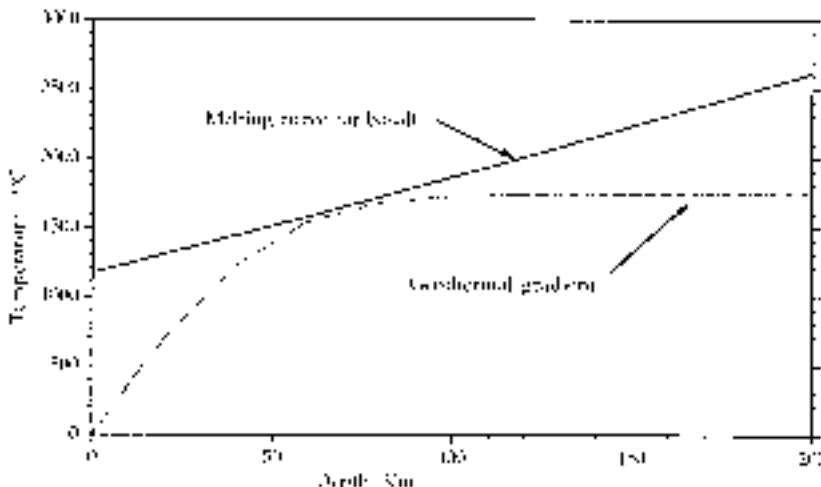

FIGURE 8 At the end of the 19th century, a geotherm had been calculated for the earth by Clarence King and others. The temperature of melting of basalt as a function of pressure had also been determined experimentally by Carl Barus. It was assumed that melting of the Earth's mantle occurred in the depth range where the geothermal gradient approached the basalt melting curve, that is, in the depth range of about 60–80 km below the surface.

logic process that could bring about a pressure decrease was not known. The American geologist Reginald Aldworth Daly stated (1933): "Local relief of pressure is hopelessly inadequate and need not be further discussed." Similarly, according to S. James Shand (1949), this pressure effect on melting of silicates was "a quantity scarcely large enough to have any important petrological consequences."

The progress made in understanding melting and the internal constitution of the Earth by the first part of the 20th century was truly profound, but it had created a paradox. All the evidence was in favor of a solid interior or an exceedingly thick crust at any rate, yet there was a need to account for the magmas erupted from volcanoes. Experimentalists and geophysicists had discovered a process by which melting could occur simply by decompression, but the geologists were unable to find an acceptable decompression mechanism to produce this melting.

### XIII. STIRRING THE POT: CONVECTION

The discovery of radioactivity caused a great stir among scientists, who quickly applied it to an understanding of the Earth. When Pierre Curie discovered in 1903 that radioactive materials emit heat, the Irish physicist John Joly was the first to point out that the abundance

and distribution of radium and other radioactive elements may determine the terrestrial heat. In 1910 the British geologist Arthur Holmes (1890–1965) began a study of the natural radioactivity of rocks, and thus began a career that would make a major contribution to both understanding of heat distribution and melting of the Earth by convective flow of solid rocks toward the surface. By 1915, Holmes had calculated a temperature profile for the Earth based on radioactive generation of heat.

After radioactivity was discovered as an internal heat source, it became even more important to establish the principal means of heat loss from the planet. How is this great flux of heat transferred from the deep Earth toward the surface? Holmes proposed that convection was the most effective mechanism to transport heat from depth to the surface. It was an idea that dates back to Osmond Fisher (1881), who proposed, in the days of an Earth with a totally molten interior, that there were convection currents rising under the ocean and descending beneath the continents. In 1928 Holmes proposed that the excess heat is discharged from the Earth by circulation of material in the solid *substratum*, or the Earth's mantle, forming thermal convection currents. Convection, and in turn continental drift, was seen as a mechanism to rid the Earth of the great heat generated by the radioactive natural reactor. He considered this substratum to be a solid peridotite rock, which could flow like a fluid at a rate plausible for a deep Earth process—about 5 cm/year. Holmes's scheme included downward currents below geosynclines, the great sedi-

mentary troughs that today we recognize as subduction zones, and ascending currents below midoceanic “swells,” where “a discharge of a great deal of heat” occurs due to upwelling of peridotite mantle, decompression, and melting. Holmes’s views in 1928 were amazingly modern and laid the foundations for the concept of plate tectonics, although this has not been generally recognized by Earth scientists.

The concept of plate tectonics had a long gestation period, and it began with the realization in the 17th century that volcanoes and earthquakes are distributed in great linear belts over the Earth. This systematic trend of volcanoes and earthquake zones, and the arrangement of the continents, eventually led to the theory known as continental drift in the early 20th century. The earliest map showing the global distribution of volcanoes was drawn by Athanasius Kircher in 1665. With the spread of geographic knowledge, a more refined picture gradually emerged, one of the systematic, linear or curvilinear arrangement of volcanoes on the surface of the globe. Ideas on the relationship between volcanic activity and major structures and tectonics date to Alexander von Humboldt (1822), who pointed out that the linear arrangement of volcanoes on the Earth was proof that the mechanism that generates volcanism was a deep-seated feature. Robert Mallet (1858) compiled the first map showing the global distribution of both earthquakes and volcanic eruptions in a “vast loop or band round the Pacific,” indicating a strong coincidence in their geographic distribution. He also recognized that most of the Earth, especially the interior of the continents, is seemingly free of earthquakes and volcanic activity. He divided the Earth into a series of basins, separated by “girdling ridges,” which are present even on the ocean floor: “It is along these girdling ridges, whether mountain-ranges or mere continuous swelling elevations of the solid, which divide these basins beneath the ocean surface one from the other, that all the volcanoes known to exist upon the earth’s surface are found, dotted along these ridges or crests in an unequal and uncertain manner.” He regarded these ridges as “sub-oceanic linear volcanic ranges” which mark “the great lines of fracture of the earth’s crust.” Mallet’s recognition of the distribution of these geological structures, which are now basic to the theory of plate tectonics, was probably the earliest.

The recognition of the linearity of volcanoes and earthquake zones coincided with a mobilistic view of the Earth toward the end of the century, a view based both on geophysical reasoning and geologic evidence. Osmond Fisher had argued in 1881 that cooling of the Earth could not be brought about solely by the process of conduction, as had been proposed by Kelvin, but was

in part brought about by convection currents in a plastic substratum. In Fisher’s view, these convection currents led to lateral movement of the overlying crust, accounting for much of the character of the Earth’s surface, including linear arrangement of volcanoes, earthquakes, and mountain chains. The ideas of a mobile Earth were first crystallized into a coherent theory of continental drift in 1912 by Alfred Wegener. One of those who sided with Wegener was Arthur Holmes, who greatly strengthened the theory by proposing in 1928 a more plausible thermal convection mechanism for crustal movement than Wegener had put forward. Holmes’s mechanism involved the flow or upwelling of the Earth’s mantle, providing a process whereby decompression of the hot mantle would occur, leading to melting and volcanism. Continental drift was an inevitable consequence of this circulation, but the process was much wider in scope: It involved the lateral motion of the oceanic crust as well. By 1931 Holmes had constructed a complete theory of continental drift, sea-floor spreading and subduction, based on this mechanism.

Holmes differentiated between a largely granitic crust in the continents and a basaltic crust in the oceans. He considered the mantle beneath the oceanic crust as most likely of peridotite composition, and argued that although it was probably crystalline and thus highly rigid, it had some of the properties of a fluid in the context of its large-scale dimensions. He proposed that the convection cells have dimensions at the scale of the mantle, some 2900 km in depth, and that their ascending limbs rise beneath the oceans, where they generate oceanic “swells” analogous to our modern concept of midoceanic ridges. Ascending currents he proposed were accompanied by decompression and partial melting of peridotite, to form basaltic magma, giving rise to volcanism. Descending currents were caused in the mantle by sinking of high-density rocks. The process he outlined was essentially the same as the modern concept of subduction: The convergence of crustal plates on the Earth leads to underthrusting of one plate and its descent deep into the mantle. Holmes estimated that the velocities of the convection current were on the order of 5 cm/year, which, as was discovered in the 1960s, is perfectly within the range of typical sea-floor spreading rates. Although widely accepted in Great Britain, Holmes’s ideas on mantle convection and a mobile Earth were generally not embraced elsewhere for some time. When the idea of sea-floor spreading was finally accepted by a majority of Earth scientists in the 1960s Holmes’s fundamental contribution was frequently ignored. One is reminded of the chilling words of Sir William Osler: “In science the credit goes to the man who convinces the world, not to the man to whom the idea first came.”

Is it more important in science to convince than to discover?

The discovery of plate tectonics has now provided the long-sought mechanism for decompression in the Earth's mantle—the most important process that brings about melting and generation of magmas. It is clearly the mechanism that generates magmas below the midocean ridges of the Earth and is thus responsible for most of our planet's volcanism.

---

#### XIV. BIRTH OF PETROLOGY

Among the earliest observations on the mineral content or petrography of volcanic rocks were Leopold von Buch's studies in 1799 on volcanic rocks near Rome. Von Buch concluded that the crystals of leucite had formed while the lava was still fluid, and discounted any hypothesis to the effect that they had been precipitated from an aqueous solution and later incorporated in the magma. Basalts and other volcanic rocks, however, are composed of exceedingly small crystals, which are invisible with the naked eye or even through a magnifying glass. The pioneer geologists were therefore unable to investigate the internal structure of these rocks and identify their tiny crystal components. The microscopic study of volcanic rocks was first carried out by Pierre Louis Cordier in 1815, who crushed basalts and other volcanic rocks to a fine powder, separated the various particles by a flotation process, and examined them by microscopic and chemical tests. He concluded that ancient basalts were very much like modern volcanic rocks in texture, mineralogy, and other characteristics—an important step in solving the Neptunist versus Plutonian controversy over the origin of basalts.

The art of making thin sections began with the sectioning of fossil wood, but the method was soon applied to rocks. They could be sliced so thin as to be transparent, and their minerals could be identified and their textures studied in detail. By 1829 the polarizing microscope had been invented by William Nicol and was used widely for the study of crystals. Henry Clifton Sorby (1826–1908) was the first geologist to make thin sections of volcanic and other igneous rocks for microscopic study.

Another crucial step in the study of volcanic rocks was the development of chemical analysis. Studies of the chemical composition of volcanic rocks date back to the work of Abbé Lazzaro Spallanzani (1794), who reported on the chemical composition of volcanic rocks in Italy in terms of weight percent of the five major

oxides of silica, alumina, lime, magnesia, and iron. In 1805 the Scottish chemist Robert Kennedy reported chemical analyses of *whinstone* or basaltic rocks. He was able to dissolve basalt by melting the rock powder with caustic potash at high temperature in a silver crucible. He then showed that it contained 48 wt% silica, 16% alumina, 9% lime, 16% iron oxide. Water and other volatile components accounted for about 5%. About 6%, then, was not accounted for. Kennedy suspected this was in part "a saline substance," and, after an elaborate analytical routine, showed that it was about 4% soda. He thus accounted for 99% of the chemical constituents of the rock—a great feat at the time.

When the early geologists began to accumulate data on volcanic rocks, they discovered that the chemical composition of the rocks, even those from the same volcano, varied greatly. Confronted with the problem of how to account for this diversity, George Poulett Scrope proposed in 1825 that all types of igneous rocks were formed from a single parent magma, which gave rise to a variety of types through a process of *differentiation* before crystallization. It was Charles Darwin, however, who laid the foundation for the process of "magmatic differentiation," through his discovery of crystal settling due to density differences between crystals and the magmatic liquid. During his exploration of the volcanic Galapagos archipelago in 1835, Darwin studied a basaltic lava flow on James Island (now San Salvador). He noted that the crystals of feldspar were much more abundant in the base of the lava than in the upper part, and deduced "that the crystals sink from their weight." Von Buch had earlier (1818) noted a similar concentration of crystals in the lower part of obsidian lava flows on Tenerife in the Atlantic, interpreting this as the settling of crystals in the lava during and after flow. In his *Geological Observations on The Volcanic Islands*, Darwin considered this observation as "throwing light on the separation of the high silica versus low silica series of rocks." He realized that once early formed crystals sink, the remaining magma would be chemically different from the initial liquid.

Another process was developed by Robert Bunsen in 1851 to account for the chemical range of volcanic rocks, after his discovery of two magmas in Iceland, with radically different chemical composition. Bunsen was struck by the abundance of two volcanic rock types: yellow and multicolored, silica-rich volcanic rocks (rhyolite), and the dark-colored basaltic rocks. A few volcanic rocks were of intermediate composition, and he proposed that they were the result of mixing of the silicic and basic magmas. Bunsen's contribution was to put forward the first viable hypothesis that could account for the diversity of the chemical composition of volcanic rocks by

the mixing of two primary magma: basalt and rhyolite. Traveling with Bunsen in Iceland was Sartorius von Waltershausen. He was the first to discuss the distribution and occurrence of the trace elements, as well as the major oxides in volcanic rocks, and listed 23 trace elements.

In the 18th century the volcanic fluid had become known as *magma*, derived from the Greek word which refers to a plastic mass, such as a paste of a solid or liquid matter. The term magma was used early on in pharmacy as in “magnesia magma,” or milk of magnesia, and the word passed from pharmacy into chemistry to represent a pasty or semifluid mixture. From chemistry it passed into petrology to replace “subterraneous lava.” What was the nature of this fluid inside the Earth? Bunsen, in *Über die Bildung der Granites*, stressed that magmas are nothing more than a high-temperature solution of different silicates: “No chemist would think of assuming that a solution ceases to be a solution when it is heated to 200, 300 or 400 degrees, or when it reaches a temperature at which it begins to glow, or to be a molten fluid.” This was a fundamental breakthrough in thinking about crystallization from magmas. Bunsen further recognized that minerals crystallized from magmas at a much lower temperature than the melting point of the pure minerals. If magmas are true solutions, then they should be able to mix, as indeed Bunsen had proposed on the basis of his Iceland work.

During the latter part of the 19th century the chemical analysis of volcanic rocks became commonplace. Leading petrologists considered that most igneous rocks were derived from basaltic magma by a process of differentiation, but no one researcher contributed more to the understanding of the processes that account for the chemical diversity of igneous rocks than the American petrologist Norman L. Bowen. From high-temperature experiments, Bowen discovered that magma could greatly change in composition as it cooled, if the early formed crystals were effectively separated from the liquid, thus providing proof for the fractional crystallization process first proposed by Darwin. Bowen was a strong advocate for fractional crystallization as the primary process responsible for differentiation, and considered that basaltic magma was the primary or parent magma of all volcanic rocks. The new understanding of magmatic differentiation was made possible by Bunsen’s recognition that magmas were true solutions, Darwin’s concept that settling of crystals resulted in a change in the composition of the liquid, and Bowen’s systematic experiments on crystallization of a primary basaltic liquid. But how, then, was this primary basaltic liquid formed?

## XV. THE SOURCE

Throughout the first half of the 20th century, two principal hypotheses existed on the nature of the source of magmas. Because the principal type of magma erupted was basalt, it appeared logical to some that the source region was also basaltic in composition, and possibly the high-pressure form of basalt known as *eclogite*. The basaltic magma would then be derived by wholesale melting of the source. The other view was that the magma was derived by partial melting of peridotite. It had long been noted that xenoliths of both peridotite and eclogite were ejected from some volcanoes. Because they were brought up in the magma, it seemed logical that these rock types might be an indication of the source region. As early as 1879 it was suggested that peridotite was the source of basaltic magmas, and by 1916 Arthur Holmes proposed that magma was generated by melting of peridotite at a depth of several hundred kilometers.

At the beginning of the 20th century, geophysical measurements were giving results in favor of a peridotite source. This was done by measuring in the laboratory the physical properties of a number of rock types under high pressure and temperature. By comparing these results with the speed of earthquake waves traveling through the deep Earth, it was shown that properties of the Earth’s interior are comparable to those of peridotite and other ultrabasic rocks under great pressure in the laboratory. Geophysicists therefore generally adopted a peridotite composition for the mantle.

Bowen (1928) also proposed that the only rock type that could give rise to basaltic magma by partial melting is peridotite, and suggested that this occurs at depths of 75–100 km. Bowen then addressed the question of whether the partial melting occurred as a result of reheating or due to pressure release. Arthur Holmes’s ideas on convective flow in the mantle were published in the same year as Bowen’s classic work, but Bowen seemed unaware of them. Having no plausible mechanism to bring about a pressure release, he stated: “It seems necessary to leave open the question whether selective fusion takes place as a result of release of pressure or as a result of reheating.” He therefore had considerable difficulty in developing a scenario of pressure-release melting in the peridotite mantle. Only with the development of geodynamics and acceptance of Holmes’s theory of mantle convection could it be shown that a peridotite mantle can rise to regions of lower pressure, thus bringing about melting without the addition of heat.

The theory of partial melting of peridotite was still debated and considered on a weak foundation by many in the first half of the 20th century. Another group of geologists adopted a totally different view, and maintained that basaltic magma was derived from a deep melted layer or from the complete melting of a basaltic layer at depth in the Earth. This view persisted with some until the 1960s. In an influential book on volcanoes, Alfred Rittmann proposed in 1936 that all volcanic rocks were ultimately derived from a global layer of basaltic magma. Rittmann's views were adopted by the petrologist Tom F. W. Barth in 1951: "The fact that wherever the crust is deeply rifted, be it in continents, oceans, or geosynclines, basaltic magma is available and capable of invasion is a proof of the existence of a subcrustal basaltic magma stratum." He was fully aware of the objections of geophysicists, that such a layer could not transmit some seismic waves, contrary to observations, and proposed that the basaltic magma behaved like glass at the high pressures beneath the Earth's crust and was thus able to transmit these waves. In his 1962 work on *Theoretical Petrology* Barth stated: "It is necessary, therefore, that the basaltic substratum is in a molten (noncrystalline) state at its subterranean locale. Otherwise it would not reach the surface with a homogeneous composition as we actually observe."

The American geologists Francis J. Turner and John Verhoogen accepted the seismic evidence for a solid character of the Earth's mantle in 1951, and considered it composed either of peridotite or of eclogite. From this it followed that primary basaltic magma had to be derived from a largely solid mantle, whose composition was other than basalt. The observed temperature increase with depth and heat generation by radioactive decay within the Earth could produce the required heat source. In their classic textbook on *Igneous and Metamorphic Petrology*, Turner and Verhoogen stated: "The problem of the origin of basaltic magma is thus not so much that of finding adequate heat sources as that of explaining how relatively small amounts of heat may become locally concentrated to produce relatively small pockets of liquid in an otherwise crystalline mantle." In what seemed like a fleeting moment, Turner and Verhoogen considered the hypothesis that basaltic magma could be produced by melting of a peridotite mantle due to pressure release, but then quickly rejected it: "This hypothesis of magma generation is possibly the most popular one, although it is unacceptable to the present writers. It is difficult indeed to see how pressure can effectively be reduced at such depths." They realized of course, that melting could occur if convective transport of mantle material occurred to shallower levels, as

originally proposed by Arthur Holmes. This was clearly a viable mechanism as long as the deep mantle temperature was greater than the melting point of the mantle at shallower depth. Yet they were not ready to accept the existence of convection in the solid Earth, which led them to conclude: "Whether convection does occur in the mantle is not definitely known, nor is it known whether it could be effective in the upper part of the mantle where magmas are generated. Thus, although convection might lead to melting, it cannot be shown that it does, and the problem of the generation of magma remains as baffling as ever."

This statement is a good reflection of the state of affairs regarding theories of magma generation at the middle of the 20th century. While great strides had been made in understanding the chemistry and mineralogy of volcanic rocks, the Earth scientists were at a loss to explain melting. This was due almost entirely to the static view taken of the Earth's interior at the time—it seemed inconceivable to most that the rigid and solid mantle could convect. However, the discoveries made on the ocean floor in the 1960s and development of geodynamics were to change all that. Although melting was poorly understood at the time, knowledge of the mantle source region was advancing through studies of xenoliths. A great number of xenoliths are of peridotite composition, giving further credence to the idea that the source region of basalt magma, the Earth's mantle, is dominantly composed of peridotite.

---

## XVI. THE ROLE OF WATER

Great clouds of gases and steam emitted by volcanoes were long considered to be derived from groundwater, surface waters, such as nearby lakes or streams, or seawater. This was evident, according to many scholars, from the location of volcanoes near the ocean or on islands. The role of water was thought to be crucial in generating explosive eruptions and to have an important effect on the viscosity of magmas. In 1794 Spallanzani recognized that several gases are important in lavas and volcanic regions, including "hydrogenous gas, sulfurated hydrogenous gas, carbonic acid gas, sulfurous acid gas, azotic gas." But another, more powerful agent, he noted, was "water, principally that of the sea," which communicates by passages with the roots of volcanoes. On reaching the subterranean fires it suddenly turns to vapor, and the elastic gas expands rapidly, causing volcanic explosions. Supporting his hypothesis, on a

more practical level, Spallanzani cited accidents in glass-making factories, in which molten glass was poured into molds not completely dry or free of water, causing dreadful steam explosions.

Scrope (1825) attributed the fluidity of magmas to water: "There can be little doubt that the main agent ... consists in the expansive force of elastic fluids struggling to effect their escape from the interior of a subterranean mass of *lava*, or earths in a state of liquification at an intense heat." These "elastic fluids" Scrope considered to be mainly steam and other volcanic gases. It was the expansion of gas in the magma that led to its rise in the Earth's crust, and led to violent and explosive eruption upon reaching the surface.

Scrope discussed in some detail the evolution of steam in magmas at depth, and was perhaps the first to point out that under great pressure, water would be dissolved in the melt, but upon decrease in pressure or increase in temperature the water would be vaporized, leading to explosive eruption. From the increase of temperature with depth in mines, Scrope concluded that at great depth, the Earth was at an intense heat, and that this great accumulation of *caloric* in the deep Earth led to continued flow of caloric toward the surface, in order for the heat to attempt to attain equilibrium. Thus Scrope considered the formation of magma as due to the passage of caloric by conduction from depth to upper levels in the Earth, where the caloric led to melting of rocks. Scrope proposed that the caloric in molten rocks was in large measure due to water: "There is every reason to believe this fluid to be no other than the vapour of water, intimately combined with the mineral constituents of the lava, and volatilized by the intense temperature to which it is exposed when circumstances occur which permit its expansion." The water of the oceans, he theorized, was derived from the interior of the Earth due to degassing through volcanoes. Large quantities of water "remain entangled interstitially in the condensed matter" in the deep-seated rocks, and the escape of steam during volcanic eruptions carries off an immense amount of caloric, leading to rapid cooling and consolidation of magmas at the surface.

By 1865 the French geologist M. Fourque had measured the amount of water in the volcanic products of Etna and estimated the amount of steam discharged from the vent. In the latter part of the 19th century geologists began to develop more sophisticated models, proposing that the steam emitted by volcanic eruptions was primordial or of deep-seated origin, rather than just recycled surface waters. Among them was Osmond Fisher (1881), who regarded volcanic gases as original constituents of magma. The potential role of escape of

water from volcanoes in the formation of the oceans began to surface as an important hypothesis. The German geologist Eduard Suess proposed that all water in the oceans and atmosphere came from the outgassing of the interior of the Earth. The concept of volcanic recycling of water from the ocean to the atmosphere and back again to the deep Earth was proposed by John Judd (1881), who pointed out that volcanoes are generally located near the ocean, and speculated that fissures may transport seawater from the ocean to the magma at depth. "Volcanic outbursts" could be due to water finding its way down to a highly heated rock mass, lowering the melting temperature and causing melting. Judd considered high temperature and the presence of water and gas as the key factors of volcanic action and argued that magmas can absorb or dissolve large quantities of water, which escapes violently during explosive volcanic eruption, as Spallanzani had first pointed out. The magmas could absorb water or gases either initially, as primordial gases during formation of the globe, or at any stage in geologic history, due to infiltration of water into the Earth's crust.

With the widespread recognition of water in magmas, it was logical to consider its role in explosive eruptions. In the age of steam during the Industrial Revolution of the 19th century, John Judd pointed out that "a volcano is a kind of great natural steam-engine." Bonney (1899) also compared volcanoes to a boiler, emphasizing that the steam in magma is the main explosive force in an eruption. He noted that the volume of steam is nearly 1700 times that occupied in the form of water, an enormous expansive force, adequate to account for volcanic explosions. The origin of volcanic water, according to Bonney, is related to the proximity of volcanoes to the ocean and the percolation of rainwater into the magma. He stressed the importance of addition of water to lower the melting point of rocks, and followed Osmond Fisher and others in attributing eruption to the presence of water. When water is depleted or withdrawn from the system, the eruption ceases.

In the latter part of the 18th century, Dolomieu had determined that many deposits in Italy and on Sicily, which at first sight looked like normal stratified sediments, were in fact consolidated volcanic ash deposits, the products of fallout from explosive eruptions. The disruption of magma as it is blown into the air leads to fragmentation and the formation of volcanic ash, tephra, scoria, and other forms of pyroclastic material. We now know that the primary agent of this disruption is the explosive expansion of steam. Sartorius von Waltershausen (1853), a true pioneer in the study of pyroclastic rocks, was the first to attribute their formation

to the effects of water on the magma. He proposed that magma rises and erupts due to pressure of water vapor escaping from the magma and that the volume increase of water vapor was also responsible for the fragmenting process—the formation and ejection of pyroclasts such as pumice and ash. He also recognized that peculiar volcanic rock deposits can result when magma enters the ocean or is erupted under water. It was during travels in Sicily in 1835 that he first came across a brown tuff, a homogenous rock, composed largely of a single mineral. He named the rock *palagonite* after the nearby town of Palagonia, and by chemical analysis determined it as one unusually rich in water and iron, with about 12–23 wt% water. He became curious as to the rock's origin, and noting that it was often associated with marine deposits, proposed that it was a volcanic product that forms thick layers in many submarine volcanic formations. In 1846 he and Robert Bunsen studied palagonite mountains in Iceland, and noted that a zone of palagonite tuffs stretches across Iceland. Often in association with palagonite he noted, was a black, water-free and glass-like material, similar to obsidian, which he gave the name *sideromelan*. He was able to show that palagonite is basically sideromelane or basaltic glass that has taken up water, and from its geologic setting, that palagonite is a product of shallow subaqueous or submarine basaltic eruptions. Von Waltershausen was correct in this deduction; we now know that the Icelandic palagonite rocks are formed by volcanic eruptions below the thick ice cap that covered Iceland during the last ice age, and that the Italian palagonites were erupted in the ocean.

Bunsen, on the other hand, disagreed with von Waltershausen, considering the palagonite tuffs as the products of basaltic rocks metamorphosed in the presence of much water and carbonate. He showed by chemical analysis that the tuffs were virtually identical to basalt lava after the high water content had been subtracted. His study was not restricted to Icelandic rocks, because Charles Darwin had given him samples of palagonite from the Cape Verde islands.

Another volcanic rock of basaltic composition is lava-like but composed of rounded or pillow-like forms. The origin of this rock does not have a bearing on water in magmas, but rather on magma in the water. The identification of *pillow lava* dates back at least to the 1870s. Later it was proposed on the basis of observations in Italy that it forms due to submarine eruption. The British geologist Tempest Anderson observed an eruption in Samoa, noting that when the basaltic lava was flowing into the sea, the submarine component of the lava formed bulbous masses and lobes with the shape of pillows. By 1914 a subaqueous origin for pillow lavas

had been established. They were already known to be present in the geologic record in association with marine sediments in Scotland, and also as products of subglacial eruptions, such as in Iceland. Oceanographers discovered only in the 1960s that basaltic pillow lava forms the floor of most of the world's oceans and is thus the Earth's most abundant volcanic rock but also the most remote for study.

When high-pressure melting experiments were first carried out at the beginning of the 20th century, it became evident that magmas residing deep in the Earth can contain much more water in solution, and that this water must be liberated when they are erupted at the surface. In 1903 C. Doepler was one of the first to propose that magmas at great pressure in the Earth's crust may dissolve water and that the magmas may become explosive when they reach the surface of the Earth. In support of this theory, the French geologist Armand Gautier carried out laboratory experiments on volcanic activity in 1906, suggesting that magma rises in the crust as a result of gas expansion, and attributed the violence of volcanic eruptions to the explosive liberation of water from the magmas. By the early 20th century the fundamental ideas about the causes of explosive volcanism and the importance of water had thus been firmly established.

# ORIGIN AND TRANSPORT OF MAGMA

Volcanic eruptions are the surface expression of processes that occur deep within the Earth. Many of these processes take place just below the Earth's outer rigid shell, whereas some volcanic eruptions owe their origin to very deep disturbances, even at the boundary between the core and the Earth's mantle at 2890 km below the surface.

The origin and transport of magma are treated in Part I of the *Encyclopedia of Volcanoes*. An understanding of these processes is an essential foundation for an appreciation of the volcanism that is observed at the surface.

We set the stage with the chapter Mantle of the Earth, describing the chemical and physical properties of the source region of virtually all magmas. Although rarely seen, the mantle is the most voluminous part of the planet, and it is here that the great heat manifest in volcanic eruptions is stored. It is hot, perhaps 1300 to 1500°C, but the mantle is for the most part stony and solid. The formation of magma occurs in only certain regions of the mantle by partial melting of the rock peridotite, as described in Melting the Mantle. This chapter explains how melting occurs either by the lowering of pressure in the mantle or by the lowering of the melting temperature of peridotite by introduction of water to the mantle from the Earth's surface during subduction.

When melting begins in the mantle, the hot silicate liquid or magma begins to migrate upward toward the surface, because of its low density compared to the surrounding high-density mantle rock. The migration and transport of magma within the Earth are perplexing problems, treated in the chapter Migration of Melt. We know that magma begins deep in the mantle, where it

forms a small part of the peridotite rock, like water in a sponge, and we know that eventually it pools into large liquid bodies near the surface. The intermediate stage in magma transport, between the source and the shallow reservoir, is one of the major problems in the study of magma evolution, as discussed here.

How does the magma percolate upward toward the surface? Does it migrate upward through the action of dikes?

Melting in the mantle determines the location of volcanoes on Earth, but the location of melting is largely determined by plate tectonics, the theory that describes the motion of the great crustal plates that make the rigid exterior shell of the Earth. As described in the chapter Plate Tectonics and Volcanism, melting occurs beneath plate boundaries where plates are either moving apart, such as below the mid-ocean ridges, or below converging plates in subduction zones. In the former case, melting is due entirely to decompression, as the mantle rises up to fill the void between the diverging plates. In the latter case, however, decompression melting is further aided by the introduction of water and lowering of the solidus. However, a significant fraction of Earth's volcanism occurs totally independent of plate motion, creating hot spots. It is hypothesized—although not yet proven—by many geologists that hot spots are the result of great mantle plumes, which may originate from a region near the boundary of the mantle and the core.

Our most important clues about the formation and origin of magmas come from studies of the chemical and mineralogical composition of volcanic rocks, as described in the chapter Composition of Magmas. These silicate liquids, drawn from deep inside the Earth, have much to tell about their peridotite source rock as well as about the history and formation of the planet. The chemical diversity of magmas or volcanic rocks seems at first bewildering, with a plethora of names used by geologists to describe all of these rock types. The reason for this great diversity is explored in the chapter Origin of Magmas, which explains the great variety of physical and chemical processes leading to the differentiation of magmas.

Virtually all of the known chemical elements occur in magmas, although most are present only in trace amounts. Many chemical compounds in magmas, including water, carbon dioxide, and sulfur dioxide, are normally dissolved in the magma at high temperatures and pressures, but come out of solution when the magma nears the surface and erupts. These are the volatiles in magmas, whose properties and evolution are dealt with in the chapter Volatiles in Magmas. The concentration and behavior of the volatiles are particularly important, as their abundance in the magma largely determines the

explosive nature of volcanic eruptions. The distinction between the quiet effusion of lava flows and the explosive ejection of volcanic ash and pumice is primarily a reflection of the original water content in the magma. However, the rheological behavior of magmas is also dictated by their physical properties, such as viscosity and temperature, as discussed in the chapter Physical Properties of Magmas. The importance of the bulk viscosity is, for example, demonstrated by the fact that volatiles can rise and escape freely to the surface as gas bubbles from a low-viscosity basaltic magma, whereas the viscosity of andesitic or rhyolitic magmas is so high that the bubbles cannot rise but are carried with the magma to the surface, with explosive results.

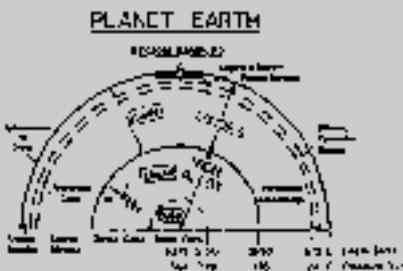

Magmas rising from the mantle may often gather in reservoirs at the base of the crust or within the Earth's crust. Reservoirs may be tens of kilometers in dimension and thus represent huge reserves of magma. The chapter Magma Chambers explains the behavior of these magma chambers, the geological and geophysical evidence for their size and dimensions, and the processes that occur within them. The chapter Rates of Magma Ascent describes how petrologic studies and geochemical research on short-lived isotopes in magma are providing information on the rates of magma ascent.

Most of the magma is transported in dikes from the deep reservoir to the surface, as described in the chapter Plumbing Systems. During dike flow the magma experiences extreme gradients in temperature and pressure as it moves through the cold and rigid upper crust of the Earth. It seems at first amazing that magma may flow for several kilometers in a 1-m-wide dike without solidifying, but as explained in this chapter, the magma may retain most of its heat during dike flow and arrive at the surface in a fiery eruption.

During its ascent in a dike or a conduit, magma experiences a very important change, as the volatiles—mainly water, carbon dioxide, and sulfur dioxide—exsolve from the magma to form a separate gas phase. Exsolution occurs when the pressure decreases below the solubility limit of these volatiles in the magma, as described in the chapter Magma Ascent at Shallow Levels. In the crust above this level, the magma in the dike or conduit behaves as a two-phase flow, consisting of a silicate melt and a gas phase that continues up the ally, expanding as pressure decreases. This is the most dynamic region of magma evolution, and rates of motion are on the order of meters per second, whereas rates of deeper magma flow are centimeters per second. The exsolving gas appears as growing bubbles that expand until they burst, tearing apart the magma in the conduit and expelling it to the surface.

## GLOSSARY

- basalt** A lava (or solidified, glassy equivalent) having the bulk composition of a gabbro.
- chondritic** Refers to a rocky meteorite, typically consisting of an ultramafic silicate assemblage plus lesser amounts of metal. The most primitive (unheated, undeformed) are the CI class, and are considered to be samples of the material left over from planet formation.
- D" region** Region at the base of the mantle that is characterized by strong lateral heterogeneity in seismic wave velocities.
- gabbro** A rock consisting primarily of pyroxene and feldspar; it may contain olivine.
- kimberlite** An explosively emplaced volcanic rock that is originally a fluid-rich ultramafic in overall composition and typically contains many xenoliths.
- liquidus** Temperature below which a molten compound begins to crystallize.
- lithosphere** Crust and uppermost mantle behaving in a quasi-rigid fashion over geological timescales; it corresponds to the tectonic plates at the Earth's surface and is typically no more than ~100–150 km thick.

**low-velocity zone** An intermittent zone exhibiting slightly reduced seismic-wave velocities and enhanced wave attenuation at depths of ~50–150 km in the mantle.

**magma** Molten rock inside the earth. Lavas are magmas that have erupted at the Earth's surface.

**moho** A discontinuous increase with depth of seismic-wave velocities, from ~7 to 8 km/s for compressional waves. Named after A. Mohorovicic, the Croatian seismologist who discovered it, the discontinuity defines the interface between the crust and mantle.

**ophiolite** A piece of oceanic crust and topmost mantle that has been uplifted and exposed at the earth's surface.

**peridotite** An ultramafic rock consisting predominantly of olivine, coexisting with other minerals rich in Mg and Fe, such as pyroxene.

**pyrolite** A ~3 : 1 mixture of peridotite and basalt that is intended to simulate undepleted ("fertile") peridotite of the upper mantle.

**refractory** Refers to an element or compound having a high condensation (or evaporation) temperature and, correspondingly, a high melting (or freezing) temperature.

**silicate** A compound containing silicon and oxygen. Most common minerals are silicates or oxides (oxygen-containing compounds), such as  $\text{SiO}_2$  quartz or  $\text{Mg}_2\text{SiO}_4$  olivine.

**solidus** Temperature above which a crystalline compound begins to melt.

**ultramafic** Rich in Mg and Fe, or in Mg- and Fe-rich minerals such as  $(\text{Mg}, \text{Fe})_2\text{SiO}_4$  olivine.

**ULVZ** Ultra-low-velocity zone; a thin zone just above certain regions of the core–mantle boundary that is charac-

terized by very low seismic-wave velocities (e.g., 20% decrease in shear-wave velocity from the overlying mantle).

**volatile** Refers to an element or compound having a low condensation (or evaporation) temperature and, correspondingly, a low melting (or freezing) temperature.

**xenolith** A rock fragment brought up from depth within a different rock or magma.

the mantle, in that the material making up the crust was initially derived from the mantle; also, it is the mantle that provides much of the heat and tectonic activity causing melting in the crust. This chapter reviews the physical and chemical properties of the Earth's mantle, and the dynamic processes that lead to the melting of the mantle.

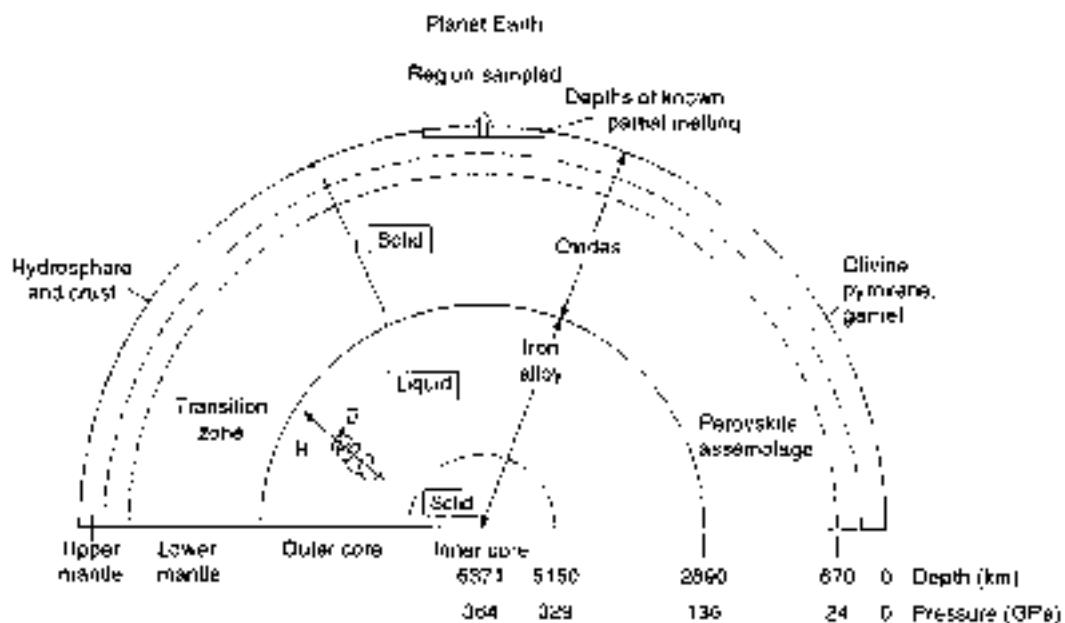

## I. INTRODUCTION

The mantle is the ~2850-km-thick shell of rock surrounding the metallic core of the earth (Fig. 1). Because it contains the bulk of the planet's rocky material, the mantle is the ultimate source of the silicate magmas that cause volcanic eruptions, even though the mantle itself is predominantly crystalline, not molten. In particular, partial melting of a few percent of the outermost mantle is the source of magma for midocean ridges, the planet's most active chain of volcanoes. Even magmas that are produced in the crust can ultimately be attributed to

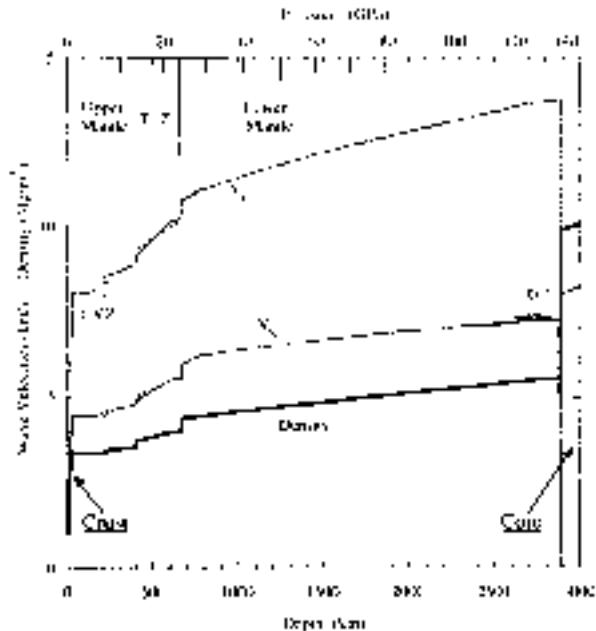

## II. STRUCTURE AND PHYSICAL PROPERTIES

### A. Overall Structure

The structure of the Earth's interior, and hence the dimensions and properties of the mantle, are primarily determined from seismological observations. Recordings of both compressional and shear waves generated by earthquakes or large explosions, as well as oscillations of the entire planet caused by large earthquakes, make it possible to derive the elastic-wave velocities and density as a function of depth (Fig. 2). That the wave veloci-

**FIGURE 1** Schematic cross section through the Earth, summarizing the seismologically determined structure as a function of depth and corresponding pressure (100 GPa = 1 Mbar). The mantle and overlying crust consist almost entirely of oxides that are not melted ("solid"). Volcanic processes bring rock fragments up to the surface from as deep as ~200 km into the mantle (and possibly deeper), thereby showing that the uppermost mantle consists of peridotite, a rock made up of olivine, pyroxene, and garnet minerals. Laboratory experiments demonstrate that peridotite transforms at conditions of the lower mantle to a rock consisting predominantly of the high-pressure perovskite phase. Cyclonic motions ( $u$ ) in the molten iron alloy of the outer core create the geomagnetic field ( $H$ ) via a dynamo process. [From Jeanloz, R. (1990). *Annu. Rev. Earth Planet. Sci.* **18**, 357–386.]

**FIGURE 2** Seismologically observed properties of the mantle, from the surface to the core. Compressional- and shear-wave velocities ( $V_p$  and  $V_s$ ; thin curves) and density (bold curve) as a function of depth (bottom) and pressure (top) through the upper mantle, transition zone (T. Z.) and lower mantle according to the preliminary reference earth model (PREM; solid curves) and iasp91 (dotted curves). The low-velocity zone (LVZ) is indicated in the upper mantle, and several illustrative  $V_s$  profiles are shown for the D'' region at the base of the mantle. The pressure is very nearly hydrostatic through the interior, so is determined directly from the density profile. [Data from Dziewonski, A. M., and Anderson, D. L. (1981). *Phys. Earth Planet. Int.* **25**, 297–356; Kennett, B. L. N., and Engdahl, E. R. (1991). *Geophys. J. Int.* **105**, 429–465; and Wysession, M. E., et al. (1998). In “The Core–Mantle Boundary Region.” American Geophysical Union, Washington, DC].

ties and density generally increase with depth throughout the mantle can be attributed to the effects of increasing pressure. Although temperature also increases with depth, the effect of pressure dominates everywhere except in the low-velocity zones described below.

The top of the mantle is identified by the depth at which the velocity of compressional waves jumps discontinuously from values typically less than 7 km/s to greater than 8 km/s (the Mohorovicic discontinuity, or Moho). The thickness of the overlying crust is approximately 25 km on average, but ranges from ~6 km in oceanic regions up to ~70 km beneath the Himalayas. The base of the mantle, at a depth of 2890 km, is defined by the disappearance of rigidity. Unlike the mantle, the

outer core is liquid; also, it is far denser than the overlying rock. Indeed, the core–mantle boundary is the most significant structure of the Earth in that the contrast in observed properties is even greater than that between the atmosphere and crust.

Two smaller but still significant discontinuities in seismic-wave velocities define the primary subdivision of the mantle, into the upper mantle, transition zone, and lower mantle (Fig. 2). These velocity jumps appear to be globally present at about 410- and 650-km depths, although the exact depths can vary by a few tens of kilometers from one location to another. In addition, both discontinuities appear to be quite sharp, taking place within a depth interval of a few kilometers (i.e., a fraction of the ~10-km minimum wavelengths of seismic waves that are used to probe its thickness).

### B. Low-Velocity Zone and D'

At a more subtle level, there are at least two additional structures that are pervasive, if not globally present, and are considered important: the low-velocity zone in the upper mantle, and the D'' region at the base of the mantle (Fig. 2). The low-velocity zone is a region exhibiting a velocity decrease, typically of no more than ~1–2%, at depths as great as ~100–200 km. The magnitude of the velocity decrease and its depth are highly variable from one location to another (and apparently not present in some locations), but it is observed often enough to be considered a common feature of the uppermost mantle. It is especially evident beneath tectonically young areas, such as oceanic crust, or the Basin and Range region of the western United States.

Because increasing temperature is known from laboratory experiments to cause the seismic-wave velocities in rock to decrease (increasing pressure has the opposite effect), the low-velocity zone is considered to be a depth at which high temperatures are reached. For example, average temperatures are thought to approach the melting point (solidus) of the mantle rock at these depths. Studies of anelasticity, the degree to which seismic waves are attenuated as they propagate, show that the low-velocity zone can be highly attenuating, and this observed “mushiness” also supports the view that it is a region of high temperatures. In fact, it may locally be partially melted, and therefore be a zone where magma is commonly present at depth.

The D'' region (“D double prime,” a historical name) is a zone in the lowermost mantle that is characterized by significant heterogeneity in seismic-wave velocities.

The detailed velocity profiles vary considerably from one region to another (e.g., beneath the central Pacific versus underneath India or the Caribbean), with both increases and decreases in velocity having been documented over the bottom 200–300 km of the mantle. The region is also characterized by enhanced scattering of seismic waves, further documenting a lateral heterogeneity in velocities. This heterogeneity extends to 500 km or more above the core–mantle boundary, in some areas; in other areas, the D'' region appears to be less than 10 km thick or perhaps missing altogether. Most notable is recent evidence for extreme velocity decreases, of up to 10 and 30% for compressional and shear waves, extending over a zone less than 20–40 km thick at the base of the mantle. Such ultra-low-velocity zones (ULVZs) have been interpreted as demonstrating that magma is present at the base of the mantle.

### III. MINERALOGY AND COMPOSITION

#### A. Samples

The mineralogy and bulk composition of the uppermost mantle can essentially be determined from direct sampling, most notably from ophiolites and xenoliths. In combination with (1) geophysical observations on the deeper mantle, (2) laboratory measurements of mineral and rock properties, and (3) general arguments from geochemistry, it is then possible to deduce the nature of most of the mantle. Before proceeding to the evidence, the result is that the upper mantle consists of peridotite, a rock made up of about 50% olivine  $[(\text{Mg}, \text{Fe})_2\text{SiO}_4]$ , 40% pyroxene  $[(\text{Mg}, \text{Fe}, \text{Ca})\text{SiO}_3]$ , and 10% garnet  $[(\text{Mg}, \text{Fe}, \text{Ca}), \text{Al}_2\text{Si}_3\text{O}_{12}]$  (Table I). Mineral names and properties are summarized in Table II.

Ophiolites are sections of oceanic lithosphere (crust plus uppermost mantle) that have been uplifted, and even emplaced onto continental crust, by tectonic processes. They classically exhibit a stratigraphic sequence of marine sediments, lying over a basaltic layer (pillow basalts—basalts that were erupted under water—above basaltic dikes and gabbros) that, in turn, is above ultramafic rocks representing the topmost mantle. This sequence of rock types corresponds well with the velocity structure obtained from seismic refraction studies in ocean basins, for example, of sediments above a ~6-km-thick layer of basalt comprising the oceanic crust. In particular, the velocities of the ultramafic rocks sampled from ophiolites can be measured in the laboratory, and

TABLE I Composition of the Upper Mantle Estimated from Natural Samples<sup>a</sup>

Oxide component	Weight fraction (%) <sup>b</sup>	Element	Atomic Fraction (%)
$\text{SiO}_2$	45.0 ( $\pm 1.4$ )	O	58.3

are found to match those observed seismologically in the topmost mantle, just below the Moho.

Ophiolites have the advantage of giving a large-scale geological cross section through the oceanic crust and uppermost mantle, so it is possible to reconstruct thicknesses and geometric relations among the different rock layers. The disadvantage, however, is that ophiolites are typically highly faulted (presumably as a part of the uplift and emplacement process), such that it can be difficult to make sense of how the different rock types are interrelated. Also, the rocks are often heavily weathered, usually

TABLE II Mineral Phases of the Mantle and their Properties<sup>a,b</sup>

Mineral phase	Chemical formula	Density $\rho$ (Mg/m <sup>3</sup> )	Bulk modulus $K_s$ (GPa)	Shear modulus $\mu$ (GPa)
Olivine	(Mg, Fe) <sub>2</sub> SiO <sub>4</sub>	3.22	129	81
Pyroxene <sup>c</sup>	(Mg, Fe, Ca)SiO <sub>3</sub>	3.21	108	76

(at least in part) due to hydrothermal circulation of ocean water, so that what is observed is a hydrated version of the primary rock types (for example, serpentine occurs instead of olivine).

Xenoliths are rock fragments brought up to the sur-

face from depth, usually by volcanic processes. Ultramafic fragments thought to come from the mantle are most commonly found in basaltic lavas, but it is the rarer ones found in kimberlite deposits that are probably the most significant (Fig. 3; also see color insert). This

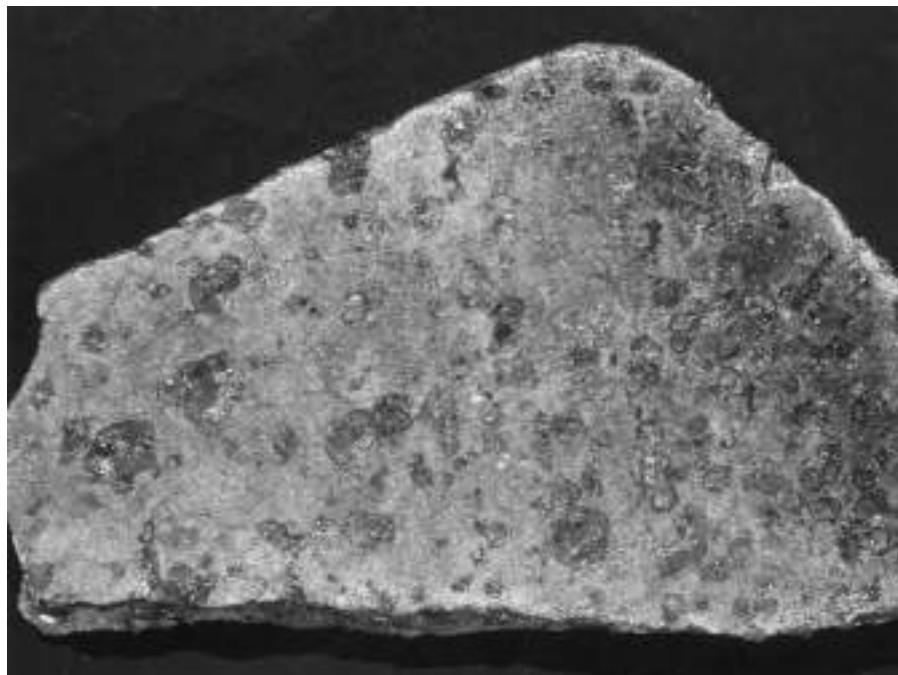

FIGURE 3 Garnet peridotite is the principal rock type in the earth's upper mantle, the source region of magmas. This colorful rock is composed of olivine (olive), orthopyroxene (gray), clinopyroxene (bright green), and garnet (burgundy). The width of this polished slab of mantle rock is 4 cm. [see Yoder, H. S., Jr. (1976). "Generation of Basaltic Magma." National Academy Press, Plate I, p. 44a]. (Also see color insert.)

is because kimberlites are explosive eruptions that extract the xenoliths very rapidly, and can be shown at least in some cases to originate from great depths. In particular, the presence of diamond in some kimberlites indicates a source at pressures of at least 4–5 GPa (40,000–50,000 atm), the pressure above which diamond is stable relative to graphite at mantle temperatures; this corresponds to depths in excess of 100–150 km. Moreover, laboratory studies show that the detailed compositions of the pyroxenes (e.g., abundances of Ca and trace amounts of Al) vary systematically with temperature and pressure at which the rock is formed. This effect has been calibrated such that it is possible to infer the temperatures and depths of origin of natural peridotite xenoliths from the compositions of their pyroxene minerals (analyses referred to as *geothermometry* and *geobarometry*). The result is that many peridotite xenoliths from kimberlites are found to originate from depths of 100–200 km or possibly deeper. Because the mineral compositions reflect the last conditions under which thermodynamic equilibrium was established, it is possible that a given xenolith was previously at a higher pressure and temperature, therefore greater depth, than is last recorded by the pyroxene compositions.

The seismic-wave velocities and density of peridotite (or its constituent minerals, averaged in the appropriate proportions) have been measured in the laboratory as a function of pressure and temperature, and do match the seismological observations on the upper mantle. Therefore, because peridotite is the rock that is brought up from the mantle by geological processes, and because its properties match those observed geophysically for the upper mantle, there is strong evidence that this is indeed the primary material making up the outer mantle of the Earth.

In addition, it is found that partial melting of peridotite produces basaltic liquids, comparable to those erupted in abundance at midocean ridges. Indeed, detailed seismological studies show that patches of reduced velocities and enhanced attenuation can be found within the top ~40 km of the mantle beneath midocean ridges, implying the presence of partial melt. Taking the melting conditions that have been determined experimentally for peridotite, one finds that enough basaltic melt of appropriate composition can be made to produce the 6-km-thick oceanic crust with about 15% (=6/40) overall melting of the upper mantle rock (the amount of melt present at any one time may be far less, however). This compatibility between laboratory studies and geophysical observations is in good accord with the conclusion that peridotite is the predominant rock of the upper mantle.

There needs to be a bit of care in describing the chemical compositions of natural peridotites, in that basaltic liquid is very mobile and therefore tends to separate quickly from its peridotite source in the upper mantle. The extraction of basalt changes the composition of the initial peridotite slightly; for example, iron, aluminum, and silicon tend to preferentially go into the liquid, leaving the residual crystalline phases slightly depleted in these elements. Most peridotite samples exhibit small but varying degrees of depletion of these key elements, so the tendency is to identify an end member composition that (as far as one can tell) has not suffered any basalt extraction and consider this to represent pristine, “fertile” peridotite. That is, the rock is fertile in the sense that it readily produces basalt upon partial melting, whereas depleted peridotite has had much of the basalt extracted from it. (Pyrolite, a synthetic model for the fertile peridotite comprising the upper mantle, consists of partially depleted peridotite plus basalt in approximately a 3 : 1 ratio.)

## B. Experiments

One test of the hypothesis that peridotite is the predominant rock of the outer mantle is to consider what happens to it, and its constituent minerals, as a function of depth (Fig. 4). Numerous laboratory experiments demonstrate that with increasing pressure, the olivine transforms to new phases having spinelloid and then spinel crystal structures ( $\beta$ -phase or wadsleyite, and  $\gamma$ -spinel or ringwoodite, respectively). In parallel, the pyroxenes dissolve into the garnet structure, which then transforms to an ilmenite-structured phase (Table II). All of these transformations are complete at pressures below that of the 650-km discontinuity. In fact, most take place at the conditions of the transition zone (pressures of ~12–20 GPa), whereupon both the olivine and the garnet-pyroxene phases transform to an assemblage of silicate perovskite [ $(\text{Mg}, \text{Fe})\text{SiO}_3$  +  $\text{CaSiO}_3$  in orthorhombic and cubic perovskite structures] plus magnesiowüstite [ $(\text{Mg}, \text{Fe})\text{O}$  in the rocksalt structure]. The elastic properties of all of these mineral phases have been measured experimentally, often as a function of temperature and pressure, and complementary theoretical calculations (including, first-principles quantum mechanical calculations) help verify and expand on the existing measurements.

The striking fact is that the peridotite minerals undergo their primary transformations at the pressures corresponding to the 410- and 650-km discontinuities.

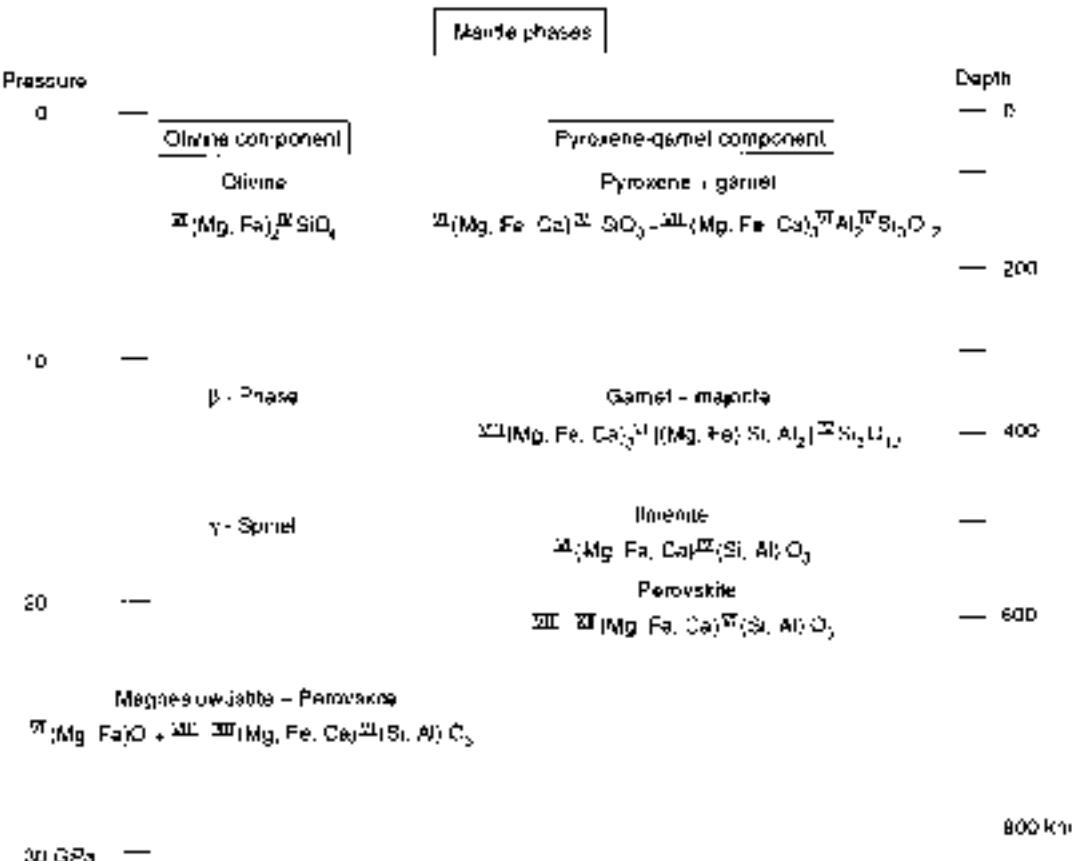

FIGURE 4. Summary of mineral transformations that take place in a rock of garnet-peridotite bulk composition as a function of pressure (equivalently, depth) in the mantle. Roman superscripts give the coordination number (number of nearest-neighbor oxygen ions) for each cation. The minerals making up peridotite can be separated into two groups, (1) olivine and (2) a combination of pyroxenes and garnet. As a function of increasing pressure through the upper mantle and transition zone, olivine transforms to the spinelloid ( $\beta$ -phase) and spinel ( $\gamma$ ) structures, whereas pyroxene dissolves into the garnet structure (ultimately forming majorite, a mineral phase having the composition of pyroxene and the crystal structure of garnet), which then transforms to the ilmenite structure. Orthorhombic and cubic perovskites become stable, along with magnesiowüstite, at lower mantle conditions. [From Jeanloz, R., and Thompson, A. B. (1983). *Rev. Geophys. Space Phys.* **21**, 51–74.]

Indeed, if one uses laboratory measurements to estimate the wave velocities and density for the transforming peridotite with increasing pressure and temperature as a function of depth, very nearly the same values and jumps are obtained as are observed seismologically. The uncertainties in such a comparison are significant, in that wave-velocity measurements are still not possible at the simultaneously high temperatures and pressures of the transition zone (i.e., it is necessary to extrapolate from lower pressures and temperatures at which measurements have been made), but the basic conclusion that a peridotite-like bulk composition reproduces the

average seismological properties of the upper mantle, transition zone, and lower mantle does seem to be robust in broad terms.

The changes in mineral properties with increasing depth in the mantle are relatively well understood, due to numerous experimental measurements and theoretical studies that have been carried out during the past few decades. Specifically, the elastic moduli (bulk modulus or incompressibility, and shear modulus or rigidity) of minerals tend to increase rapidly as the crystal structures are compressed under pressure. The overall packing of the atoms increases with depth in the mantle,

both due to simple compression of the crystal structures and as a result of the phase transformations. These processes yield the observed increases in both density and wave velocities through the transition zone region. For example, the olivine structure is made up of sheets of oxygen ions that are closely packed in two dimensions but loosely packed in the third (a loose stacking of hexagonal close-packed sheets); the cations are situated in octahedral (for Mg and Fe) and tetrahedral (for Si) pockets in between the oxygens. The effect of the transformation to the spinel or spinelloid structure is to cause the packing of the oxygen ions to become dense in all three dimensions (a nearly ideal cubic-close packing), with the remaining cations still in octahedral (six nearest-neighbor oxygens) and tetrahedral (four nearest-neighbor oxygens) sites.

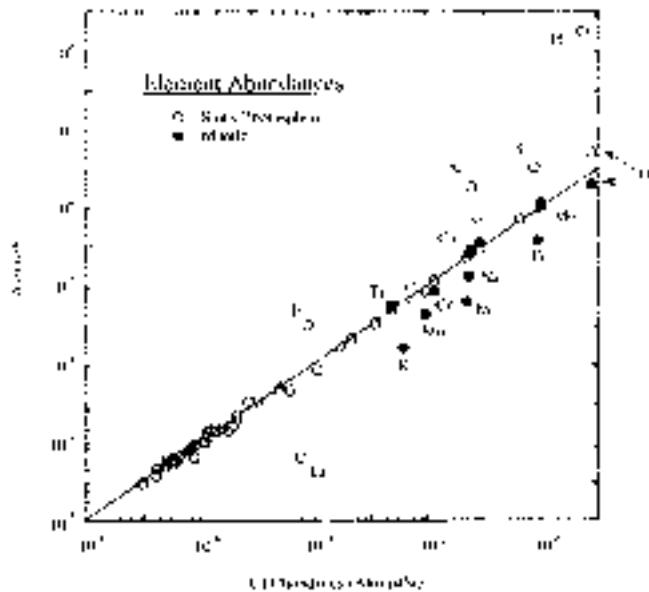

Perhaps the most profound change in atomic packing is that the tetrahedral (fourfold) coordination of silicon by oxygen that is typical of crustal and upper-mantle minerals transforms to an octahedral (sixfold) coordination of silicon by oxygen at lower-mantle conditions. For example, olivine and pyroxene contain, respectively, isolated units and chains of  $\text{SiO}_4$  tetrahedra, whereas the ilmenite and perovskite phases of  $(\text{Mg}, \text{Fe})\text{SiO}_3$  contain  $\text{SiO}_6$  octahedra.

The perovskite phase is notable for its ultradense packing of ions, with the Mg and O ions together forming a cubic close-packed array. Also, it is the high-pressure product (along with coexisting oxide) of all the primary upper mantle minerals, and it appears to be stable at all pressures existing throughout the lower mantle. Thus, Mg-silicate perovskite is expected to be the predominant mineral of the lower mantle, and its properties are found to match closely the observed density and wave-velocity values of the lower mantle. Consequently, although it is only stable above 20 GPa, silicate perovskite is considered to be the single most abundant mineral of the planet.

### C. Cosmochemistry

In addition to the evidence provided by xenolith and ophiolite samples, the composition of any terrestrial (rocky, Earth-like) mantle is expected to be broadly peridotite-like based on general cosmochemical arguments. Because the Sun contains the bulk of the mass of the solar system, its composition provides a good estimate of the composition of the solar nebula from which the planets formed (the composition of the Sun, in turn, is understood based on the properties of atomic nuclei and

theories of stellar evolution). During or shortly after their formation, high temperatures caused the terrestrial planets to lose most of their volatile (nonrefractory) elements, particularly the lightest ones such as hydrogen and helium; in fact, the Earth is still losing hydrogen to space. The more refractory elements, however, are thought to be largely retained in their original abundances. This is empirically found to be the case, in that the primitive chondritic meteorites, silicate-plus-metal assemblages representing fragments of the material left over from planet formation, do exhibit relative abundances of nonvolatile elements that are generally in close agreement with the spectroscopically observed distribution of abundances for the Sun (Fig. 5). Although there are discrepancies in detail (most of which are well understood), the agreement over many orders of magnitude of abundance is significant.

**FIGURE 5** Comparison of element abundances, expressed as number of atoms per Si atom, shown for the Sun's photosphere (open symbols; H, O, C, N, F, and Li are labeled) and the Earth's upper mantle (filled symbols: data from Table I, all elements are labeled) relative to the Orgueil meteorite, which is a typical primitive chondritic composition (CI chondrite). Chondrites are depleted in the volatile elements H, O, C, N, and F, relative to the Sun, and the upper mantle is further depleted in O, Na, and K (presumably due to volatility) as well as Fe and Ni (perhaps due to inclusion in the core). Not visible at this scale is the significantly higher Mg/Si ratio for the upper mantle (1.27) relative to chondrites (1.03) and the Sun (1.07). [Data from Anders, E., and Ebihara, M. (1982). *Geochim. Cosmochim. Acta* **46**, 2363–2380; Anders, E., and Grevesse, N. (1989). *Geochim. Cosmochim. Acta* **53**, 197–214.]

Similarly, estimates of the Earth's upper mantle composition based primarily on xenolith samples (Table I), are in general agreement with the solar system ("cosmic") abundances of refractory elements (Fig. 5). This is not surprising, in that chondritic meteorites generally consist of ultramafic assemblages ( $\sim 80\%$  olivine + pyroxene together, plus  $\sim 20\%$  iron alloy). During accretion of the Earth, the metal presumably sank to form the core, with the remaining silicates building up the mantle to yield a peridotite-like assemblage of minerals that is just like the silicate portion of meteorites. The agreement is imperfect in detail, in that the predominant element of the mantle (oxygen) is apparently volatile enough to have been partially depleted (relative to Si) during Earth formation. Also, the ratio of the next most abundant elements, Si/Mg, is found to be systematically ( $\sim 20\%$ ) higher for chondritic than Earth-mantle compositions (the olivine:pyroxene ratio observed for meteorites is lower than that observed for samples from the upper mantle; Table I). Against the backdrop of broad agreement between mantle and chondritic abundances for nonvolatile elements, the significance of these smaller deviations remains unclear.

#### IV. DYNAMICS

##### A. Heat Transfer and Mantle Temperatures

The distribution of temperature with depth in the mantle is determined from a combination of measurements (Fig. 6): (1) the observed temperature and its depth dependence in the crust, (2) geothermometry and geobarometry on mantle xenoliths, and (3) comparison of laboratory experiments giving the pressure at which olivine transforms to the  $\beta$ -phase at various temperatures, with the pressure at which the transformation is observed (as the 410-km seismic discontinuity) in the Earth. The last of these provides a determination of  $1400^\circ$  ( $\pm 200$ ) C at the top of the transition zone, with the geotherm rising to temperatures above  $2000^\circ$ C in the lower mantle.

To understand the temperature distribution throughout the mantle and, hence, the conditions under which magmas are formed at depth, it is necessary to characterize how heat is transported through the planet. The observation of plate-tectonic motions clearly documents that the uppermost mantle convects in a fluidlike manner over geologic time periods (Fig. 7): The  $\sim 1$ – $10$  cm/yr rates of plate motion are now measured nearly in real

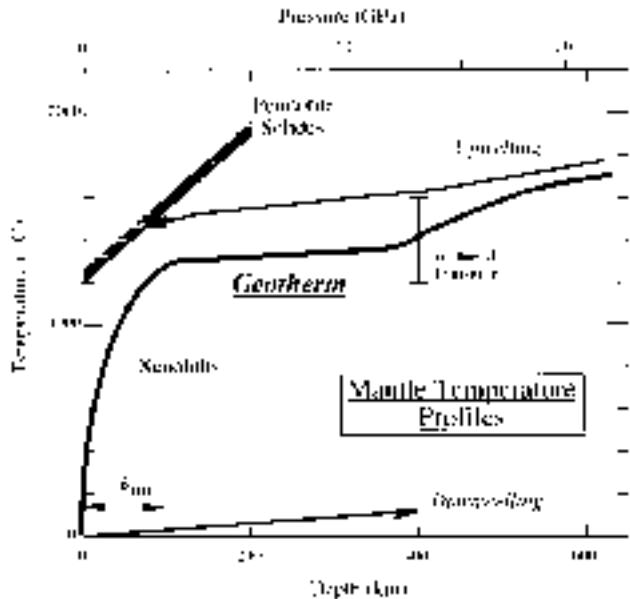

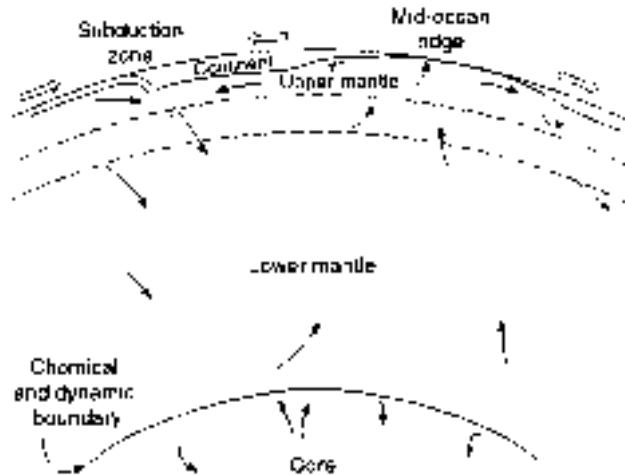

FIGURE 6 Average temperature profile through the upper mantle (geotherm: bold curve), as determined by mineral compositions in xenoliths (stippled) and comparisons of the seismologically observed depth (equivalently, pressure) of the 410-km seismic discontinuity with laboratory measurements of the effect of temperature on the pressure for the transformation of olivine to the spineloid  $\beta$ -phase (uncertainty indicated by error bar). The thermal boundary layer, the region across which vertical heat transfer occurs primarily by conduction, is characterized by a steep temperature gradient and a thickness  $\delta_{TBL}$ . Temperature profiles for upwellings (e.g., hottest temperatures beneath mid-ocean ridges) and downwellings (e.g., coldest temperatures beneath subduction zones) are shown for comparison: Both are characterized by adiabatic temperature gradients ( $\sim 0.2$ – $0.5^\circ$ C/km), as is the geotherm below the thermal boundary layer. For comparison, typical solidus temperatures for peridotite are indicated as a function of pressure (shaded line). Geothermometry on xenoliths only represents the geotherm (average) temperature to the degree that the rocks are fragments that have been fortuitously sampled by a rapidly moving flow originating at greater depths; to the degree that the xenoliths are samples of the upwelling portion of the mantle (ultimately bringing the rocks to the surface), the geothermometry should reflect higher than average temperatures.

time using GPS (global positioning system) and related technologies. Indeed, it has long been recognized that the "solid" Earth behaves as though it is a fluid body, in that it has the flattened-spheroidal shape of a rotating fluid. The early assumption was that the Earth's interior is molten; however, this became problematic about 100 years ago, when seismological observations began to show definitively that the crust and mantle are solid, in the sense of transmitting shear waves (i.e., supporting

**FIGURE 7** Schematic illustration of the possible flow pattern in the convecting mantle, and the consequent motions of lithospheric plates observed at the surface. New lithosphere is formed at midocean ridges, moves horizontally along the surface (large arrows), and sinks into the mantle at subduction zones. In this figure, the mantle is assumed to be of uniform composition and to be thoroughly stirred by convection. The underlying core is liquid, and convects at a rate  $\sim 10^6$  times faster than the mantle. [After Jeanloz, R. (1981). In "Proceedings of the American Chemical Society 17th State-of-the-Art Symposium." American Chemical Society, Washington, DC, p. 74.]

shear stresses). The apparent conflict between the evidence in favor of a solid versus a fluid interior has now been resolved by the recognition that *both* views are correct; although the crust and mantle are predominantly crystalline, not molten, they can undergo sufficient plastic deformation to behave in a fluidlike manner over periods of millions of years or longer.

Geodetic observations of how the Earth's surface is uplifting since the melting of the last major ice sheets, starting about  $2 \times 10^4$  yr ago, yield values for the mantle's effective viscosity in the range of  $\eta \sim 0.5\text{--}10 \times 10^{20}$  Pa s. Analysis of the resulting force balances leads to the modern conclusion that the mantle undergoes vigorous, probably chaotic convection. The pattern of convection is not well understood at present, and is likely to be time dependent over Earth history. Nevertheless, it is possible to reach general conclusions about the temperature distribution at depth based simply on the knowledge that the vertical transfer of heat across the bulk of the mantle is by convection. In contrast, conduction of heat through rock is so poor that it does not contribute significantly to cooling the interior on a global scale: With a typical thermal diffusivity of  $\kappa \sim$

$10^{-6}$  m<sup>2</sup>/s for rock, heat is only transported a distance of  $\sim[(10^{-6}\text{ m}^2/\text{s})(4.5 \times 10^9 \text{ yr})(3.2 \times 10^7 \text{ s/yr})]^{1/2} \sim 380$  km by conduction over Earth history.

Midocean ridges are the surface manifestation of hot upwellings of (predominantly) crystalline rock rising through the mantle (Fig. 7). Because of the low thermal conductivity of rock there is relatively little heat lost from the upwelling, and its temperature therefore decreases adiabatically upon rising through the mantle. The hottest region in the upwelling becomes partially molten near the surface, releasing basalt that forms the oceanic crust. The crust and underlying mantle comprising the lithosphere must then move sideways in order to make room for more rock coming up from depth. Because it is moving laterally, the only way that the lithosphere (or tectonic plate) can transfer heat vertically is by conduction. Thus, as the lithospheric plate moves the  $\sim 10^3$ -km distance across an ocean basin, it cools from above by conduction.

The depth to which cooling extends over the  $\sim 10^8$ -yr life of the oceanic plate is  $\delta_{\text{TBL}} \sim 10^2$  km, and defines the thickness of the thermal boundary layer (Fig. 6). The theory of thermal boundary layers, which evaluates the vertical heat loss by conduction from the laterally moving plate, can be used to determine the bathymetry and the heat flow for oceanic crust as a function of age (or, for a given plate velocity, distance from the midocean ridge); the success in fitting observed values provided one of the first quantitative verifications of plate tectonics. Furthermore, because the effective viscosity of rock increases exponentially with decreasing temperature, the cool region of the thermal boundary is very stiff, giving it the platelike characteristics that define the lithosphere. There is thus a close connection between the thermal boundary layer at the top of the mantle (defined by thermal characteristics) and the lithosphere (defined by mechanical properties).

As with most materials, rock expands on heating and contracts on cooling. Therefore, the oceanic lithosphere becomes denser as it cools, so much so that it ultimately sinks into the mantle. At a subduction zone, where oceanic lithosphere plunges back downward, there is effectively a cold and dense sheet of material being inserted into the mantle (Fig. 7). The temperature of the downwelling rock increases adiabatically with depth (Fig. 6). Ultimately, part or all of this subducted material becomes slowly reheated, either by the hot outer core that underlies the mantle or by heat sources within the mantle, and therefore becomes buoyant again.

The result of the convective motions is that temperatures vary at any given depth by an amount comparable

(to within a factor of  $\sim 2$  after removing the adiabat) to the temperature difference between the bottom and top of the mantle. The geotherm merely describes the average temperature at each depth, whereas it is the temperature difference at each depth that causes buoyancy differences—with hot rock rising and cold rock sinking—driving mantle convection. The temperature distribution is thus both a cause and a consequence of mantle dynamics.

The buoyancy driving convection is given by the density difference of the upwelling relative to the downwelling regions of the mantle. It is a remarkable fact that because the thermal expansion coefficient of rock is of the order of percent per  $1000^{\circ}\text{C}$  ( $\alpha \sim 10^{-5} \text{ K}^{-1}$ ), mantle convection and the resulting plate tectonics are driven by density variations of only a few percent (temperature variations of order  $10^3\text{C}$ ). The stresses driving convection are similarly minuscule. These equal the viscosity times the strain rate, the latter being given roughly by plate velocities divided by the thickness of the mantle:  $\varepsilon_t \sim (10^{-2} \text{ m/yr}) / [(3 \times 10^6 \text{ m}) (3 \times 10^7 \text{ s/yr})] \sim 10^{-16} \text{ s}^{-1}$ . Therefore, the magnitude of stresses driving the thermal and tectonic evolution of the mantle is of the order  $\eta \varepsilon_t \sim (10^{20} \text{ Pa s})(10^{-16} \text{ s}^{-1}) \sim 10^4 \text{ Pa}$ , which is less than atmospheric pressure at sea level and far less than the pressures reached in the mantle. (This is why pressures throughout the mantle can be taken to be very nearly hydrostatic.)

## B. Heat Sources

The energy sources that ultimately heat the Earth's interior, hence cause mantle convection and volcanism, are a combination of heat left over from the accumulation of the planet (accretionary or "primordial" heat) and heat that has been produced by naturally occurring radioactive elements present in rock. It is difficult to estimate how much the planet was heated on accretion because the gravitational energy that is released (basically, the heating produced on impact as material is swept together to form the planet) is enormous, and would amount to a temperature rise for the mantle of  $\sim 3-4 \times 10^4\text{C}$  except that most of this heat is reradiated to space. Moreover, the last stages of the Earth's accumulation were no doubt characterized by giant impacts, of which one is thought to have involved a glancing blow from a Mars-sized object that effectively splashed the Moon out of the Earth. Modeling studies show that such giant impacts cause temperatures of the mantle

rock to reach values as high as  $\sim 10^5\text{C}$ . Although the amount of this heat that is retained within the planet is not well determined, it is clear that temperatures of  $\sim 1-5 \times 10^3\text{C}$  could well have been reached throughout most of the interior. In fact, current theories suggest that part or all of the mantle was molten  $4.5 \times 10^9 \text{ yr}$  ago, forming a "magma ocean" right after the Earth had formed. If so, much of the Earth's currently high internal temperature could be a remnant of the accretion process: volcanism at the surface is, at least to some degree, caused by 4.5-billion-year-old heat that is only now emerging from the deep interior.

Chemical analyses of meteorites and terrestrial rocks (samples of both mantle and crust) show that the decay of K, Th, and U isotopes produce most of the planet's natural radioactive heating, amounting to an estimated  $\sim 25-30 \text{ TW} (\sim 1.5 \times 10^{-4} \text{ J kg}^{-1} \text{ yr}^{-1})$  for the present Earth. Accounting for the decay of the isotopes over time, the radioactive heat production was at least four to five times higher at the time the Earth was formed. Therefore, naturally occurring radioactivity has also contributed to the planet's internal heat.

To put these values into perspective, the current heat flow out of the Earth's surface is about 44 TW [average flux of  $87 (\pm 2.0) \text{ mW m}^{-2}$ ], and was no doubt higher early in Earth history. This is significantly higher than the rate at which heat is being produced by radioactivity, but only by a factor of 50–80%. Part of this difference can be ascribed to the contribution of primordial heating. According to the estimates given here, roughly one-third to one-half ( $\sim 15-20 \text{ TW}$ ) of the heat currently lost from the interior is left over from the Earth's accretion. However, there is also the fact that the Earth is cooling, and probably has been cooling since its formation, hence that more heat is being lost than is being produced. Indeed, convection of the "solid" mantle is the mechanism by which the deep interior is being cooled. Modeling studies suggest that the heat lost from the surface is only a small amount larger than the magnitude of all internal sources (both accretionary and radioactive), such that the interior has only cooled by several hundred degrees during the past 4 billion years.

In addition to the physical origin of the Earth's internal heat, the distribution of heat sources within the planet is also of importance. In particular, estimates of the temperature in the core indicate that this region is hotter than the overlying mantle, perhaps by as much as  $1000^{\circ}\text{C}$  or more, which implies that the mantle is to some degree heated from below. Most current models suggest that only about 20–50% of the heat driving mantle convection comes from the underlying core, with

the remainder (50–80%) originating internally. Such values are uncertain but seem reasonable: Given that the mantle makes up 84% and the core 15% of the planet on an atomic basis, the bulk of the Earth's internal heat probably comes from the rocky portion rather than the metallic core.

### C. Causes of Melting

The measurements of naturally occurring radioactivity in rocks demonstrate that, although radioactive decay has contributed to heating the planet over its geologic history, it probably plays only a minor role in directly heating rock to the melting point and producing any magmas at depth. For example, the specific heat ( $C_p \sim 10^3 \text{ J K}^{-1} \text{ kg}^{-1}$ ) can be used to convert radioactive heat production to a corresponding temperature rise:  $\Delta T \sim (1.5 \times 10^{-4} \text{ J kg}^{-1} \text{ yr}^{-1})/(10^3 \text{ J K}^{-1} \text{ kg}^{-1}) \sim 10^{-7} \text{ K/yr}$ , using the present-day value of average heat production given earlier. Even taking into account the increase in radioactive heat production as one goes back in geologic time, most of the Earth's 4.5-billion-year history is required to achieve a temperature increase of  $1-2 \times 10^3 \text{ }^\circ\text{C}$  by radioactive decay. Thus, a sizable fraction of the Earth's  $\sim 2000 \text{ }^\circ\text{C}$  internal temperature is likely due to radioactive heating, but the  $\sim 10^2-10^3 \text{ }^\circ\text{C}$  heating required to bring rocks to the melting point can only be accomplished over time periods of hundreds of millions of years.

Over a time period of  $10^8 \text{ yr}$ , upwelling mantle rock rises  $\sim 10^3 \text{ km}$  (using plate-tectonic velocities of  $\sim 10^{-2} \text{ m/yr}$ ) and a piece of the deep mantle reaches the surface before radioactivity can produce very significant heating. Instead of the upwelling rock being heated to its melting temperature, it is because the adiabatic temperature drop on rising is sufficiently small that the temperature of the upwelling crosses the melting point of the mantle rock (Fig. 6). In general, melting on adiabatic decompression of initially hot rock being brought up from depth is considered one of the most common causes of melting in the mantle and crust. Thus, it is not so much by direct heating but primarily by way of the convective motions they induce throughout the mantle that both primordial and radioactive heat sources eventually lead to the formation of magmas in the Earth.

From this point of view, one would expect melting of the mantle to be exclusively associated with upwellings, such as the regions beneath midocean ridges. It is a fact that most of the Earth's volcanism occurs at midocean ridges, and it is no coincidence that most of the heat

flow from the interior is also concentrated along the ridges. It might therefore appear surprising that a considerable amount of volcanic activity, and the predominant volcanism associated with continents, occurs at subduction zones—exactly where the coldest lithosphere is sinking into the mantle.

The basic reason that magmas are formed at subduction zones is that water is drawn into the mantle, along with the sinking slab of cold lithosphere. The water is present as a fluid phase, within pore spaces of sediments and along grain boundaries of crustal rocks being subducted. It is also dissolved within crystal structures (as  $\text{OH}^-$  hydroxyl molecules) of hydrated minerals that have been formed by weathering of the crust and uppermost mantle rocks of the oceanic lithosphere (exactly the weathering and hydration referred to in describing ophiolites).

The effect of water is to lower dramatically the solidus temperature of most rocks, so that it effectively acts as a flux at subduction zones. As the sinking lithosphere heats up, water is released and can migrate upward toward hotter rock within the wedge of mantle material and the deep crust lying above the subducted slab. Because the effective melting temperatures of the mantle and crustal rocks are reduced by hundreds of degrees, simply due to the presence of water, the result is that magmas are formed as water-rich fluid percolates upward from the slab of subducting lithosphere.

The magmas formed by water-fluxing in the mantle tend to be more silica-rich than the basalts formed at midocean ridges, and have nearly the average composition of continental crust. In truth, it is thought that most continental crust is produced by water-induced lowering of the melting temperature above subduction zones. It is for this reason that water is thought to be necessary for the formation of the continental crust, such that Earth-like continental rocks would not be expected on terrestrial planets devoid of water.

In summary, the formation of magmas within the Earth is predominantly due to two events: (1) adiabatic decompression of upwelling rock and (2) lowering of the solidus by water (and other volatile components) brought into the mantle by subduction. Once a melt is formed at depth, it can move relatively quickly (meters to kilometers per year; near the surface, velocities up to kilometers per day are recorded), thereby separating the liquid from its source rock. Because melts typically differ in bulk composition from their source rocks, the combination of melt formation and (relatively) rapid migration is the essential process of geochemical differentiation: the separation of large-scale portions of the planet into chemically distinct regions.

#### D. Plumes and the Core–Mantle Boundary

Although plate tectonics and the thermal-boundary layer model describe much of the global pattern of volcanism at the Earth's surface, a notable exception is provided by hot spots. Each hot spot is characterized by a chain of volcanoes exhibiting a systematic age dependence along the length of the chain, making it appear that the volcanism is the result of a stationary source of heat in the mantle underlying the moving tectonic plate. The Hawaiian-Emperor chain of volcanic islands and seamounts is the clearest example, and also corresponds to the largest hot spot in terms of flux of heat or lava volume.

One of the most remarkable features of the few dozen hot spots that have been identified is that they appear to be nearly stationary with respect to each other, moving at less than  $\frac{1}{10}$  the rate at which tectonic plates move. This has led to the idea that each hot spot represents the tip of a plume, an axially symmetric jet of hot rock (in contrast to the sheetlike upwellings beneath midocean ridges, or downwellings at subduction zones) emanating from the great depth—perhaps even the lowermost mantle—in order to explain the apparent lack of any influence from the plate-tectonic motions at the Earth's surface.

The evidence for where plumes originate is, like any discussion of large-scale motions across the depth of the mantle, not well resolved at present. Some of the most direct evidence comes from recent advances in seismic tomography, which involves the determination of horizontal variations in wave velocity at each depth as determined by an analysis of seismic records from cross-cutting ray paths. That is, by comparing the arrival times and amplitudes of seismic waves traveling between many combinations of sources (earthquakes or explosions) and receivers (primarily, modern digital seismometers), it is possible to reconstruct the three-dimensional velocity structure of the mantle.

Because seismic-wave velocities are influenced by temperature, with propagation through hotter rock being slower than through colder rock, one can roughly ascribe low and high velocities at a given depth with, respectively, higher and lower temperatures (hence, more and less buoyant rock) at that depth. The correspondence with temperature is confounded somewhat by the fact that changes in rock type (differences in bulk composition or constituent minerals) also influence the wave velocities and densities. However, there is clear evidence of slabs of fast seismic-wave velocities observed in the upper mantle beneath subduction zones and, in several notable examples (e.g., around the Pacific basin),

these appear to depths of 1500 km or more. There appears to be, therefore, a strong indication that many if not all slabs of subducted material penetrate well into the lower mantle (some slabs appear to become deflected at, and perhaps stopped by, the transition zone at depths of  $\sim 400$ –700 km).

Although regions of faster seismic velocity are systematically easier to image than regions of slower wave velocities, recent studies have revealed a few clear examples of plumes exhibiting a slow ("hot") seismic signature to depths well into if not through the transition zone, for example beneath Hawaii and Iceland. Such observations support the idea that plumes may originate from the lower mantle.

More remarkably, there are indications of very strong seismological anomalies at the core–mantle boundary beneath some plumes. For example, there appears to be a distinct ultra-low-velocity zone (ULVZ) directly under Iceland, and Hawaii is situated above (or nearly above) another ULVZ. The connection between ULVZ and plume is circumstantial and perhaps even speculative at present, but does suggest the possibility that hot spots represent the surface markings of heat emanating from the Earth's core. In this sense, volcanism at hot spots may provide a relatively direct link between the core and the Earth's surface.

More generally, the preponderance of volcanic activity—at midocean ridges and subduction zones, as well as at hot spots—is a manifestation of large-scale mantle convection and hence the mechanism by which the bulk of the planet has evolved geologically over its 4.5-billion-year history.

## GLOSSARY

- adiabatic** A thermodynamic process during which heat flow by conduction is negligible.
- batch melting** Melting process in a closed system in which liquid and solid remain in equilibrium.
- component** A chemical formula. The number of components in a system is the minimum needed to describe all possible chemical variations in the system, so a pure system with no chemical variation has one component.
- equilibrium** A state in which all natural processes have gone to conclusion and no further change is observed in any macroscopic variable.
- fractional melting** A melting and distillation process in which liquid is continuously and instantaneously removed from the system as it forms.
- isentropic** A thermodynamic process occurring at constant entropy; equivalent to *adiabatic* and *reversible*.

**liquidus** The temperature at which a liquid of given composition begins to crystallize at a given pressure.

**phase** A compositionally and structurally homogeneous material such as a mineral, liquid, or vapor.

**productivity** The increase in extent of partial melting per unit decrease in pressure, expressed in percent per gigapascal and usually a positive number.

**reversible** An idealized path that proceeds through a sequence of equilibrium states with no spontaneous processes occurring.

**solidus** The temperature at which a solid assemblage of given composition begins to melt at a given pressure.

## I. INTRODUCTION

The stony part of the Earth is solid under normal conditions at the present day. Volcanism is the eruption of molten or partially molten rock, that is, magma. The first stage of any volcanic process therefore must be melting: We have to produce a liquid by partial melting before it can migrate from the source region (see Migration of Melt chapter) and subsequently erupt (Part II). The locations of volcanoes on Earth are controlled primarily by where melting takes place. The volume, frequency, and style of eruptions are dependent on many factors but the first considerations are how much magma is supplied by melting, at what depth melting takes place,

and the distribution of melt production in the source region in space and time.

Before roughly 1960, igneous petrology was mostly concerned with the evolution and differentiation of magma after it left its source region. In the following two decades, attention shifted to the pressure ( $P$ ) and temperature ( $T$ ) at which primary melts were extracted from the mantle, without detailed understanding of how the melts were produced. In the last 20 years, however, the application of ideas from thermodynamics, experimental petrology, and fluid dynamics has provided a strong basis for understanding the basic physical processes underlying the melting of Earth's mantle. This chapter explores *how* and *why* the crust and mantle of the Earth melt, which together with information about tectonic processes and chemical composition (discussed in other chapters in this part) determines *where* and *when* melting takes place.

## II. HOW TO MELT A ROCK

There are three ways to melt a rock. The most obvious way is to *raise the temperature* ( $T$ ). In the Earth, however, the other two methods are dominant: melting by *lowering the pressure* ( $P$ ) and by changing the chemical composition of the system to *lower its solidus temperature* below the current temperature. The *solidus* is the temperature at which a system of given composition begins to melt at a given pressure, whereas the *liquidus* is the temperature at which the system becomes completely liquid. Rocks melt over a range of temperatures so it is imprecise to speak of the melting point as we would for a pure substance. Melting by decompression and melting by addition of a flux (i.e., a component that lowers the solidus) dominate in the mantle because in the asthenosphere mass transport is much faster than heat transport and because internal heat generation by radioactivity is minor at the present era. In the lithosphere, which includes the crust, mass transport is slower and ambient temperatures are low enough that a temperature increase, whether by conductive heat flow or local heat generation, is required. For the earth as a whole, however, asthenospheric melting generates a much larger volume of magma every year than lithospheric melting.

Why three ways? The answer derives, like most of our reasoning about the physical and chemical behavior of rock systems, from thermodynamics and from the assumption of chemical *equilibrium*. Situations certainly occur, such as explosive eruptions, in which equilibrium

is a poor assumption, but at the source of melting temperatures are quite high and the processes considered are fairly slow. Long times and high temperatures favor the achievement of equilibrium, so while we know that equilibrium reasoning is an approximation, we consider it a rather accurate one at least for the early stages of magma production. For a system in chemical equilibrium, we must specify its chemical composition and two additional parameters (such as  $P$  and  $T$ ) to define uniquely the state of the system. Therefore, to cause a change of state such as melting, we see that we can group all the ways we can act on the system into changes in  $T$ , changes in  $P$ , and changes in composition. It is, as far as we know, universally true that high  $T$  favors the liquid state over the solid state, so that *raising the temperature* or *lowering the solidus temperature* (by changing composition) can lead to melting. On the other hand, while it is more common for low  $P$  to favor the liquid state over the solid state so that *lowering the pressure* can lead to melting, this is by no means universal (water is a well-known exception, and mantle rocks may experience the opposite behavior at very high pressures as well).

We can define the state of a system by specifying parameters other than  $P$  and  $T$  and in many cases it is quite convenient to do so because other parameters may be conserved or controlled (i.e., independent) during the physical process we are considering. Likewise,  $P$  or  $T$  may be dependent parameters, in which case we learn little by trying to specify them or by using them as axes on our diagrams. In an isochoric system such as an inclusion in a rigid mineral host, volume (or density) is held constant and  $P$  changes in a dependent manner as we approach equilibrium. For mantle melting, we are concerned with an approximately *adiabatic* system, that is, one in which heat flow by conduction is negligible. This is a reasonable approximation because the source regions of magmas in the mantle are large, thermal gradients are low, and the timescale for material to be transported across the source region by advection is shorter than the time for temperatures to equilibrate across the source region by thermal diffusion. If an adiabatic process is also *reversible*, then the independent variable is not  $T$  but entropy,  $S$  (see Table I). This follows directly from the second law of thermodynamics,

$$dS = \frac{dq}{T} + d\sigma, \quad (1)$$

which states that the change in entropy for any process is equal to the ratio of heat flow  $dq$  to temperature plus the irreversible entropy production  $d\sigma$ . If a process is adiabatic ( $dq = 0$ ) and reversible ( $d\sigma = 0$ ), then  $dS =$

TABLE I Symbols Used

Symbol	Name	Units
$T$	Temperature	°C, K
$P$	Pressure	GPa
$S$	Specific entropy	J/K/kg
$q$	Heat	J/kg
$\sigma$	Irreversible entropy production	J/K/kg
$H$	Specific enthalpy	J/kg
$F$	Extent of melting by mass	
$s$	Solid phase	
$l$	Liquid phase	
$\Delta S_{\text{fus}}$	Entropy of fusion (one-component system)	J/K/kg
$\Delta V_{\text{fus}}$	Volume of fusion (one-component system)	J/GPa/kg
$\alpha$	Coefficient of thermal expansion, $\frac{1}{V} \left( \frac{\partial V}{\partial T} \right)_P$	K <sup>-1</sup>
$\rho$	Density	kg m <sup>-3</sup>
$C_p$	Specific heat capacity at constant pressure	J/K/kg
$\left( \frac{\partial T}{\partial P} \right)_S$	Slope of an isentrope in $P$ - $T$ space	K/GPa
$\left( \frac{\partial T}{\partial P} \right)_{\text{solidus}}$	Slope of the solidus curve in $P$ - $T$ space	K/GPa
$-\left( \frac{\partial F}{\partial P} \right)_S$	Isentropic productivity	%/GPa
$\left( \frac{\partial T}{\partial P} \right)_F$	Slope of a constant $F$ contour in $P$ - $T$ space	K/GPa
$\left( \frac{\partial F}{\partial T} \right)_P$	Isobaric productivity	%K
$\left( \frac{\partial S}{\partial F} \right)_P^{\text{rxn}}$	Isobaric entropy of melt reaction	J/K/kg
$\left( \frac{\partial S_X}{\partial P} \right)_F$	Entropy change due to compositional effects per unit change in $P$ at constant $F$	J/K/GPa/kg
$\left( \frac{\partial S_X}{\partial F} \right)_P$	Entropy change due to compositional effects per unit increase in $F$ at constant $P$	J/K/kg
$G$	Gravitational constant ( $6.67 \times 10^{-11}$ )	m <sup>3</sup> kg <sup>-1</sup> s <sup>-2</sup>
$M_\oplus$	Mass of the Earth ( $6 \times 10^{24}$ )	kg
$R_\oplus$	Radius of the Earth (6371)	km
$X_Y^{\text{bulk}}$	Mole fraction of component $Y$ in bulk system	
$X_Y^l$	Mole fraction of component $Y$ in liquid phase	
$D_Y$	Partition coefficient for component $Y$ : $(X_Y^l/X_Y^{\text{bulk}})$	

0, which is to say  $S$  is constant and we call the process *isentropic*. For our purposes, this property defines entropy. We can also imagine an adiabatic but irreversible process such as the Joule-Thomson experiment of forced flow through a nozzle in which enthalpy  $H$  is conserved. Some authors have suggested that adiabatic upwelling is an isenthalpic process (using a definition of enthalpy corrected for the presence of gravity), but although mantle melting is not strictly reversible, it is not clear why it should be isenthalpic. We find it easier to begin with the isentropic case and add known sources of entropy production (gravity and viscosity) to arrive at an accurate description of the natural process. In the section on decompression melting, we shall see why it is instructive to use the conserved quantity  $S$  in our thinking and on our diagrams rather than the dependent parameter  $T$ .

In the following sections, we review the essentials of decompression melting, flux melting, and melting by direct heating. Our principal focus is on decompression melting, since at least for the present-day terrestrial mantle, that is the dominant mechanism.

### III. DECOMPRESSION MELTING

Decompression melting is the best understood mechanism of melt production. It occurs at midocean ridges and ocean islands such as Hawaii and Iceland. The melting process underlying convergent margin volcanism is different and is discussed in a later section. The main points of this section are that from simple considerations we can show why the mantle melts when decompressed and how much melt we should expect to be produced during decompression.

#### A. One-Component System

We begin by considering a pure substance or one-component system (a *component* is a chemical formula, and the number of components in a system is the minimum needed to describe all possible chemical variations in the system, so a pure system with no chemical variation has one component). The mantle is a multicomponent system, but we can learn a great deal from the very simplest system that can then be generalized to systems that are more complex. First, let us imagine that this substance can only form two phases, a solid  $s$  and a liquid  $l$  (a *phase* is a compositionally and structurally

homogeneous material). Let our system be well behaved so that liquid is favored by high temperature and low pressure, so if we map the stable assemblage in  $P$ - $T$  space we will find a *phase diagram* like that shown in Fig. 1a. A phase diagram divides a plane or space according to what phases are stable at each point. There are three elements to the phase plane in Fig. 1a: a one-phase region where solid  $s$  is stable, a one-phase region where liquid  $l$  is stable, and a two-phase curve where  $s$  and  $l$  coexist. In this space, this two-phase curve is both solidus and liquidus. Thus if we take  $P$  and  $T$  as our independent variables, for example, along an isothermal decompression path, our one-component system in passing from one equilibrium state to another as we reversibly lower  $P$  would melt completely at a single point along the path.

Pressure and temperature have the special property that they are equal among all phases coexisting at equilibrium (except for surface tension effects), which is why the two phases  $s$  and  $l$  coexist along a curve in the  $P$ - $T$  plane. Entropy (as well as enthalpy and volume), on the other hand, differs between coexisting phases. If, therefore, we draw the phase diagram for our one-component system in the  $P$ - $S$  plane, we obtain something like Fig. 1b. This plot still has one-phase regions where  $s$  and  $l$  are stable alone, but now we see a two-phase region  $s + l$  crossed by vertical tie-lines showing  $s$  and  $l$  coexisting at the same pressure but different entropies (the length of the tie-line at each pressure is  $\Delta S_{\text{fus}}$ , the entropy of fusion). Now we recognize the boundary between the  $s$  and  $s + l$  regions as the solidus and the boundary between regions  $s + l$  and  $l$  as the liquidus. By taking entropy  $S$  as an independent variable, we have opened the two-phase curve up into a region and we see that in this case we no longer expect the system to melt or freeze completely at a single pressure. Instead, even in this one-component system, isentropic decompression leads to *partial melting*. An isentropic decompression path is shown in Figs. 1c and 1d. In the  $P$ - $S$  plane (Fig. 1d), this is a straight line, and it is obvious that the melting begins at the pressure where the solidus crosses the prescribed entropy and ends at the pressure where the liquidus crosses the prescribed entropy. On the other hand, in the more conventional  $P$ - $T$  plane (Fig. 1c), the isentropic decompression path kinks to follow the two-phase boundary for what seems an arbitrary interval: There is no simple way to predict the behavior of the system at fixed  $S$  by looking at a diagram that considers  $T$  independent.

During isentropic decompression melting, it is clear from Fig. 1c that the temperature actually decreases as the system melts, contrary to intuition. At constant

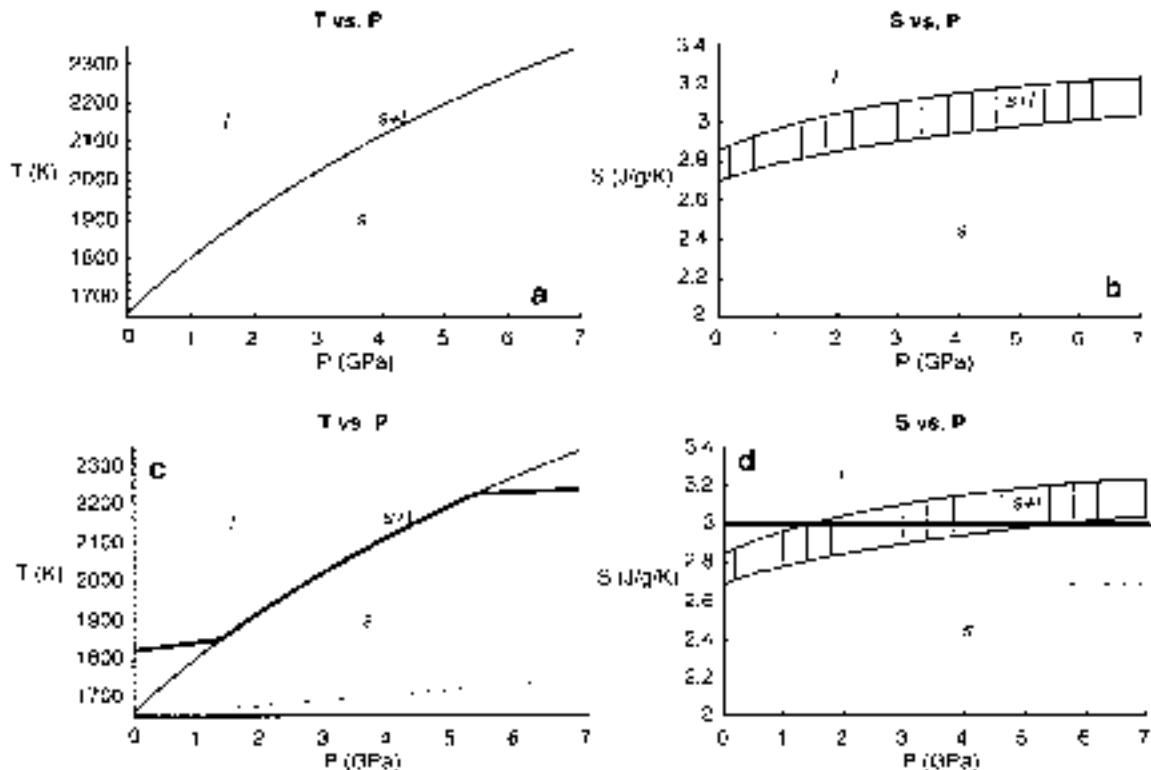

FIGURE 1 Phase relations and isentropic decompression melting of a one-component system. (a) A phase diagram in the pressure ( $P$ ) versus temperature ( $T$ ) plane is divided into a region where solid phase  $s$  is stable, a region where liquid phase  $l$  is stable, and a curved boundary  $s + l$  where the two phases coexist at equilibrium. (b) The same system plotted in the  $P$  versus entropy ( $S$ ) plane; here the two phases coexist over a region  $s + l$  bounded by the solidus and liquidus curves (which coincide in part a). The vertical tie-lines in the  $s + l$  field indicate that solids coexist with liquids at higher entropy but the same pressure. (c) The  $P$ - $T$  diagram with two isentropic decompressions path indicated; the slope of isentropes in the one-phase regions is about 10 K/GPa. The bold path shows a typical partial melting path. The light dashed path shows an adiabat so cold that melting would not occur even if adiabatic upwelling continued to the surface. During partial melting, the  $P$ - $T$  path in a one-component system is restricted to the coexistence curve  $s + l$ , but there is no way to read from this diagram how much melt is present at any point or how long the melting interval is. (d) The bold constant-entropy line superposed on the  $P$ - $S$  diagram shows that the size of the isentropic melting interval as well as the melt fraction at any point can be read directly from this diagram using the lever rule (see Fig. 2). Again, the light dashed line shows an isentrope cold enough to avoid melting.

total entropy, this behavior results because the entropy of fusion required to transform solid to liquid can only be obtained by decreasing the temperature of the system.

### B. Beginning of Melting

Isentropically lowering the pressure on a solid will generally cause it to intersect the solidus and begin partial melting. This is clear immediately on the  $P$ - $S$  diagram, where the isentrope is horizontal and the solidus has a positive slope, so that only isentropes with less entropy

than the intersection of the solidus with atmospheric pressure can avoid decompression melting altogether. On the  $P$ - $T$  diagram, this is not quite as obvious, but we can assign approximate numerical values to the slopes of the adiabat and the solidus in  $P$ - $T$  space and hence make the same argument. The slope of the subsolidus isentrope, that is, the change in temperature per unit change in pressure at constant entropy, is written in partial derivative notation  $(\partial T / \partial P)_S$  and is given by the formula

$$\left( \frac{\partial T}{\partial P} \right)_S = \frac{T\alpha}{\rho C_p}, \quad (2)$$

where  $\alpha$  is the coefficient of thermal expansion,  $\rho$  the density, and  $C_p$  the isobaric heat capacity of the solid phase. For mantle minerals, this slope is approximately 10 K/GPa. In the one-component system, the slope of the solidus is given by the Clausius-Clapeyron equation:

$$\left(\frac{\partial T}{\partial P}\right)_{\text{solidus}} = \left(\frac{\Delta V_{\text{fus}}}{\Delta S_{\text{fus}}}\right), \quad (3)$$

where  $\Delta V_{\text{fus}}$  is the difference in specific volume and  $\Delta S_{\text{fus}}$  the difference in specific entropy between liquid and solid. This slope is approximately 130 K/GPa for mantle minerals at low pressure. This value is much larger than the slope of the adiabat such that once again the adiabat will intersect the solidus on decompression unless the temperature of the adiabat at atmospheric pressure is less than the solidus at atmospheric pressure (see Fig. 1c). For mantle minerals, this “no melting” adiabat is much colder than today’s mantle adiabat; anywhere the adiabatic geotherm extends to near the surface will be a region of melting. Conversely, the bulk of the shallow parts of the earth are subsolidus only because the lithosphere cools conductively to the surface and does not lie on the mantle adiabat.

### C. Progress of Melting

To describe fully a system undergoing partial melting, we need to keep track of the composition of liquid and residue as well as the quantity of melt produced. The compositions of liquids produced by mantle melting are dealt with in later chapters. Here, we focus on the amount of melt generated. To track the amount of melt during progressive upwelling the quantity we most need to know is the *productivity*,  $-(\partial F/\partial P)_S$ , the increase in extent of partial melting  $F$  per unit decrease in pressure (expressed in percent per gigapascal and usually a positive number) and how the productivity evolves during progressive upwelling and melting. This variable is particularly hard to obtain by direct experimental measurement or from  $P$ - $T$  phase diagrams, but many authors have estimated that productivity should be about 10% GPa for adiabatic mantle melting, which is an adequate average value.

For many purposes, the average estimate of 10% / GPa is sufficient. Going beyond this average, we may ask whether we should expect any systematic behavior in the variations of productivity during the progress of melting. Different authors have argued, variously, for

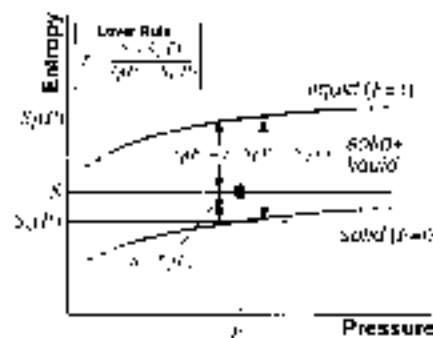

increasing, constant, and decreasing productivity. We can demonstrate, however, simple reasons why we should in fact expect productivity to increase from the beginning of adiabatic melting until the exhaustion of a phase (usually clinopyroxene) from the residue. We can see some of the variables that cause increasing productivity on the  $P$ - $S$  diagram for a one-component system. Geometrically, on the  $P$ - $S$  diagram and in any two-phase region of any phase diagram, we apply the *lever rule* (Fig. 2) to calculate relative proportions of the phases. At any point  $(P, S)$  in the two-phase region the extent of melting  $F$  is given by the ratio of the distance from the entropy of the system,  $S$ , to the entropy at the solidus,  $S_s(P)$ , divided by the length of the tie-line between the entropy of the liquidus,  $S_l(P)$ , and  $S_s(P)$ :

$$F = \frac{[S - S_s(P)]}{[S_l(P) - S_s(P)]} = \frac{1}{\Delta S_{\text{fus}}} [S - S_s(P)]. \quad (4)$$

If we take the partial derivative of Eq. (4) with respect to  $P$  at constant  $S$  and rearrange a little, we obtain an expression for the productivity, which is simplest in the case that  $\Delta S_{\text{fus}}$  is constant:

$$-\left(\frac{\partial F}{\partial P}\right)_S = \frac{1}{\Delta S_{\text{fus}}} \left(\frac{\partial S_s}{\partial P}\right)_{\text{solidus}}, \quad (5)$$

that is, productivity is given by the slope of the solidus divided by the entropy of fusion  $\Delta S_{\text{fus}}$ . To relate this

**FIGURE 2** Graphical illustration of the lever rule. The lever rule is just a statement of conservation of an intensive property in a two-phase system. On the  $(P, S)$  plane, if the system has total specific entropy  $S$  then at equilibrium and at pressure  $P$ , the system will be totally solid ( $F = 0$ ) if  $S < S_s(P)$ , the specific entropy of the solid phase at the solidus. The system will be totally molten ( $F = 1$ ) at  $S > S_l(P)$ , the specific entropy of the liquid phase at the liquidus. If  $S_s(P) < S < S_l(P)$ , however, the system will be partially molten and the mass fraction of liquid  $F$  will be given by the lever rule as shown.

expression to known or measurable quantities requires some thermodynamic identities, but the result is

$$\begin{aligned} -\left(\frac{\partial F}{\partial P}\right)_S &= \frac{1}{\Delta S_{\text{fus}}} \left[ \frac{C_p}{T} \left( \frac{\partial T}{\partial P} \right)_{\text{solidus}} - \frac{\alpha}{\rho} \right] \\ &= \frac{1}{\Delta S_{\text{fus}}} \left[ \frac{C_p}{T} \left( \frac{\Delta V_{\text{fus}}}{\Delta S_{\text{fus}}} \right) - \frac{\alpha}{\rho} \right], \end{aligned} \quad (6)$$

where  $C_p$  is the heat capacity of the system [ $C_p = (1 - F)C_p^s + FC_p^l$ ],  $\alpha$  is its coefficient of thermal expansion, and  $\rho$  is its density. Equation (6) is correct even in the case that  $\Delta S_{\text{fus}}$  is not constant because it is written in terms of the heat capacity, thermal expansivity, and density of the partially molten system rather than the solid phase; the assumption of constant  $\Delta S_{\text{fus}}$  is equivalent to the statements  $C_p^s = C_p^l$  and  $(\alpha'/\rho') = (\alpha'/\rho)$ . How then does productivity evolve during progressive decompression melting of a one-component system? In general,  $\Delta S_{\text{fus}}$  and  $C_p$  are effectively constant while  $\alpha/\rho$  is a very small number. Hence, changes in productivity in this system are dominated by  $T$ , which decreases as we move down the solidus from high pressure to low pressure (the solidus has a positive slope), and  $\Delta V_{\text{fus}}$ , which increases with decreasing pressure because liquids are typically much more compressible than solids (hence the solidus has negative curvature, i.e.,  $(\partial T/\partial P)_{\text{solidus}}$  increases with decreasing pressure). Both of these effects contribute to *increasing productivity* with decreasing pressure or progressive decompression melting from a given intersection with the solidus. For melting of pure diopside ( $\text{CaMgSi}_2\text{O}_6$ ) beginning at 7 GPa, productivity increases from 6%/GPa at 7 GPa to 35%/GPa when it reaches the surface at  $F = 0.9$ .

#### D. Multicomponent Systems

Earth's mantle, of course, is not a pure substance. It contains at least 10 different oxide components in amounts greater than 0.1 wt%. Here we attempt to generalize the simple insights apparent in the one-component example to systems more like the mantle. In systems of more than one component, two or more phases that differ in composition can often coexist anywhere in a region of the  $P$ - $T$  plane, so that the solidus and the liquidus can be distinct in  $P$ - $T$  space and partial melting is to be expected even when temperature is the independent variable. In other words, the isobaric productivity  $(\partial F/\partial T)_P$ , which is infinite for one-component systems, generally has a finite value. The derivation of a productivity equation for multicomponent systems

is more complicated than the one-component example above since it involves conservation of mass as well as conservation of entropy, but the general form of Eq. (6) turns out to be:

$$-\left(\frac{\partial F}{\partial P}\right)_S = \left[ \frac{\frac{C_p}{T} \left( \frac{\partial T}{\partial P} \right)_F - \frac{\alpha}{\rho} + \left( \frac{\partial S_X}{\partial P} \right)_F}{\frac{C_p}{T \left( \frac{\partial F}{\partial T} \right)_P} + \left( \frac{\partial S}{\partial F} \right)_P^{rxn}} \right], \quad (7)$$

which requires a little explanation:  $C_p$ ,  $\alpha$  and  $\rho$  are, as before, the heat capacity, thermal expansivity, and density of the partially molten system, respectively; they depend on the composition of the phases as well as  $P$ ,  $T$ , and  $F$ . Instead of the  $P$ - $T$  slope of the solidus, we have the analogous quantity  $(\partial T/\partial P)_F$ , which is the slope of the constant  $F$  contour calculated locally; away from the solidus, the slope of the solidus itself is not relevant. The isobaric productivity  $(\partial F/\partial T)_P$  appears in the denominator; when this quantity goes to infinity [which implies  $(\partial T/\partial P)_F$  is the same for all  $F$  between 0 and 1 and is therefore equal to  $(\partial T/\partial P)_{\text{solidus}}$ ], we recover the one-component version, Eq. (6). Instead of the entropy of fusion (which is ill-defined for multicomponent systems) we use  $(\partial S/\partial F)_P^{rxn} = S' - S^s + (\partial S_X/\partial F)_P$ , which we call the *isobaric entropy of melt reaction*. The terms  $(\partial S_X/\partial P)_F$  and  $(\partial S_X/\partial F)_P$  involve a subtle point in the entropy budget, but for multicomponent systems they must be included both to obtain an accurate productivity equation and to define precisely the quantity that acts like the entropy of fusion. In a closed system where the coexisting phases differ in composition (e.g., basalt and residual peridotite), moving an increment of mass from solid to liquid necessarily involves changes in the composition of at least one (and generally all) of the phases. Similarly, changing pressure at constant melt fraction involves changes in the equilibrium composition of various phases because phase equilibria and partition coefficients depend on pressure and temperature. In turn, the specific entropies of the phases depend on their composition and the specific entropy of the system depends on which phases the components reside in. Therefore an equation such as Eq. (7) that expresses conservation of mass and conservation of entropy needs to include sums over all components and phases of the partial specific entropy of each component in each phase times the changes in mass fractions of the components and phases per increment of melting at constant pressure,  $(\partial S_X/\partial F)_P$ , and per increment of pressure change at constant melt fraction,  $(\partial S_X/\partial P)_F$ .

With Eq. (7) in hand, we can discuss the variables that determine productivity and how it changes during melting of various simple and natural multicomponent systems. We need to know all the variables in Eq. (7) to calculate the actual value of productivity, but here we focus on variations in productivity during progressive upwelling. As in the one-component case,  $C_p$ ,  $\alpha$ , and  $\rho$  are not important sources of variation. It also turns out that  $(\partial S_x / \partial P)_F$  is small and that, although according to some models  $(\partial S / \partial F)_P^{\text{ext}}$  may vary by nearly a factor of 2 during melting of fertile peridotite, the first term in the denominator is larger in magnitude and dominates the variations in productivity. Also,  $T$  varies systematically, but we find that its influence is generally swamped by the variations in  $(\partial T / \partial P)_F$  and especially  $(\partial F / \partial T)_P$ . To a reasonable approximation then, we can understand the behavior of productivity during isentropic upwelling of multicomponent systems just by considering the behavior of  $(\partial T / \partial P)_F$  and  $(\partial F / \partial T)_P$ . We can state with considerable certainty that except in the vicinity of changes in the solid phase assemblage  $(\partial T / \partial P)_F$  increases with decreasing pressure like the slope of the solidus in the one-component system, simply because silicate liquids are more compressible than minerals. This contributes to increasing productivity with decreasing pressure, just as in the one-component system.

The behavior of  $(\partial F / \partial T)_P$  has been the subject of considerable disagreement among researchers. We present here a simple argument that leads us to expect that  $(\partial F / \partial T)_P$  increases with  $F$  away from the solidus in natural peridotites, but experimental data are equally consistent with nearly constant  $(\partial F / \partial T)_P$  and many authors have constructed models in which  $(\partial F / \partial T)_P$  decreases with  $F$ . Indeed isobaric productivity is sometimes taken as infinite up to some  $F$ , which is the case for univariant melting as in the one-component system; this behavior is sometimes misleadingly called *eutectic*. The idea that melting of peridotite is invariant descends from the behavior simple systems such as CaO-MgO-Al<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub>, which are thought to be suitable analogues of the mantle because these oxides constitute roughly 90% of the mass of mantle rocks. It turns out, however, that minor components and solid solutions dominate the melting behavior at low melt fractions. The simplest model system that captures the effect of a minor component such as Na<sub>2</sub>O on productivity is a binary system with one major component  $Z$  that forms a nearly pure solid phase and one minor component  $Y$  that partitions preferentially into the liquid phase [that is, its partition coefficient  $D_Y \equiv (X_Y^l / X_Y^s)$  is less than one, where  $X_Y^s$  and  $X_Y^l$  are the mole fractions of component  $Y$  in the solid and liquid phases, respectively]. At low concentrations of  $Y$ , the liquidus temperature of such a system is described

approximately by the cryoscopic or freezing point depression relation

$$X_Y^l = k(T_Z^{\text{fus}} - T), \quad (8)$$

where  $T_Z^{\text{fus}}$  is the melting point of pure solid  $Z$  and  $k$  is a constant that depends only on the properties of  $Z$ . To solve for the behavior of  $F$  and  $(\partial F / \partial T)_P$ , we only need the standard equations for the concentration of a trace element in the liquid as a function of  $F$  during batch and fractional melting (*batch melting* is a closed system in which liquid and solid remain in equilibrium; *fractional melting* is a distillation process in which liquid is continuously and instantaneously removed from the system as it forms):

$$X_Y^l = \frac{X_Y^{\text{bulk}}}{F + (1 - F)D_Y} \text{ (batch)} \quad (9)$$

$$X_Y^l = \frac{X_Y^{\text{bulk}}}{D_Y} (1 - F)^{(1/D_Y - 1)} \text{ (fractional).} \quad (10)$$

The phase diagram and isobaric melting relations of this system are shown in Fig. 3. For any given bulk composition, the productivity  $(\partial F / \partial T)_P$  is lowest at the solidus, where the concentration of the incompatible element in the liquid and hence the temperature [these are linearly related per Eq. (8)] is changing most quickly per unit change in  $F$ . At the solidus the productivities of batch and fractional melting are equal, but the productivity of batch melting increases more quickly at low  $F$ . At higher  $F$ , where the concentration of  $Y$  in the liquid during fractional melting becomes nearly constant at zero, the productivity of fractional melting becomes larger than that for batch melting. Furthermore, at equal  $F$ ,  $(\partial F / \partial T)_P$  is *lower* in instances of this system with higher bulk concentrations of the incompatible component  $Y$ , although the opposite is true at equal  $T$ .

The productivity behavior of the systems described by Eq. (8) through (10) is much like that of systems like forsterite-fayalite or diopside-hedenbergite, that is, a nearly ideal solid solution in equilibrium with a liquid solution. Using the solidus and thermodynamic properties of the minerals diopside and hedenbergite, the isentropic melting behavior of such a system can be calculated using Eq. (7) and is compared with the isentropic melting behavior of the diopside-anorthite eutectic binary and with the results of a thermodynamic model of natural peridotite melting in Fig. 4. The eutectic and peridotite systems all show a prominent drop in productivity at the exhaustion of clinopyroxene from the residue, but as long as the residual phase assemblage remains the same, all of these systems show very similar behavior, namely, monotonically increasing productivity as a function of increasing  $F$  or decreasing  $P$ . Figures 4e and

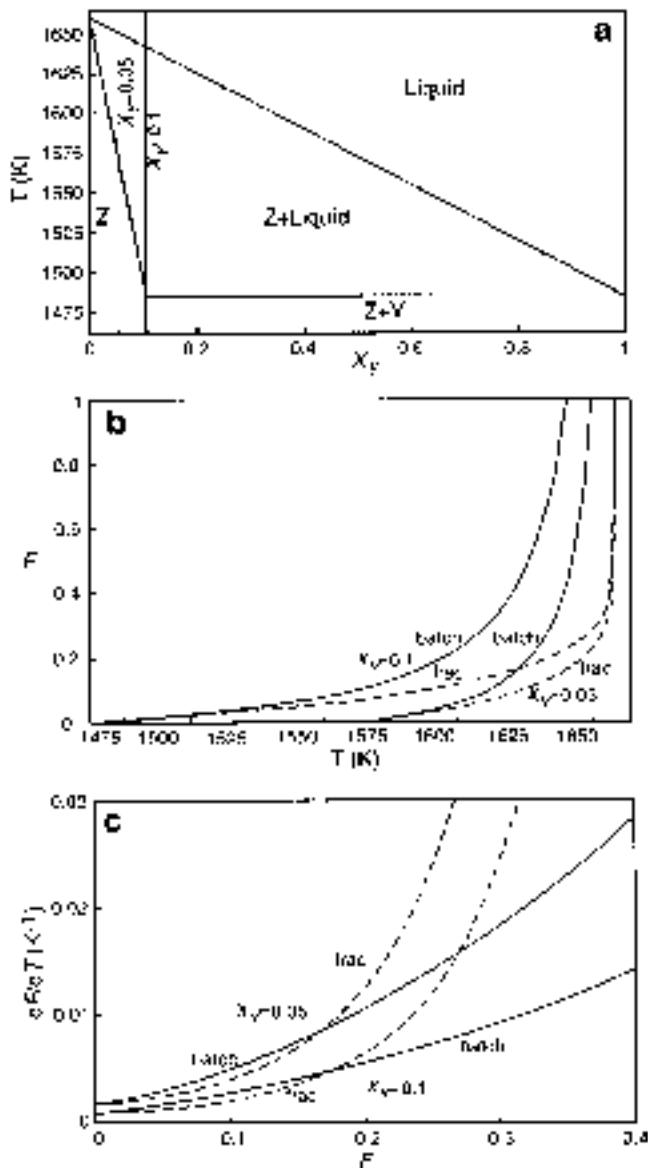

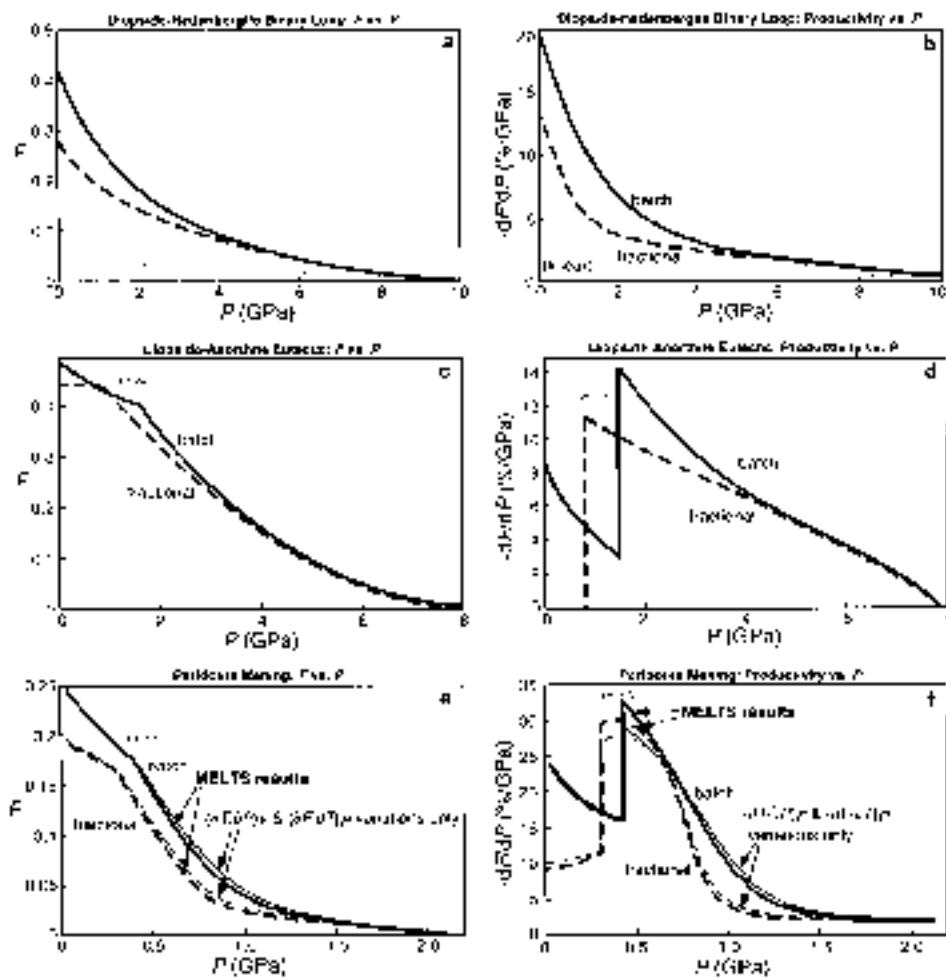

FIGURE 3 Isobaric melting behavior of a simple binary system containing a solid phase  $Z$  in which the component  $Y$  is incompatible. The partition coefficient  $D_Y$  has the constant value 0.1 in this example. (a) A phase diagram in the  $T - X_Y$  plane is divided into a one-phase region where solid  $Z$  exists alone, a one-phase region where liquid solution exists alone, a two-phase region where  $Z$  coexists with liquid 10 times richer in  $Y$ , and a two-phase region where  $Z$  coexists with pure solid  $Y$ . Two bulk compositions are marked by vertical lines. For any bulk composition  $X_Y$  and temperature  $T$  in the two-phase  $Z +$  liquid region, the equilibrium melt fraction  $F$  can be read from this diagram using the lever rule. (b) The isobaric melting behavior of the two bulk compositions marked in part (a), plotted as melt fraction  $F$  versus  $T$ . (c) Isobaric productivity  $(\partial F / \partial T)_P$  versus  $F$  along the melting paths plotted in part (b).

4f show that, for natural peridotite, a calculation of productivity that holds all variables constant except  $(\partial T / \partial P)_P$  and  $(\partial F / \partial T)_P$  provides an adequate approximation to the results of the full thermodynamic calculation of all the variables in Eq. (7).

The results of all of these considerations are that adiabatically upwelling mantle will produce melt with an average productivity of about 10%/GPa, but this average probably conceals variations from as little as 2%/GPa to as much as 30%/GPa. Melting proceeds from the intersection of the adiabat and the solidus up to the base of the lithosphere. Specifically, melting is stopped either by the mechanical lithosphere (which arrests upwelling) or the thermal lithosphere (where conduction cools the system), whichever is thicker. A thick lithosphere, such as we expect at oceanic islands like Hawaii, stops melting without regard to considerations of productivity. Where lithosphere is thin, for example, at a fast-spreading midocean ridge, the large productivity approaching exhaustion of clinopyroxene and the decreased productivity thereafter imply that over a fairly wide range of mantle temperatures, the peak extent of melting will be near that required to exhaust clinopyroxene from the source. This corresponds to observations of many oceanic peridotite samples and to the typical melt fractions inferred from normal midocean ridge basalt. Under most circumstances, the low productivity "tail" at the beginning of melting contributes a small volume of high-pressure melts, often with distinctive chemistry, to the aggregate liquid.

#### IV. MELTING BY CHANGING COMPOSITION

After decompression melting, melting induced by changes in composition is the next most important melting process in the earth. It is mostly responsible for island-arc volcanism, whose often explosive manifestations dominate the rest of this encyclopedia. The origins of arc volcanism are only imperfectly understood; tracing contributions from the subducting slab, subducted sediment, mantle wedge, and overriding plate represents a major area of contemporary research. Still, the basic phenomenon of subduction puts a cold slab into the mantle, generating low temperatures and downward flow. We know from midocean ridges and hot spots that decompression melting requires upward flow and generates more magma given higher temperature. The only reasonable process to induce melting in such a setting is the addition of components such as water that

**FIGURE 4** Isentropic, polybaric melting behavior of three multicomponent systems; bold solid lines are batch melting paths, bold dashed lines are fractional melting paths. (a) and (b) show  $F$  and productivity  $-(\partial F/\partial P)_S$  against  $P$  for a binary system with complete solid-solution (diopside-hedenbergite), plotted for a bulk composition close to the high-temperature endmember diopside (10% hedenbergite, 90% diopside) along an isentrope that intersects the solidus at 10 GPa. The light dotted lines show a hypothetical constant-productivity melting path for comparison. (c) and (d) show the behavior of a binary system with no solid solution and a eutectic point, diopside-anorthite. The particular case shown has a starting composition of 75% anorthite, 25% diopside; while both phases and liquid are present, the system is restricted to the eutectic curve and behaves much like the one-component system. When diopside is exhausted from the residue, there is a large drop in productivity of batch melting and a total cessation of fractional melting. (e) and (f) show a thermodynamic model of natural peridotite melting that combines aspects of the behavior of both of the preceding systems. Within regions where the residual phase assemblage does not change, productivity increases during progressive melting. The thin curves show an approximate calculation in which all variables are held constant except  $(\partial T/\partial P)_F$  and  $(\partial F/\partial T)_P$  (see text); this approximation captures most of the productivity variations in this system. As in the binary case, there is a large drop at the exhaustion of clinopyroxene from the residue, but it does not stop melting altogether, even for the fractional case.

drastically lower the solidus temperature of peridotite. That the magmas produced and erupted at arc volcanoes contain abundant water is evident from their explosive behavior.

We can use the binary system illustrated in Fig. 3, with some caution, to discuss the effect of addition of water to peridotite. Like any component that preferen-

tially partitions into silicate melts rather than solids, it expands the stability field of liquid and lowers the solidus temperature. Hence, a water-bearing system can be partially molten at temperatures where the dry system would be entirely solid. The amount of melt produced is a function of the amount of water added as well as temperature. At temperatures below the dry solidus, the

amount of melt is small and is limited by the amount of water present and ultimately by the solubility of water in the melt under appropriate conditions. The binary system of Fig. 3 approximates this behavior at temperatures well below the dry solidus, but it is quite misleading as we approach the dry solidus temperature, since it implies that even for a small amount of water the melt fraction increases to unity at the dry solidus temperature. This results from using a one-component system where liquidus and solidus are equal for the water-free part of the model system. For peridotite plus a small amount of water, it is evident that the melt fraction does not approach 1 until nearly the dry *liquidus* temperature, since with a large quantity of melt present the concentration of water in the melt becomes quite dilute and the liquidus depression correspondingly small.

The fundamental problem for models of melting at arc volcanoes is the large volume of magmas produced. It is not clear that the water flux from the subducted slab is sufficient to explain the flux of melt from the mantle wedge by simple water-induced melting at temperatures well below the dry solidus. An alternative is that addition of water induces a small amount of melting and a large drop in viscosity that allows buoyancy-driven diapirism to begin. Rising blobs will undergo additional melting due to decompression as described earlier. In this way, a small amount of water may nucleate processes that lead to a large amount of melting.

---

## V. MELTING BY TEMPERATURE INCREASE

Several distinct mechanisms can directly increase the temperature of a rock mass so as to induce melting. None is volumetrically significant on today's Earth, but each may have been important at some time in Earth's history or on other planets.

### A. Impact Melting

Impacts of extraterrestrial objects large enough to induce substantial amounts of melting are rare at present. When earth was forming, however, it was constantly being bombarded by large objects, including possibly a few impacts large enough to melt the entire mantle and induce a magma ocean. We can easily calculate the amount of energy carried by the impact of an object of given mass and hence to place some bounds on the amount of melting that may occur. In detail, though,

large impacts are complex and only imperfectly understood and the efficiency of melt production is difficult to calculate with any precision.

For concreteness, let us consider impacts on Earth after the time when it had essentially achieved its modern mass ( $M_{\oplus} = 6 \times 10^{24}$  kg) and radius ( $R_{\oplus} = 6371$  km). The minimum kinetic energy per unit mass of an incoming object is equal to the gravitational potential at the Earth's surface relative to infinite separation,  $GM_{\oplus}/2R_{\oplus} = 3.14 \times 10^4$  kJ/kg, corresponding to a minimum velocity  $\sqrt{2GM_{\oplus}/R_{\oplus}} = 11.2$  km/s. The enthalpy of fusion of the Earth's mantle is about 750 kJ/kg. Hence if all the kinetic energy of the impact went into melting (requiring the target to start at the melting point, and totally unphysical compression behavior) an impactor can melt at most itself plus 40 times its own mass of the target planet. The impact of a Mars-sized planetesimal with  $\sim 10\%$  the mass of the Earth (such as the event which is thought to have created the Moon) seems likely to result in complete melting of the mantle.

In practice, hypersonic collisions heat and compress the target material along an irreversible thermodynamic path and accelerate much of the target material out of the crater. Thus, much of the impact energy goes into dissipation and kinetic energy. For large cratering events, the work against gravity involved in excavating the crater and lofting the ejecta consumes more of the impact energy. Also the target is generally well below the melting point and so much of the energy goes into heating without inducing melting. Furthermore, the energy of impact ends up very unevenly distributed in the target. Closest to the impact, materials will receive so much energy as to be vaporized, which consumes a great deal of energy and leaves less available to melt rocks that see lower shock pressures.

When large craters on Earth are examined, there typically is a thin (a few meters) sheet of impact melt lining the crater and underlying the ballistic ejecta blanket. Likewise, roughly 1% of the lunar soil consists of glass droplets that presumably originated as molten ejecta from nearby craters. These observations demonstrate that impacts do produce some melt, but at the same time support the argument that impact is an inefficient process for generating magma. On Venus, radar observations taken by the *Magellan* spacecraft reveal evidently fluid outpourings from large impacts, but it is not at all clear whether these flows consist of impact melt or fluidized debris. Finally, although the largest impact basins on the Moon are filled with voluminous floods of Mare basalt, this volcanism was not a direct product of the impact but a later process that preferentially filled the topographic depressions of the impact basins with basaltic magma denser than the lunar crust.

## B. Radioactive Heat Generation

Natural radioactive heat sources are too weak at the present day to bring any rock mass to its melting point or power its melting. Furthermore, the Earth almost certainly began very hot, not because of radioactivity, but rather from the release of gravitational potential energy involved in assembling a planet (unless it accreted so slowly that radiation to space maintained a cool starting Earth, but this scenario is not favored by dynamic models or radiometric studies of accretion). Nevertheless, radioactivity bears mention as a source of heat for melting for two reasons. First, it has certainly contributed to keeping the Earth hot and volcanically active for longer than would have been possible with only the heat of accretion. Second, in the very early solar system it was the principal source of heat for the melting of small planetesimals that formed the igneous meteorites.

The principal heat-producing isotopes at present are  $^{40}\text{K}$ ,  $^{235}\text{U}$ ,  $^{238}\text{U}$ , and  $^{232}\text{Th}$ . In material of bulk-Earth composition these presently contribute a total of  $\sim 1.5 \times 10^{-4} \text{ J/kg/year}$  in radiogenic heat. These elements are all strongly partitioned into liquids during melting, however, and so are highly concentrated in the continental crust. Average continental crust generates about 100 times more radiogenic heat than bulk-Earth material. While the excess heat flow from the continental crust is clearly measurable, it is still insufficient to heat crust of normal thickness to its melting point or provide the latent heat of fusion on reasonable timescales. Only in the very early solar system, when the heat flux from K, U, and Th was  $\sim 5$  times higher but more importantly short-lived radionuclides such as  $^{26}\text{Al}$  and  $^{129}\text{I}$  were active, could radioactivity by itself heat an asteroid-sized body enough to cause differentiation (melting and core formation).

## C. Heating by Conduction

In continental regions, away from plate boundaries and hot spots, volcanoes do occur that require a mechanism other than decompression melting. Their source materials are embedded in the lithosphere, which, aside from rapid and large-scale tectonic extension, prevents drops in pressure fast enough to overwhelm thermal conduction. Conduction therefore is the most likely mechanism for bringing these sources into their melting range by direct heating. This begs the question of why conduction should deliver more heat in one place than another, and the answer generally goes back to decompression melting in the underlying mantle. Geochemical and geophysical evidence typically shows that, although the

principal source of intraplate volcanism lies within the crust, there is often a mantle component. Ponding of basaltic magma and subsequent underplating of basaltic rocks at the base of the crust is the most efficient way to focus a large heat flow into a specific region of the crust. Because basalts crystallize at temperatures above  $1000^\circ\text{C}$  and the rocks of the continental crust can begin melting (in the presence of water) near  $700^\circ\text{C}$ , it is clear that crustal melting is a likely consequence of the arrival of a large mass of basalt at the base of the crust.

## D. Frictional Heating and Viscous Dissipation

Neither of these mechanisms is likely to generate a sufficient mass of magma to migrate to the surface and form a volcano. Exhumed fault zones do sometimes contain a narrow zone of glassy rock called pseudotachylite that appears to represent melt produced by frictional heating, and this process has recently been invoked to explain the faulting mechanism of some very large deep-focus earthquakes. Furthermore, exposed low-angle normal faults and metamorphic core complexes are spatially associated with syntectonic plutonism and some volcanism, but the mechanisms more likely include decompression by isostatic rebound of the footwall and melting of the hanging wall by direct juxtaposition against a hot footwall.

---

## VI. THE MANTLE ADIABAT

In the preceding discussion of decompression melting, we noted that decompression is likely to cause mantle rocks to intersect their solidus and begin melting. Very cold mantle, however, could reach atmospheric pressure without intersecting its solidus, and very hot mantle might be partially molten all the way to the core–mantle boundary. The Earth’s mantle happens to be in between these two states such that its typical adiabat intersects the solidus in the range of 50 to at most a few hundred kilometers (Fig. 5). This depth range corresponds to a temperature range (measured at equal depth below the solidus) of  $200$ – $300^\circ\text{C}$  sampled along midocean ridges, ranging from the deepest, thinnest crust ridge segments up to ridge-centered hot spots such as Iceland. Away from ridges, it is more difficult to map the temperature variation in the mantle because the depth of melting is not generally available as a probe. Instead, we rely on models of thermal convection and on other indirect

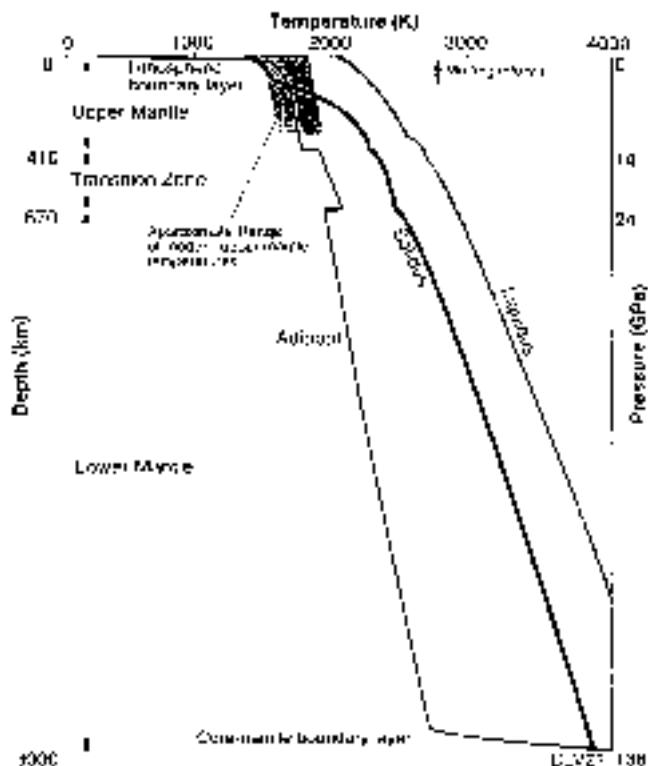

FIGURE 5 Schematic illustration of the temperature structure of the Earth's mantle at the present era. The mantle is conventionally divided into upper mantle, transition zone, and lower mantle, with the boundaries set at the 410- and 670-km seismic discontinuities. The solidus (heavy black curve) and liquidus (heavy shaded curve) are inferred from melting experiments on probable mantle compositions; these curves bracket the range where partial melting can occur. A probable typical temperature structure of the mantle is shown assuming whole-mantle convection with a cold upper boundary layer (the lithosphere) and a hot lower boundary layer where heat is conducted out of the core. In between these boundary layers the temperature profile is adiabatic (see text and glossary). The shaded band shows the likely global range of temperatures of oceanic upper mantle; anywhere the adiabatic part of any of these geotherms extends to shallow pressure, melting will occur. Except possibly for the recently discovered ultra-low-velocity zone (ULVZ) at the core–mantle boundary, melting is restricted to the upper 100 or 200 km of the mantle.

indicators of temperature such as seismic velocity, seafloor depth, and gravity. All of these lines of evidence are broadly consistent with a mantle that contains a very cold upper thermal boundary layer that is subducted into the interior at trenches as well as hot thermal plumes rising from a lower boundary layer that transport ~10% of total heat flow through the upper mantle. The magnitude and origin of temperature variations away from slabs and plumes remain controversial.

Considering that the mantle is 2900 km deep, the depths at which mantle adiabats intersect the solidus are remarkably close to the surface. It is legitimate to inquire whether this is a coincidence or the result of some regulating mechanism, and hence whether this depth range is particular to the present era and steadily declining or else maintained at a quasi-steady value over long periods of geologic history. Because the viscosity of rocks is exponentially dependent on inverse temperature, it is clear that the temperature of a convecting system such as the mantle does regulate itself so that it can flow fast enough to deliver to the surface all the heat that enters the bottom and is produced internally. There is, however, no necessary relationship between the temperature that provides sufficiently low viscosity for mantle convection and the temperature at which melting occurs. Standard plate tectonic theory assigns no particular role to basaltic volcanism in the heat engine of convection; the mantle cools itself primarily by forming and subducting oceanic lithosphere (not crust). One may speculate, however, that the mantle adiabat dwells in the range where basaltic volcanism occurs because basaltic volcanism is somehow a necessary part of the plate tectonic cycle. Perhaps the formation of basalt, which converts to the very dense rock eclogite when subducted, is necessary to sustain subduction. If so, it seems likely that the mantle temperature will remain high enough to support ocean ridge volcanism until its heat flow is low enough to be transported by a qualitatively different and less efficient mechanism than plate tectonics. This remains a question for future work.

## VII. SUMMARY

Decompression melting occurs anywhere that upward flow of mantle reaches shallow depths. Such upward flow occurs at midocean ridges due to plate spreading and at hot spots due to thermal plumes in the mantle. Melting begins at the intersection of the adiabat with the solidus curve of the mantle source composition. Melting proceeds at an increasing productivity with an average value near 10%/GPa until the base of the lithosphere stops upwelling or cools the system off the adiabat. The addition of components such as water that substantially lower the solidus temperature of mantle rocks induces melting above subducting slabs in spite of low temperatures and downward flow. Occasional small volumes of magma may be produced by other means such as conductive heating by underlying magma intrusions, but decompression and fluxing are the domi-

nant sources of the magmatic liquids that supply the world's volcanoes.

### GLOSSARY

**compaction** A process in which the solid matrix deforms to expel intergranular melt. Compaction processes could include granular flow or rearrangement of matrix grains without any distortion of individual grains, or changes in grain shape as a result of intracrystalline plasticity or diffusive transfer processes.

**compaction length** The distance over which the compaction rate in a column of partially molten rock decreases by a factor of  $e$ . The compaction length,  $\delta_c$ , is the characteristic length scale in gravity-driven compaction models of melt migration. This distance is a function of the viscosity and permeability of the matrix and the viscosity of the melt migrating through the matrix.

**dihedral angle** Measured at triple junctions where two grains and melt meet; it is the angle at which the two grains intersect. The value of the dihedral angle is a function of the ratio of the solid–solid interfacial energy to the solid–melt interfacial energy. Dihedral angles

lower than  $60^\circ$  imply an interconnected melt network is present at all melt fractions.

**permeability** A measure of how easily fluid flows through a porous medium. Ease of flow is a function of the size, shape, and connectivity of the porosity network.

**viscosity** A measure of the resistance of a material to flow in response to stress.

**M**AGMA ERUPTED ON the Earth's surface is generated by partial melting of rocks at depth. How does this melt separate from the residual solid and migrate to its eruption location? Recent models of physical processes, combined with constraints imposed by the chemical and isotopic compositions of erupted lavas and magmas, suggest that melt migration in the Earth's interior occurs by porous flow along grain-size channels and by flow through larger conduits.

---

### I. POROUS FLOW MODEL OF MELT MIGRATION

Because melting of rocks results in a distribution of melt throughout the rock, the separation of melt from the

residual solid requires that melt flow for at least some distance through a connected network of grain-size channels. This type of flow is referred to as *two-phase* or *porous flow*; the partially molten region is regarded as a porous medium. As such, the flow of melt can be described by Darcy's law:

$$v = K/\mu dP/dx, \quad (1)$$

where  $v$  is the flux of melt (i.e., the volume of melt per unit time passing a unit cross-sectional area perpendicular to the flow direction),  $K$  is the permeability,  $\mu$  is the viscosity of the fluid, and  $dP/dx$  is the pressure gradient that drives melt flow. The driving force for melt migration can be chemical and/or physical in nature. Chemical driving forces can be related to differences in interfacial energies; physical forces can be related to the buoyancy of melt relative to residual solids or to applied nonhydrostatic stress. All three of these types of driving forces have been exploited in laboratory studies of melt migration.

The permeability  $K$  is a measure of how easily melt flows through the partially molten rock. Ease of flow, as measured by permeability, is a function of the size, shape, and connectivity of the network of porosity or melt channels. Because the permeability of partially molten rocks is difficult to measure directly, permeability is usually calculated using an expression such as:

$$K = a^2 \varphi^n / b, \quad (2)$$

where  $a$  is the grain size,  $\varphi$  is the melt fraction,  $n$  is usually assumed to be 2 or 3, and  $b$  is a geometric constant of the order 1000. Basically, as grain size and melt fraction increase, permeability increases because the size of melt channels becomes larger. The larger the melt channel, the easier it is for melt to flow. Channel shape and connectivity can also affect permeability; these characteristics are taken into account in the geometric constant  $b$  as well as the melt fraction dependence  $n$ .

Darcy's law is applicable as long as the total amount of melt in the system remains constant. If the amount of melt entering the system is different from the amount leaving the system, then Darcy's law must be modified to take this fact into account. Gains in melt volume, perhaps due to increases in melting rate relative to melt extraction rate, result in either increases in rock volume or increases in the melt pressure. Ramifications of high melt or pore pressure will be discussed in a later section. Reduction of the total amount of melt, perhaps due to rapid melt extraction relative to the melt production rate, implies that the solid matrix must deform to accommodate the change in fluid volume. The reduction in

pore volume requires that the matrix compact. Compaction processes could include granular flow or rearrangement of matrix grains without any distortion of individual grains, or changes in grain shape as a result of intracrystalline plasticity or diffusive transfer processes. Compaction means that the mechanical properties of the matrix must be considered when determining the melt flux.

Gravity-driven compaction models of melt migration have dominated theoretical work on the problem of melt extraction for the last 20 years. In these models a column of partially molten rock with an underlying impermeable base compacts due to density differences between melt and solid. Figure 1 shows the stages of this compaction process. At the base of the column, melt volume decreases as the matrix compacts. Above this compacting layer, the upward flux of melt from the compaction zone maintains the melt volume. At the top of the column, melt accumulates, forming a melt-rich layer. Essentially, the extraction of melt due to buoyancy is resisted by the strength of the matrix and the viscosity of the melt.

The thickness of the compacting zone depends on the properties of both the matrix and melt; the matrix can compact only if melt is removed and melt will be expelled only if the matrix compacts. Compaction occurs most rapidly at the base of the column; the rate of compaction decreases exponentially with distance from the base. The distance over which the compaction rate decreases by a factor of  $e$  is the characteristic length scale

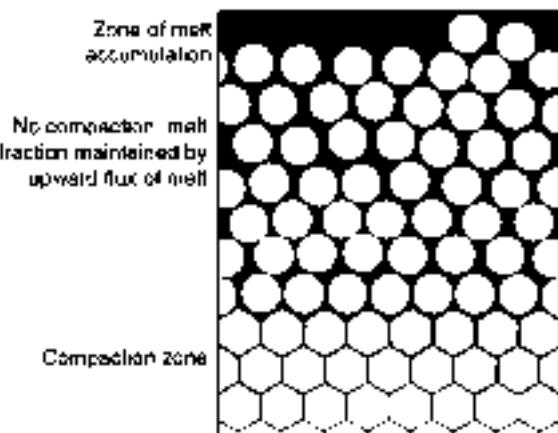

FIGURE 1 Illustration showing the stages of compaction that result from gravity-driven melt migration. At the base of the column, melt volume decreases as the matrix compacts. Above the compacting zone is a layer in which melt fraction does not change. At the top of the column, melt accumulates.

of the compaction process. Known as the compaction length,  $\delta_c$ , this length scale is:

$$\delta_c = [K(\lambda + 4\eta/3)/\mu]^{1/2}, \quad (3)$$

where  $\lambda$  and  $\eta$  are the effective bulk and shear viscosities, respectively, of the partially molten rock. The expression within the parentheses ( $\lambda + 4\eta/3$ ) describes how the partially molten rock deforms in response to the applied pressure gradient. In this model both the melt and the matrix are assumed to be linearly viscous. That is, the flow of matrix and melt depends linearly on the applied stress. A characteristic timescale for this process is given by  $\tau_0$ , which is the time required to reduce the melt fraction by a factor  $e$  at the base of the compacting layer:

$$\tau_0 = \delta_c/[w_0(1 - \varphi)]. \quad (4)$$

In this equation,  $w_0$  is the relative velocity between the melt and matrix in the interior layer where no compaction is occurring. If melt migration is driven by density contrasts only, then:

$$w_0 = K(1 - \varphi)(\rho_s - \rho_f)g/\mu\varphi, \quad (5)$$

where  $(\rho_s - \rho_f)$  is the density contrast between solid and melt.

Another way to compare characteristic extraction times is to calculate the time,  $t_b$ , to reduce the porosity of a layer of thickness  $b$ , by a factor of  $e$ :

$$t_b = \tau_0(b/\delta_c + \delta_c/b). \quad (6)$$

If the thickness of the layer  $b$  is much greater than the compaction length, then:

$$t_b = \tau_0 b/\delta_c = b/[w_0(1 - \varphi)]. \quad (7)$$

In essence, this means that if the total thickness of the partially molten region is much greater than the compaction length, the time to reduce the melt volume by a factor of  $e$  is independent of the viscosity of the matrix.

These equations suggest that the important physical parameters in the two-phase flow model of melt migration are melt viscosity,  $\mu$ , permeability,  $K$ , and, depending on ratio of compaction length to layer thickness, the mechanical properties of the matrix, ( $\lambda + 4\eta/3$ ). Substituting the values of the physical parameters into these equations allows one to calculate characteristic times and distances over which melt migration via porous flow occurs, allowing one to evaluate the likelihood of sufficiently rapid or volumetrically significant melt extraction occurring in a particular geologic environment by this process.

The next three sections of this chapter focus on our current understanding of the physical factors (i.e., melt viscosity, permeability, and matrix mechanical properties) that affect rates of melt migration in both the crust and mantle. Although it is likely that the behavior of a layer containing an initially constant melt fraction is much simpler than that of any real geologic problem, examining the effects of physical parameters using this one-dimensional model can provide a great deal of insight into the melt extraction process. The solutions to more complicated models show that various instabilities can develop during melt migration by porous flow. These instabilities may allow melt to be extracted into melt channels that are larger than those present along individual grains, allowing for much more rapid melt migration. These and other flow focusing mechanisms of melt extraction are discussed in the later portion of this chapter.

## II. MELT VISCOSITY

The rate of melt migration depends on the viscosity of the melt that is percolating through the rock. Melt viscosity can vary by more than a factor of  $10^{14}$  depending on the composition of the melt. For example, a dry rhyolitic melt at  $700^\circ\text{C}$  has a calculated viscosity on the order of  $5 \times 10^{11} \text{ Pa s}$ , whereas a carbonatite melt has a viscosity of less than  $5 \times 10^{-3} \text{ Pa s}$ . These differences translate into large variations in compaction length, separation velocity, and compaction time. These characteristic length, velocity, and timescales were calculated using Eqs (3)–(7) and are listed in Table I for melts with different viscosities. These values were calculated assuming the same melt fraction (0.1), grain size (1 mm), matrix viscosity ( $10^{18} \text{ Pa s}$ ), permeability ( $K = 1 \times 10^{-12} \text{ m}^2$ ), and driving force ( $\rho_s - \rho_f = 0.5 \times 10^3 \text{ kg m}^{-3}$ ). Hence, the differences listed in Table I are only the result of variations in melt viscosity.

Mantle melts of basaltic or picritic composition have viscosities of  $\sim 1 \text{ Pa s}$ . These melts separate rather easily from the residual solid matrix. If the average melt fraction produced beneath a midocean ridge is 0.1, then the compaction length is  $\sim 1 \text{ km}$ , assuming that the average grain size of mantle rocks is 1 mm. If the partially molten region extends vertically for roughly 50 km,  $b/\delta_c$  is  $\sim 50$ . From Table I,  $\tau_0$  is  $\sim 800 \text{ yr}$ , implying that  $t_b$ , or the time to reduce the melt fraction by a factor of  $e$ , is  $\sim 40,000 \text{ yr}$ . Since this time is about 1000 times less than the cooling time for a lithospheric plate, melt extraction

TABLE I Characteristic Compaction Length, Separation Velocity, and Compaction Time for Melts with Different Viscosities

Melt composition	Melt viscosity (Pa s)	Compaction length $\sigma_c$	Separation velocity (m/yr)	Compaction time $\tau_0$ (yr)
Dry rhyolite	$5 \times 10^{11}$	1.4 mm	$2.8 \times 10^{-12}$	$5.5 \times 10^8$
Wet granite	$5 \times 10^4$	4.5 m	$2.8 \times 10^{-5}$	$1.8 \times 10^5$
Basalt	1	1 km	1.42	$8 \times 10^2$
Carbonatite	$5 \times 10^{-3}$	14 km	280	56

beneath the ridge should be rapid enough to keep the melt fraction well below 0.1 at any given time. Geophysical data support this conclusion. Although shear wave velocities beneath midocean ridges are anomalously slow, a melt fraction of less than 0.03 can account for these anomalies as long as the melt is present as an interconnected network. Reducing the thickness of the partially molten layer to 100 m, however, changes the efficacy of melt extraction as  $b/\delta_c$  is reduced to 0.1. The time for significant melt extraction  $t_h$  then becomes  $\sim 8000$  yr; comparison of this time with the time required for cooling a 100-m-thick partially molten region suggests that not much compaction or melt segregation would occur before the melt crystallized due to cooling.

Crustal melts with characteristically high viscosities take much longer to separate from their solid residuum than more fluid mantle-type melts. Consider a 1-km-thick layer of partially molten crustal rocks with a grain size of 1 mm. If 10% of the layer is melted to form a dry rhyolitic melt, how long will it take for most of the melt to separate by gravity driven grain-scale flow? From Table I, the compaction length is  $\sim 1$  mm, so  $b/\delta_c$  is  $\sim 1 \times 10^6$ . The value of  $\tau_0$  is  $\sim 10^8$  yr, implying that  $t_h$ , or the time to reduce the melt fraction by a factor of  $e$ , is  $\sim 10^{14}$  yr. In other words, insignificant volumes of melt would segregate over the whole of geologic time.

Reducing the viscosity of the melt by adding water, however, does make gravity-driven segregation in crustal environments somewhat more feasible. If the same 1-km-thick layer of partially molten crust now contains 10% of wet granitic melt, the compaction length is increased to about 5 m with  $b/\delta_c$  decreased to  $\sim 10^2$ ;  $\tau_0$  is also reduced to  $\sim 10^5$  yr, implying that  $t_h$ , or the time to reduce the melt fraction by a factor of  $e$ , is  $\sim 10^7$  yr.

Even this timescale is problematic for efficient segregation of melt in crustal environments by gravity-driven compaction alone. Separation of melt will be more rapid than that described here if the permeability of the resid-

ual solid is higher than that assumed above; increasing the grain size of the matrix by a factor of 10 to 1 cm would increase the permeability by a factor of 100. This change would decrease the time required for significant melt extraction by a factor of 10. Separation of high-silica melts may also require that the driving force for melt extraction be related to pressure gradients in excess of those induced by density contrasts between melt and solid. Nonhydrostatic stress resulting from tectonic activity or due to contrasts in matrix strength with composition are discussed in a later section.

### III. PERMEABILITY

Permeability is a measure of how easily fluid flows through a porous media. From Darcy's law it is clear that melt flux scales directly with permeability. So, if permeability increases by a factor of 10, melt flux will increase by a factor of 10. Table II shows the values of the characteristic length, velocity, and compaction time as a function of permeability. These values were calculated using Eqs. (3)–(7), assuming the same melt fraction (0.1), matrix viscosity ( $10^{18}$  Pa s), melt viscosity (1 Pa s), and driving force ( $\rho_s - \rho_f = 0.5 \times 10^3$  kg m $^{-3}$ ). Hence, the differences listed in Table II are only the result of variations in permeability. Clearly, the permeability of the partially molten rock can have a huge effect on the rates of melt extraction.

At the Earth's surface the permeability of rocks to the flow of water and other low-temperature fluids can be directly measured. At depth or in rocks at their melting temperature, these direct measurements are difficult to impossible to make. As a result, the permeability of partially molten rocks is constrained using observations about the geometry of melt networks present in the rock or through laboratory experiments.

TABLE II Characteristic Compaction Length, Separation Velocity, and Compaction Times for Different Matrix Permeabilities

Permeability $K$ ( $m^2$ )	Compaction length $\delta_c$ (m)	Separation velocity $w_0$ (m/yr)	Compaction time $\tau_0$ (yr)	Time for significant melt extraction in a 50-km-thick layer $t_h$ (yr)
$10^{-10}$	$10^4$	6	$2 \times 10^3$	$10^4$
$10^{-12}$	$10^3$	$6 \times 10^{-2}$	$2 \times 10^4$	$10^6$
$10^{-14}$	$10^2$	$6 \times 10^{-4}$	$2 \times 10^5$	$10^8$
$10^{-16}$	10	$6 \times 10^{-6}$	$2 \times 10^6$	$10^{10}$
$10^{-18}$	1	$6 \times 10^{-8}$	$2 \times 10^7$	$10^{12}$

Textural observations of melt networks can be made on both rock analogues synthesized in a laboratory or on natural rocks. Observations made on natural samples are often difficult to interpret because the original geometry of the melt phase may be obscured by the effects of crystallization or other subsequent processes. Estimates of permeability using textural observations are also complicated by the fact that most observations are made on planar sections; this means that determining permeability first requires one to put two-dimensional features together into a three-dimensional network geometry, then deduce what that complicated three-dimensional topology means about the permeability of the rock. Uncertainties can creep in at either stage of this process. Laboratory measurements of permeability are hampered by experimental difficulties and by uncertainties related to interpretation of the results.

### A. Models of Permeability

Permeability models can be used to estimate the permeability of partially molten rock. In these models, melt flow is generally assumed to be steady and nonturbulent, with a parabolic velocity structure across the melt channel. This assumption of Poiseuille flow means that simple relationships can be derived between permeability and melt fraction or porosity if the melt channel geometry is not very complex. For example, the permeability relationships used in most two-phase flow models assume that melt flows either through parallel cracks ( $K \propto \varphi^3$ ) or through cylindrical tubules ( $K \propto \varphi^2$ ). Although these relationships can be useful as first-order approximations and have been used very extensively, observations of partially molten rocks indicate that melt networks are more complex than these simple relationships suggest.

More accurate approximations of permeability are derived using one of two approaches. In the first approach, the rock is approximated by an equivalent porous medium or an idealized representation of the melt network in order to derive analytic solutions for permeability as a function of measurable physical characteristics of the rock. Examples of these measurable characteristics include melt fraction, pore shape and size, and the tortuosity of the melt network. Tortuosity is the ratio of the length of the actual path to the length of the apparent path (Fig. 2). Essentially, the partially molten rock is presumed to be equivalent to a channel with a highly complex cross section of constant area. Permeability in these models is often defined by the Kozeny-Carman equation:

$$K = \frac{\varphi^3}{[bT^2S^2(1 - \varphi)^2]}, \quad (8)$$

where  $b$  is a constant,  $T$  is the tortuosity, and  $S$  is the surface area of pores per unit volume of solid. Although this approach has been applied with some success to the

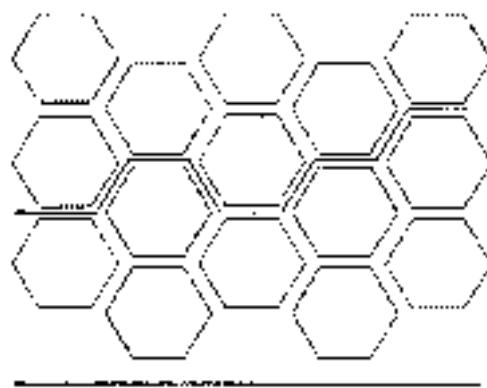

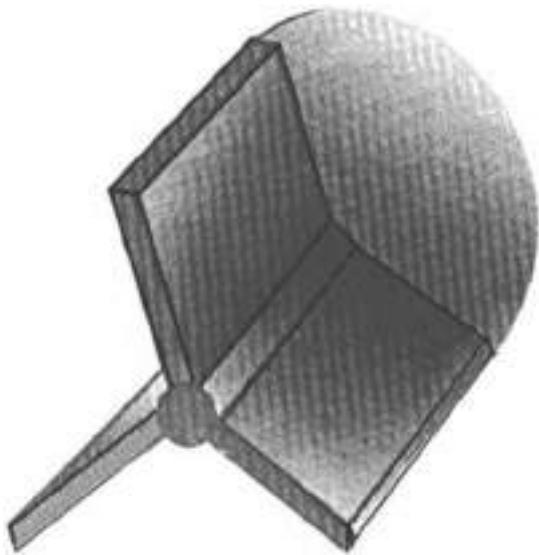

FIGURE 2 Tortuosity is the ratio of the actual flow path (the zigzag line) to the shortest flow distance (straight line). Very complex flow paths have high tortuosity.

**FIGURE 3** A typical model of a melt network used in permeability models. Spherical pores are connected to one another through tubes and sheetlike channels.

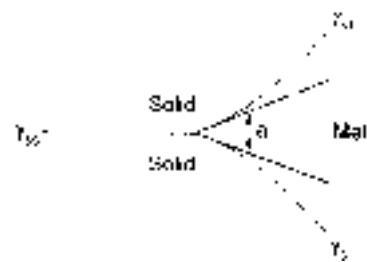

flow of low-temperature fluids in sandstone, it has at least two drawbacks. First, both  $S$ , the melt–solid interfacial area, and  $T$ , the tortuosity, are difficult to measure accurately in partially molten rocks. This difficulty is partly due to the fact that both require detailed knowledge of the three-dimensional structure of the melt network, knowledge that has been difficult to obtain using conventional microscopy of planar sections. Three-dimensional reconstructions of the melt network using such techniques as serial polishing or confocal microscopy combined with image analysis could result in more accurate measurements of these properties. Second, the model assumes that the flow network is homogeneous, implying that the network has no dead-ends or preferred flow paths. Because melt channels in partially molten rocks are typically quite heterogeneous in terms of shape and size, the equivalent channel or medium approach may not accurately predict permeability.

A second approach to estimating or measuring permeability uses numerical simulations of flow in networks that approximate those found in natural materials. The melt network in some of these models consists of a collection of tubes, penny-shaped or sheetlike channels, and spherical pores of different sizes (Fig. 3). These individual porosity elements are distributed on a grid; equant pores are connected by tubes or sheetlike channels. The permeability is controlled by the size and connectivity of the channels; the pores contribute to the storage capacity of network. By changing the relative

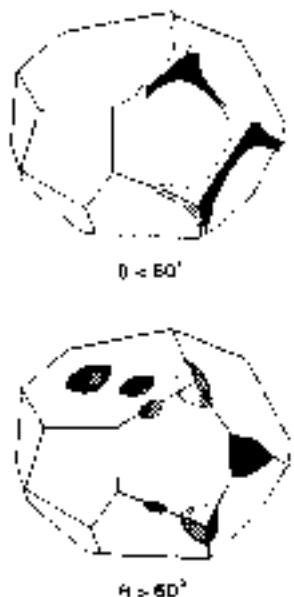

proportion, distribution, and connectivity of these elements, the permeability of different melt networks and melt fractions can be determined. For example, a melt network that has spherical pores connected by penny-shaped or sheetlike channels will have lower permeability than a network with the same pores connected by cylindrical tubes.

#### B. Geometry of Melt Networks in Partially Molten Rocks

Application of these permeability models to partially molten rocks requires a detailed knowledge of the melt network geometry. The initial melting of a rock occurs at the junctions of grains taking part in the reaction. Once melt is present, the melt–rock system adjusts to minimize its total energy. The energy of the system is reduced by minimizing the area of high-energy interfaces and by changing the shapes of interfaces to reduce chemical potential gradients. This energy reduction results in the redistribution of melt, with melt wetting grains if melt–crystal interfaces are of lower energy than crystal–crystal boundaries or melt pooling if the opposite is true. This equilibrium grain-scale distribution of melt in partially molten rock can be characterized by the dihedral angle. The dihedral angle is measured at triple junctions where two grains and the melt meet; it is the angle at which the two grains intersect (Fig. 4). In an ideal rock, composed of identical grains with no variation of surface energies with crystal orientation, dihedral angles less than  $60^\circ$  imply that the melt network is composed of completely connected triangular-shaped tubules along three-grain junctions, whereas dihedral angles greater than  $60^\circ$  imply that at low melt fractions melt is isolated in more spherically shaped pockets at four-grain corners (Fig. 5). In rocks with dihedral angles

**FIGURE 4** The dihedral angle is the angle at which the two grains intersect with melt. The value of the dihedral angle is a function of the ratio of the solid–solid interfacial energy ( $\gamma_{ss}$ ) to the solid–melt interfacial energy ( $\gamma_{si}$ ).

**FIGURE 5** Idealized melt networks in partially molten rocks with dihedral angles. (A)  $<60^\circ$  and (B)  $>60^\circ$ . For dihedral angles  $<60^\circ$  melt forms an interconnected network along three- and four-grain junctions. For dihedral angles  $>60^\circ$ , melt is isolated at four-grain junctions or along some grain boundaries. (Adapted from Wark and Watson, 1998, with permission from Elsevier Science).

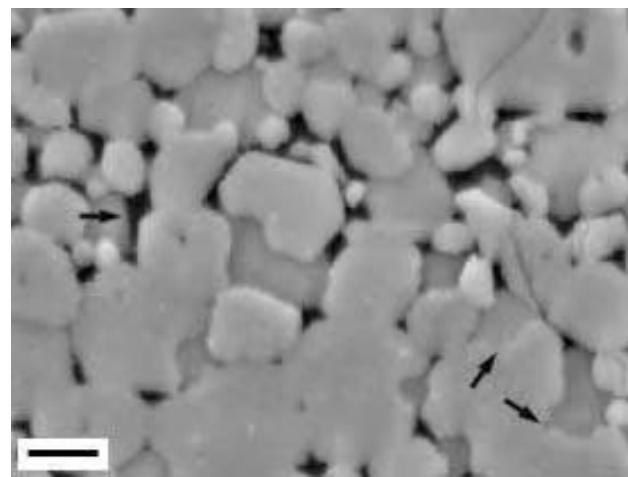

in the range of 1–40°, permeability should follow the relationship for flow in tubes, that is,  $K \propto \varphi^2$ . In this ideal rock, boundaries between two grains are free of melt unless the dihedral angle is zero or the melt fraction exceeds a critical value.

Most rocks contain more than one mineral. Because surface energies vary among minerals, these additional phases will alter the connectivity of the melt network. The addition of a mineral with a high dihedral angle will decrease the connectivity of the melt network; the reduction in connectivity and change in shape of melt channels will depend on the concentration and distribution of additional minerals.

Dihedral angles in a wide range of rock types have been measured and interpreted using this ideal model. Almost all measured angles for melt in contact with crystals are  $\leq 60^\circ$ . As a first-order approximation of melt network geometry, these measurements suggest that partially molten rocks in both the crust and mantle will have an interconnected melt network at all melt fractions. Recent work on the melt distribution in olivine-rich mantle rocks, however, points to a more complicated melt geometry in these and other rock types due to the effects of crystalline anisotropy with respect to surface energy. Olivine has been demonstrated experi-

mentally to be anisotropic with respect to surface energy; the contact angle between basaltic melt and (100) olivine crystal surfaces are a factor of 3 to 10 greater than between other surfaces. Flat crystal–melt interfaces, rather than the smoothly curved boundaries predicted for isotropic minerals, are prevalent and preferentially developed perpendicular to *b* axes, parallel to (010) (Fig. 6). Quantitatively, more melt is present in these planar channels between two grains than is found in tubules as would be predicted from simply examining the characteristic dihedral angle. As melt fraction increases, this effect is amplified, because more penny-shaped channels develop as two-grain junctions become melt filled. Increasing the melt fraction in these rocks essentially causes the growth of penny-shaped or sheetlike channels rather than simply increasing the size of tubular channels. These penny-shaped channels contribute very little to the overall melt flow until they reach a critical thickness. Hence permeability may increase slowly with increasing melt fraction until a critical melt fraction is attained.

Because all rock-forming minerals show some degree of anisotropy with respect to surface energy, the dihedral angle-based tubule model in Fig. 5 may not be the best melt network geometry to assume when estimating permeability. This conclusion may be especially applicable to rocks containing minerals such as amphibole, feldspar, and biotite, which are highly anisotropic with re-

**FIGURE 6** Reflected light image of an undeformed Iherzolite. Olivine is light gray, pyroxene is medium gray, and quenched melt is darkest gray. Arrows point to planar melt–mineral interfaces and melt-free triple junctions, both features which indicate that crystalline anisotropy with respect to interfacial energy is an important determinant of melt distribution. Scale bar is 10  $\mu\text{m}$ .

spect to surface energy. Biotite, for example, because of its layered structure and high degree of anisotropy, develops very prevalent planar rational crystal faces in contact with melt. Although the range of dihedral angles measured in rocks exhibiting such clear evidence of anisotropy may give one some qualitative idea about the permeability of the rock to melt, any attempt to evaluate quantitatively the permeability using these measurements would be suspect. As a result, recent textural observations of melt geometries tend to focus on using image analysis techniques to more quantitatively measure the size, shape, and other important characteristics of melt channels.

Melt distribution is also complicated by nonhydrostatic stress and deformation. The ideal model is derived assuming hydrostatic stress conditions and, thus, no inelastic deformation of the rock. The distribution of melt in rocks that have been deformed while partially molten, however, can be significantly different from that predicted by the isotropic model depending on the mechanism of deformation (Fig. 7). At low differential stresses, the melt geometry appears unaffected and is indistinguishable from that present in undeformed rocks. As differential stress increases, however, the melt geometry is modified. In partially molten peridotites deformed at differential stresses up to 40 MPa, the majority of grain boundaries exhibit melt along all or part of their length, regardless of orientation with respect to the compression axis. This result, attributed to rapid grain boundary migration during dynamic recrystallization, is in contrast to the primarily melt-free grain boundaries of partially molten peridotites and olivine-silicate melt aggregates annealed under hydrostatic conditions but is similar to microstructures present in some mantle xenoliths. This stress-induced wetting results in more thin sheet-like channels and so could cause a reduction in the permeability of the rock.

In partially molten lherzolite deformed at higher differential stresses, melt forms a network of channels along recrystallized grain boundaries preferentially oriented at angles of 20–30° to the compression axis, but is not found on other grain boundaries (Fig. 7). In this case, differential stress applied to a partially molten rock leads to variations in the stress field associated with the melt network. Depending on the orientation of melt pockets or segments of the network, local pressures may be high or low. These pressure gradients lead to the growth of melt pockets as melt migrates into those pockets preferentially oriented at some angle to the compression axis. This melt redistribution could lead to high permeability in the direction in which melt is preferentially oriented relative to the permeability in the direction

perpendicular to the preferred orientation. In fact, permeability parallel to the melt preferred orientation could be enhanced by as much as a factor of 50, greatly increasing the ease of melt migration in that direction.

A similar melt distribution has also been observed in deformed partially molten granitic rocks, where after deformation melt occupies grain boundary segments and transgranular cracks parallel to compression leaving grain boundaries normal to compression essentially melt free. This melt preferred orientation, however, is attributed to melt redistribution in response to cracking of the rock. This cracking or brittle failure of the rock occurs if local pressure gradients near a melt pocket or inclusion are high enough to exceed the strength of the rock. Cracks are melt-filled and oriented with respect to the applied stress; cracks initially open at orientations similar to those described earlier for partially molten peridotites, but eventually grow or extend parallel to the axis of maximum compression (Fig. 8).

Deformation to high strains with subsequent annealing under hydrostatic stress conditions also affects melt network geometries due to the development of a preferred crystallographic orientation of the minerals in the rock. Preferred orientation of crystals typically develop during dislocation creep. For example, in olivine deformed in the dislocation creep regime during uniaxial compression, the *b* axes (010) are preferentially aligned parallel to the compression axis. This preferred orientation of olivine leads to an anisotropic melt distribution with melt preferentially oriented perpendicular to the axis of compression as (010) crystal faces are preferentially wetted by the melt. This preferred orientation of melt again leads to an anisotropy in permeability. This permeability anisotropy would be much stronger in rocks containing minerals with anisotropies in interfacial energy stronger than those of olivine. For example, biotite-rich layers that develop a high frequency of flat crystal faces and tend to have crystals aligned could act as a barrier to melt migration across the layers while enhancing melt flow parallel to the layers. The anisotropy in permeability and its effects on melt migration in biotite-rich layers is enhanced by the development of a shape fabric or foliation defined by the flattening and elongation of grains with respect to the compression axes. Elongation of grains results in elongation of the melt channels perpendicular to the compression axis because melt channels occur along the edges of grains, that is, along triple junctions.

Clearly, the network of melt channels present in partially molten rocks is much more complicated than the simple relationship  $K \propto \varphi^n$  would imply. Estimates of permeability based on geometry abound, but most are still

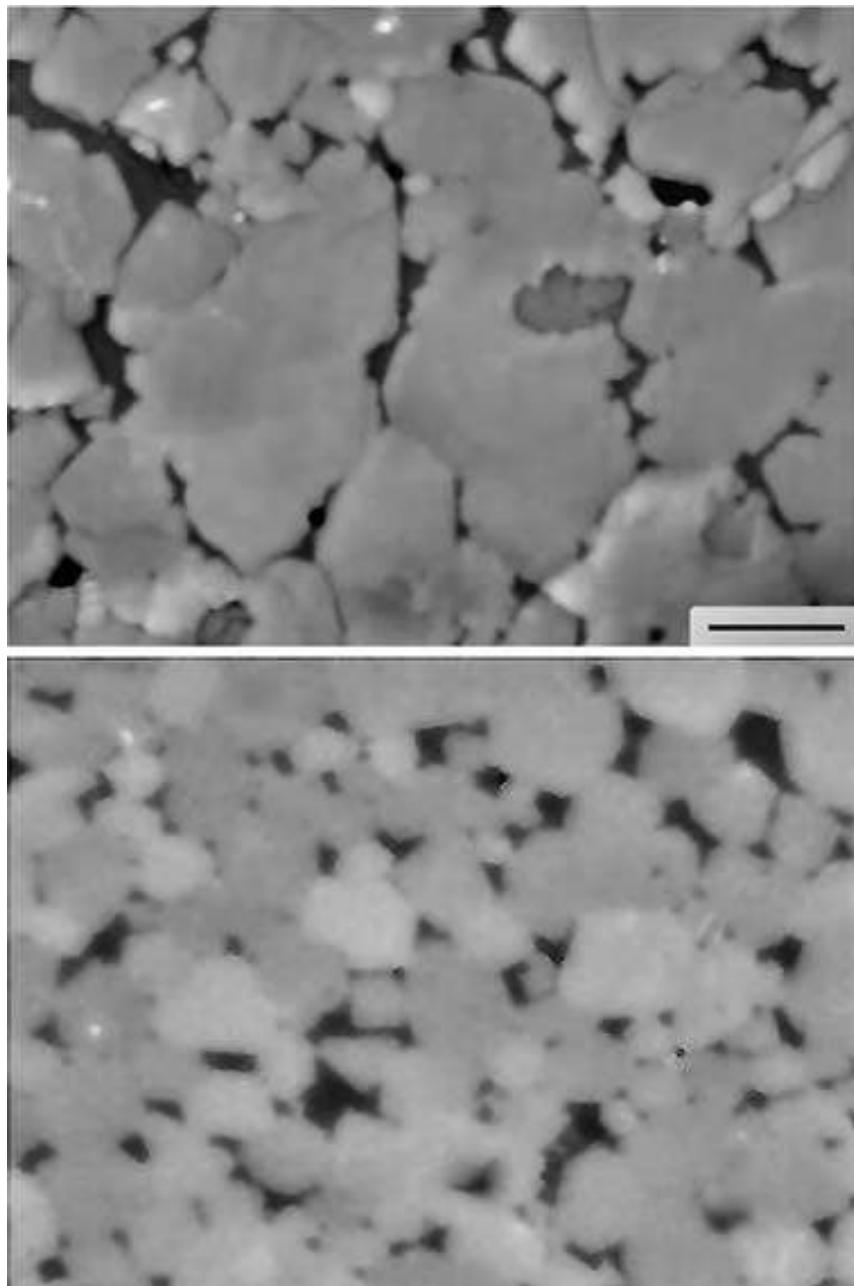

FIGURE 7 Reflected light images of olivine-basalt aggregates deformed at differential stresses of (A) 152 MPa and (B) 42 MPa. Olivine is light gray, quenched melt is dark gray, pores are black and circular. The orientation of the maximum compressive stress ( $\sigma_1$ ) is vertical. Melt pockets in part (A) show a distinct preferred orientation relative to  $\sigma_1$ . This preferred orientation is not present in part (B). Scale bar is 20  $\mu\text{m}$  for (A), but 10  $\mu\text{m}$  for (B). (From Daines and Kohlstedt, 1997.)

based on highly simplified versions of the melt network. The focus has also been primarily on establishing the relationship between permeability and porosity. Investigations of the relationship between grain size, melt geometry, and permeability have only begun.

### C. Laboratory Measurements of Permeability

Attempts to determine experimentally the permeability of partially molten rocks as well as the relationship be-

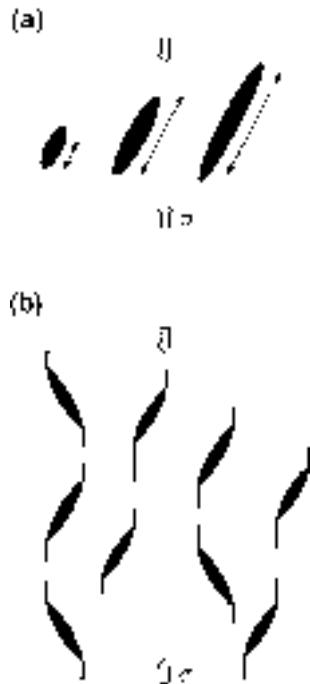

FIGURE 8 Anisotropic permeability structures can develop in deforming partially molten rocks either by (a) extension of melt pockets favorably oriented relative to the maximum compressive stress ( $\sigma_1$ ) or by (b) microcracking. Propagation and coalescence of cracks results in the development of veins parallel to  $\sigma_1$ , whereas extension of the melt pockets results in the development of veins oriented at an angle of  $\sim 30^\circ$  to  $\sigma_1$ .

tween permeability and melt fraction have led to somewhat ambiguous results. Experiments using aggregates of glass spheres as analogs of partially molten systems indicate that  $K \propto \varphi^2$  holds true in the range of  $0.005 < \varphi < 0.25$ . These experiments suffer from the fact that the glass spheres used were the same size and did not interact with the fluid phase in the same manner that grains in a partially molten rocks interact with the melt.

A variety of experiments using more realistic materials have led to other conclusions. For example, experiments designed to look at migration rates of basalt in olivine-rich rocks indicate that  $K \propto \varphi$ , a relationship not predicted by any theoretical considerations of flow in any shaped network. Melt migration in these experiments was driven by differences in initial melt content; capillary forces resulting from interfacial energy considerations led to the movement of melt from a melt-rich disk to a melt-poor disk. In some experiments the melt-poor disk initially contained no melt, whereas in other experiments the melt-poor disk initially contained a melt fraction of  $\sim 0.01$ . For both starting conditions, perme-

ability in these experiments was determined through comparison of numerical simulations of two-phase flow with the actual melt migration profiles of the experiment. From these comparisons permeability was found to range from  $5.2 \times 10^{-15} \varphi \text{ m}^2$  to  $1 \times 10^{-18} \varphi \text{ m}^2$ , depending on the initial quantity of melt in the melt-poor disk and on the composition of the melt. Only in experiments in which the melt-poor disk was melt free was permeability found to be linearly dependent on melt fraction; in other experiments it was impossible to resolve the relationship between melt fraction and permeability. The unexpected linear dependence of permeability on melt fraction yields relatively high permeabilities at low melt fractions, implying that melt extraction by porous flow through grain size channels is efficient enough to keep melt fractions beneath midocean ridges below 0.001.

In contrast, direct permeability measurements on monomineralic aggregates of quartz and calcite synthesized at high pressure and temperature in the presence of water suggest that, for melt–fluid fractions greater than 0.01, the functional dependence of permeability on melt or fluid fraction is cubic ( $K \propto \varphi^3$ ), the same as that predicted by some theoretical models. In these experiments, the annealed sample contains a network of pores filled with a water-rich fluid during the synthesis process. To measure the permeability of this now empty network, a pressurized air reservoir is placed against one end of the sample. As air moves through the pore network in rock, the decrease in the pressure of the air reservoir is recorded. From the decay in pressure, permeability is calculated. For melt–fluid fractions above about 0.01, permeability in quartz aggregates is

$$K = d^2 \varphi^3 / [1800(1 - \varphi)^2] \text{ m}^2. \quad (9)$$

At melt–fluid fractions below 0.01, however, permeability levels off or increases if the dihedral angle is  $< 60^\circ$ . This permeability relationship should apply to other natural fluid- or melt-bearing rocks provided no major differences exist in the degree of crystalline anisotropy or the extent of development of flat faces.

#### IV. MECHANICAL PROPERTIES OF THE MATRIX

Partially molten material will deform if subjected to stress. In gravity-driven compaction models, the stress arises from the density differences between the solid and

the interstitial melt; stress can also arise from tectonic activity. In any case, the deformation or compaction of the matrix results in melt pressure gradients; melt flows in response to these gradients. The importance of matrix deformation during melt migration by porous flow depends on the relative values of the compaction length and the height of the partially molten column. Table III shows the values of the characteristic length, velocity, and compaction time as a function of the mechanical properties of the matrix. These values were calculated from Eqs. (3)–(7), assuming the same melt fraction (0.1), melt viscosity (1 Pa s), and driving force ( $\rho_s - \rho_f = 0.5 \times 10^3 \text{ kg m}^{-3}$ ). Hence, the differences listed in Table III are only the result of variations in matrix viscosity. The times for significant extraction of melt from two layers of different thickness (50 km and 50 m) are also listed. Clearly, compaction of the matrix has little effect on melt migration rates unless the thickness of the partially molten region is less than or about the same as the compaction length. When the matrix viscosity is relatively high, the compaction length is relatively large, so that the deformation of the matrix is more likely to control the rate of melt expulsion.

Calculation of the compaction length requires that one know the values of  $\lambda$ , the bulk viscosity, and  $\eta$ , the shear viscosity of the matrix. These values are difficult to determine independently from typical deformation experiments. Deformation experiments can determine flow laws that govern the partially molten rock's response to stress. These laws can be used to calculate an effective viscosity ( $\eta_{pm}$ ) that can be substituted into the equation for compaction length. For example:

$$\eta_{pm} = \sigma/\varepsilon = A\sigma^{1-n}a^{-p} \exp(Q/RT), \quad (10)$$

where  $\sigma$  is differential stress,  $\varepsilon$  is the axial strain rate,  $a$  is grain size,  $n$  is the stress exponent,  $A$  is a materials parameter,  $Q$  is the activation energy for creep,  $R$  is the ideal gas constant, and  $T$  is absolute temperature. With sufficient data, the effective viscosity can be calculated. Unfortunately, data are not currently available for all rock types.

The effective viscosity of a partially molten rock is dependent on the amount of melt present in the rock. Increasing the melt fraction decreases the viscosity of the rock. The degree to which melt affects the rheology of the rock depends on the mechanism by which the rock is deforming. A range of deformation mechanisms has been observed in partially molten rocks exposed to stress. These mechanisms are dependent, in part, on the amount of melt in the rock. One of several deformation mechanisms may be dominant: diffusion creep, dislocation creep, or granular flow with or without fracturing.

At relatively low melt fractions, diffusion and dislocation creep mechanisms may dominate. In diffusion creep-dominated deformation, deformation may be limited by the rate of diffusion through the matrix grains or grain boundaries or by the rate of interface reaction. The presence of melt along grain boundaries can accelerate creep by providing high diffusivity paths and by enhancing the stress concentration at melt-free boundaries. For a melt fraction of about 0.03 and a dihedral angle of 35°, the presence of melt enhances the rate of diffusion creep by a factor of 2. Because higher melt fractions lead to more two-grain boundaries containing melt, this enhancement factor also increases as melt fraction increases. In partially molten fine-grained olivine-rich aggregates deformed in the laboratory, a marked change in diffusion creep rate or effective viscos-

TABLE III Characteristic Compaction Length, Separation Velocity, and Compaction Times Calculated Assuming Different Matrix Viscosities

Matrix viscosity (Pa s)	Compaction length $\delta_c$ (m)	Separation velocity $w_0$ (m/yr)	Compaction time $\tau_0$ (yr)	Time for significant melt extraction in a 50-m-thick layer $t_h$ (yr)	Time for significant melt extraction in a 50-km-thick layer $t_h$ (yr)
$10^{14}$	10	1.5	7.4	38.6	$3.7 \times 10^4$
$10^{16}$	$10^2$	1.5	$7.4 \times 10$	$1.9 \times 10^2$	$3.7 \times 10^4$
$10^{18}$	$10^3$	1.5	$7.4 \times 10^2$	$1.5 \times 10^4$	$3.7 \times 10^4$
$10^{20}$	$10^4$	1.5	$7.4 \times 10^3$	$1.5 \times 10^6$	$3.85 \times 10^4$
$10^{22}$	$10^5$	1.5	$7.4 \times 10^4$	$1.5 \times 10^8$	$1.85 \times 10^5$

$K = 1 \times 10^{-12}$ ;  $\mu = 1 \text{ Pa s}$ ;  $\phi = 0.1$ ,  $\rho = 0.5 \times 10^3$ .

ity occurs at melt fractions above about 5%, the melt fraction at which high percentages of grain boundaries contain melt. However, based on model results and geo-physical evidence described earlier, this melt fraction is not likely to be present, at least in midocean ridge environments, because melt extraction processes are efficient enough to maintain melt fractions below this value.

An enhancement of deformation rates with increasing melt fraction has also been observed in partially molten fine-grained mantle rocks deformed in the dislocation creep regime. Theoretically, this enhancement should be limited to that associated with the increased concentration of stress at melt-free grain boundaries, and so should be quite small, depending on the geometry of the melt network. Models based on the dihedral angle melt network geometry predict a creep rate enhancement of less than 15% for a melt fraction of 0.03. Measured enhancements in mantle rocks, however, can be much greater. For example, the presence of melt fractions of 0.03 and 0.1 increased the creep rate by factors of 1.5 and 25, respectively, in olivine-rich rocks deformed in the dislocation creep regime. This increased enhancement probably results from unexpected but significant contributions of grain boundary deformation mechanisms to the creep process. These processes include grain boundary sliding as well as grain boundary diffusion. The involvement of grain boundary processes implies that this increased creep rate enhancement in the dislocation creep regime is in part a grain-size dependent phenomenon; estimating its applicability in partially molten regions of the mantle requires grain size constraints.

The diffusion and dislocation creep data for the viscosity of partially molten mantle rocks can be fit by the following relationship:

$$\eta_{pm} = \eta_s \exp(-45\varphi), \quad (11)$$

where  $\eta_{pm}$  and  $\eta_s$  are the viscosity of the solid with and without melt, respectively. This relationship is plotted in Fig. 9, assuming that  $\eta_s$  is  $10^{18}$  Pa s. Use of this effective viscosity when calculating compaction length decreases the compaction length by factors of 1.5 and  $\sim 10$  if melt fractions are 0.01 and 0.1, respectively. Again, the impact of this reduction on melt extraction will depend on the total thickness of the partially molten layer of interest.

In crustal rocks, because of low dihedral angles and crystalline anisotropy, the penetration of melt into grain boundaries may be even more prevalent than in mantle lithologies, suggesting that enhancements of diffusion

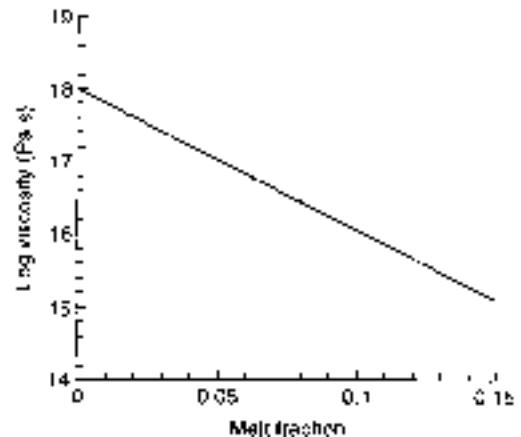

FIGURE 9 The viscosity of mantle rocks decreases with increasing melt fraction calculated using Eq. (11). A melt-free viscosity of  $10^{18}$  Pa s was assumed in the calculation. Equation (11) is based on data from Hirth and Kohlstedt (1996).

or dislocation creep rates could be even greater in these rocks. Unfortunately, partially molten granites rarely show evidence of diffusion or dislocation creep processes when deformed in the laboratory. Instead, these materials deform by a combination of cataclastic deformation of grains and granular flow. As a result, quantitative determination of the matrix viscosity as a function of melt fraction during creep has not yet been accomplished. The minimal experimental data that do exist, however, suggest that, at the low strain rates and stresses at which partially molten granites deform in nature, melt-enhanced diffusion creep will be important.

Despite the fact that flow mechanisms may be dissimilar to that in natural rocks, results of deformation experiments on partially molten granites and other crustal compositions have been used to estimate the strength and viscosity of crustal materials. Based on these experiments the strengths of these partially molten rocks as a function of melt fraction can be approximated by:

$$\log(\sigma) = 9.15 - 5.1\varphi, \quad (12)$$

where  $\sigma$  is the differential stress in Pa. This relationship is plotted in Fig. 10. The effect of melt fraction on matrix viscosity is evident. These and other data indicate that partially molten crustal materials likely have effective viscosities between  $10^{17}$  Pa s for low melt fractions to  $10^{14}$  Pa s at moderate melt fractions.

The data shown in Fig. 10 call into question the notion of a rheologically critical melt fraction at least for the dry granitic material on which these experiments were performed. The rheologically critical melt fraction

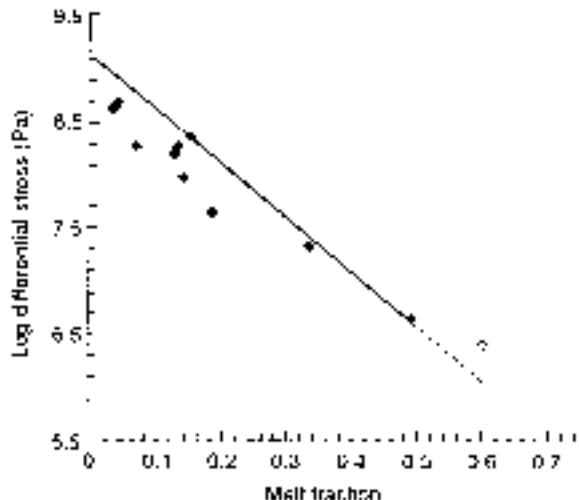

FIGURE 10. The strength of granitic rocks decreases smoothly with increasing melt fraction. The heavy line is calculated using Eq. (12), which was taken from Bagdassarov and Dorfman (1998). Diamonds are experimental data from Rutter and Neumann (1995).

is the melt fraction at which partially molten rocks cease to be frameworks of interlocking solid grains and begin to behave as dense suspensions with effective fluid properties. Estimates of the critical melt fraction in crustal materials range from 0.2 to 0.4; the change in the effective viscosity associated with this transition has been proposed to be as much as 14 orders of magnitude. The data plotted in Fig. 10, however, do not show this abrupt change in viscosity associated with the rheologically critical melt fraction; it may be that the conditions of the experiment or the composition of the materials increased the aggregates' resistance to grain boundary sliding, damping out an abrupt transition. The concept of a critical melt fraction has not been applied to a great extent to mantle materials, primarily because melt migration rates are rapid enough to keep melt fractions well below this theoretical critical limit.

#### V. MELT LOCALIZATION AND FLOW FOCUSING

Although the initial segregation of melt from the solid residuum must occur by the two-phase model for percolation described earlier, calculation of melt migration rates and length scales, combined with field evidence

and geochemical constraints, suggests that at some stage in the extraction process melt must be focused into larger conduits for more rapid melt extraction.

In mantle rocks this conclusion is based in part on chemical and isotopic signatures of both melt and residuum. Abyssal peridotites, assumed to be the residues of partial melting that formed midocean ridge basalts (MORB), are strongly depleted in light rare Earth elements and so are not in trace element equilibrium with MORB. MORB is also not saturated in orthopyroxene, one of the major constituents of these residual peridotites. This disequilibrium requires the efficient extraction of very small amounts of melt (<0.01) throughout the melting region, and little or no reequilibration between melt and solid as melt is transported from depth to the surface. Essentially, the melt extraction is efficient enough to generate near-fractional melting. Pervasive two-phase flow of large volumes of melt through grain scale channels would result in extensive chemical interaction, wiping out these disequilibrium features.  $^{238}\text{U}$ - $^{230}\text{Th}$ - $^{226}\text{Ra}$  abundances in MORB and other tholeites also indicate a fractional mode of melting. Field relationships in ophiolites also indicate that melt flow is focused into larger conduits at some stage of melt extraction. Elongate dunite bodies and ductile shear zones in ophiolites and ocean floor drill core have both been interpreted as former channels for focused melt flow in the shallow mantle.

In the crust, calculations of compaction times and segregation velocities indicate that gravity-driven flow alone can not efficiently segregate significant volumes of melt over geologic time scales unless melt viscosity is less than  $\sim 10^4$  Pa s. Partially molten crustal regions must be subjected to an applied stress if significant melt segregation is to occur in most of these rocks. Or high-viscosity crustal melts must collect and migrate through a network of veins and dikes, minimizing the distance over which melt must migrate through intragranular channels. Field evidence abounds, both for the inefficiency of gravity-driven compaction and for the focusing of flow into veins and larger conduits. For example, layers, pods, or veins of granitic material (leucosomes) found in plastically deformed metamorphic rocks could represent melt crystallized in a drainage network in the end stages of melt extraction or melt crystallized before any appreciable melt migration has even occurred. Shear zones, however, undoubtedly represent relatively high permeability channels for melt extraction.

The next sections examine several mechanisms for localizing melt and focusing melt flow into larger conduits. These larger conduits serve to increase the perme-

ability of the partially molten region and to chemically isolate the melt from the residual solid as the melt moves to the surface.

## A. Effects of Deformation

### 1. Role of Strength or Viscosity Contrasts

Most rocks are not homogeneous on some scale. Heterogeneities can lead to strength or viscosity contrasts. In a partially molten region that is deforming at a comparable rate throughout, weaker regions will develop slightly lower melt pressures than strong regions. These lower pressures are contingent on the assumption that the strain rate is the same in all areas. Because melt pressure correlates with stress and weak regions deform at lower stresses than strong regions, melt pressures in weak regions are lower than in strong regions, provided they are deforming at the same rate. As a result of these pressure gradients, melt will flow into weaker regions from surrounding stronger regions. For this mechanism to operate effectively, the pressure gradients due to differing strength must be greater than the pressure gradient produced by interfacial energy forces, which are generally trying to redistribute melt homogeneously. Estimates of pressure gradients produced by differing strength suggest that pressure differences could be on the order of hundreds of bars if strength differs by a factor of 10. Interfacial energy forces, assuming appropriate grain sizes and melt fraction contrasts, generally lead to pressure gradients of less than 1 bar/m.

Rheological contrasts can develop as a result of differences in mineralogical composition, grain size, and/or melt content. Mineralogical variations on a variety of scales are present in both crustal and mantle rocks. Source rocks for crustal melts are frequently compositionally layered. Strength contrast due to compositional differences may be further amplified when melting occurs, because melt fraction is negatively correlated with the strength of the partially molten rock. The degree of amplification of the strength contrast may depend on where melting occurs. For example, if an already weak layer also produces more melt than a nearby strong layer at the same temperature and pressure conditions, the relative strengths of the two layers will become even more disparate due to the dependence of viscosity on melt fraction. In essence, the original rheologic contrast results in a dynamic instability with respect to melt distribution, leading to concentrations of melt or melt veinlets. With continued growth, these veinlets could

become interconnected, providing a higher permeability path for melt extraction.

### 2. Development of Anisotropic Permeability

Deformation of a partially molten rock can result in the development of an anisotropic permeability structure that may focus melt flow. Two different types of deformation-related anisotropic melt distributions were discussed in Section III—those due to stress and those due to strain.

Stress-induced anisotropic melt distributions are defined by an increase in the size, length, and melt content of melt pockets oriented relative to the axis of maximum compressive stress ( $\sigma_1$ ). In fine-grained (<40- $\mu\text{m}$ ) partially molten peridotites deformed both in compression and in shear, a large fraction of the total melt present is in those segments of the melt network oriented at 20–30° to  $\sigma_1$  (Fig. 7). This preferred orientation develops due to the concentration of stress that develops at the edges or ends of melt pockets. If the melt network is treated as an interconnected network of elliptical melt inclusions, then in a compressive stress field, melt inclusions inclined at an angle  $\gamma$  to  $\sigma_1$  will yield the greatest tensile stress concentration. The value of  $\gamma$  is given by:

$$\cos 2\gamma = 0.5(\sigma'_1 - \sigma'_2 + \sigma'_3), \quad (13)$$

where  $\sigma'_3$  is the least compressive stress. The primes in this equation indicate effective stress components, meaning that each has been reduced by a value equal to the melt pressure (i.e.,  $\sigma'_{ij} = \sigma_{ij} - \alpha\delta_{ij}P_m$  where  $\sigma_{ij}$  is the applied stress,  $\delta_{ij}$  is the Kronecker delta,  $P_m$  is the melt pressure, and  $\alpha = 1$ ). In this formulation, the melt inclusions act as defects in the rock; these defects produce local stress concentrations and gradients in mean pressure, which depend on the orientation of the defect in the stress field. In response to these gradients, melt flows into regions of the melt network that have the lowest mean pressure, essentially extending the melt inclusions in the most favorable orientation with respect to stress (Fig. 8A). This extension results in an anisotropy in permeability. In the case of partially molten mantle rocks deformed in the laboratory, substituting appropriate experimental conditions into Equation 13 gives  $20^\circ < \gamma < 30^\circ$ . These values are in excellent agreement with the preferred orientation of melt measured in these experiments.

For this mechanism to operate effectively in the mantle, the pressure gradients due to stress in the mantle must be greater than the pressure gradient produced by surface tension, which are generally trying to redistrib-

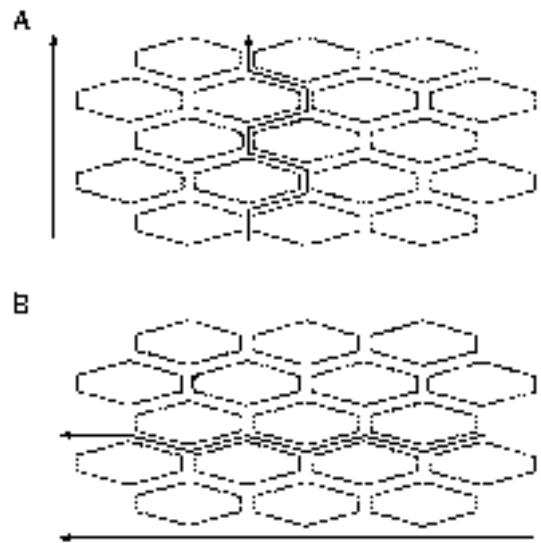

ute melt homogeneously. The driving force for melt redistribution due to applied stress scales approximately with the square root of the grain size ( $a$ ); the driving force for melt redistribution due to surface tension, based on the relationship between pressure and radius of curvature ( $P \propto 1/r$ ), scales approximately with the reciprocal of grain size. Comparison of these relationships between grain size and driving force indicates that as grain size increases the driving force for development of a stress-induced melt distribution will increase by a factor of  $a^{1.5}$  relative to the driving force for melt redistribution due to surface tension forces. This observation, combined with laboratory results, suggests that the stress-induced melt distribution should be observed at differential stresses of a few kilopascals for rocks with grain sizes of  $\sim 1$  mm. These stresses are considerably lower than those expected in the upper mantle, implying that stress-induced anisotropic melt distributions will dominate in deforming regions of the mantle. An important point to note is that, because of limitations of experiments (i.e., total strain, duration, stress resolution), the full extent of stress-induced melt redistribution has not been investigated. Some important questions remain unanswered. For example, with continued deformation will the melt network simply be reduced to long parallel channels as virtually all melt moves into network segments with favorable orientations and these segments link? If so, this stress-induced melt redistribution could lead to the focusing of melt flow into larger conduits. In any case, the permeability anisotropy that results from stress-induced melt redistribution in partially molten rocks is significant and, when combined with appropriate models for mantle flow beneath midocean ridges, is one possible mechanism for focusing of melt toward ridge axes, even if the melt flow occurs in grain scale channels.

Anisotropic melt distributions are also present in partially molten crustal rocks deformed in the laboratory. In these rocks, however, melt is not preferentially oriented at  $20\text{--}30^\circ$  to  $\sigma_1$ , but rather is parallel to  $\sigma_1$ . This difference in orientation indicates that the mechanism for melt redistribution in crustal rocks might be different than for mantle rocks. This mechanism is discussed in the next section.

Strain-induced anisotropic melt distributions can also be defined by an increase in the size, length, and melt content of melt pockets oriented relative to the axis of maximum compressive stress ( $\sigma_1$ ). In this case, however, the melt redistribution is not associated with the stress, but rather with the changes that occur in the shape and orientation of minerals in the rock in response to the stress. Shape fabrics, defined by the elongation and

alignment of grains, could enhance flow in parallel to the developed foliation. This enhancement results from the reduced tortuosity of the melt path parallel to the foliation relative to that perpendicular (Fig. 11). If this shape fabric is combined with a crystallographic preferred orientation of crystals and anisotropy in interfacial energies corresponding to elongation of grains, the effect could be amplified, resulting in high permeability parallel to the foliation.

As described in Section III, strain-induced melt redistribution accounts for the preferred orientation of melt observed in fine-grained partially molten mantle rocks deformed to high strain and annealed. This effect may also dominate in partially molten crustal rocks in which the original source rock initially was foliated. For example, a major component of crustal rocks is biotite, a mineral that has a high anisotropy in interfacial energy, commonly displays a strong crystallographic preferred orientation, and is often found in layers. In a partially molten crustal rock, biotite-rich layers could effectively inhibit melt transport perpendicular to the layering while enhancing layer parallel flow, depending on the orientation of these layers relative to the driving force for melt migration. If layers are perpendicular to the flow direction favored by the driving force, melt might accumulate, unable to migrate through the bordering impermeable layer. This melt accumulation or localization could lead to the development of melt veins.

**FIGURE 11** The development of a shape fabric during deformation can result in an anisotropic permeability structure as tortuosity increases perpendicular to the direction of grain elongation (A) and decreases parallel to that direction (B).

### 3. Brittle Failure

Perhaps the most attractive mechanism for melt localization and focusing of melt flow has been brittle failure or magma fracturing. On the laboratory scale this process may begin with microcracking along grain boundaries and through grains. In partially molten rocks these cracks are filled with melt. With continued deformation, these cracks link, eventually forming networks of veins and dikes at scales larger than the grain size. Failure can be distributed throughout the partially molten region or localized in shear zones.

In a rock containing melt, the melt pressure acts to reduce the effective stresses. If the effective confining pressure is low enough and the differential stress is high enough, microcracking will occur. As stated earlier, the effective stresses that govern failure in rocks containing melt or fluid are

$$\sigma'_{ij} = \sigma_{ij} - \sigma \delta_{ij} P_m. \quad (14)$$

If melt does not flow easily out of the partially molten rock so that deformation occurs at constant volume, the conditions are described as *undrained*. Most deformation experiments are carried out under undrained conditions. The melt pressure when volume is constant is

$$\sigma_3 \leq P_m \leq (\sigma_1 + 2\sigma_3)/3, \quad (15)$$

where  $\sigma_3$  is the confining pressure and the quantity on the right-hand side is the mean pressure. In rocks in which the fluid can move freely in response to stress, the pore pressure equals the confining pressure, whereas in rocks in which the fluid cannot move freely the pore pressure is more likely to equal the mean pressure.

If the melt network is again treated as an interconnected network of elliptical melt inclusions, then in a compressive stress field, the same analysis used earlier for stress-induced melt distribution holds true. That is, melt inclusions inclined at an angle  $\gamma$  to  $\sigma_1$  will yield the greatest tensile stress concentration. Melt migrates into those most favorable oriented cracks as above, but in this case, the maximum local tensile stress around the melt inclusion exceeds the tensile strength of the rock and cracking of the solid matrix occurs. The stress condition for failure is

$$\sigma_3 - P_m = T, \quad (16)$$

where  $T$  is the tensile strength of the rock. Cracks will be oriented initially at the same angle to  $\sigma_1$  as described for stress-induced melt redistribution, but will propagate more nearly parallel to  $\sigma_1$  (Fig. 8B). On failure, melt pressure decreases within the crack; this decrease results in additional pressure gradients that drive melt

into the crack. If melt is distributed throughout the rock, these cracks will develop throughout the rock. As cataclastic failure continues, these cracks grow and coalesce, leading to the formation of a network of veins and fractures in the rock. Under certain conditions (e.g., low temperature and pressure), cracks may coalesce to form localized shear zones. The melt distribution observed in many partially molten granites deformed in the laboratory is due primarily to this process.

The development of fractures or veins depends on the ability to generate melt pressures that exceed the tensile strength of the solid matrix as well as on the temperature, pressure, and stress conditions.

Conditions in the crust are generally favorable for the formation of veins and fractures due to the relatively low pressures and temperatures at which deformation occurs. High melt pressures can also develop in partially molten crustal rocks as a consequence of the high viscosity of the melt and positive volume changes associated with melting. As described in Section II, high melt viscosity considerably reduces the ability of melt to migrate in grain scale size channels. If melt cannot migrate quickly enough to keep up with the imposed rate of deformation, melt pressure will increase locally, possibly leading to failure. If slow melt migration within grain scale channels is combined with melting in which a positive change in volume occurs, this effect is exacerbated. A positive change in volume occurs on melting in relatively dry granitic systems. Not only is melt pressure increased by the positive volume change on melting, but also by the step-wise manner in which melt is produced in these systems. Laboratory experiments of melting in dry crustal rocks indicate that melt fraction increases rapidly over very small temperature intervals due to the breakdown of hydrous minerals such as biotite, muscovite, or hornblende. These rapid increases in melt fraction combined with the positive volume changes associated with melting favors the development of high melt pressures, cataclastic failure, and the development of vein or fracture networks.

In the mantle, brittle failure seems unlikely, primarily because, at typical pressure and temperatures, mantle rocks can deform viscously at differential stresses much lower than the tensile strength of the rocks. However, as discussed earlier, brittle failure can occur if melt pressure is high enough to exceed the confining pressure and the tensile strength of the rock [Eq. (16)]. The mechanisms described for inducing high melt pressures in crustal rocks generally do not apply to mantle rocks, primarily because melt movement in response to deformation and imposed pressure gradients is relatively rapid. The maximum possible difference between the

melt pressure and the confining pressure that can be generated due to melt buoyancy in the compacting mantle is

$$\sigma_3 - P_m = (\rho_s - \rho_f)g\delta_c. \quad (17)$$

Fracture will occur if the right-hand side of this equation is  $\geq T$ , the tensile strength of the rock. Estimates of  $T$ , based on laboratory experiments, suggest that  $T$  is at least  $\sim 50$  MPa. This minimum estimate means that, for appropriate density contrasts, the compaction length  $\delta_c$  must be greater than  $10^4$  for fracture to occur. In contrast, most estimates of compaction length in the mantle beneath midocean ridges are less than  $10^3$ . In fact, many theoretical models of melt migration beneath midocean ridges assume that the compaction length is of order 0. In other mantle environments, it may be possible that  $\delta_c$  is  $\sim 10^4$ , but only if mantle viscosities are high or if melt is already focused into high-porosity channels with coarse grain sizes. Focusing melt into coarse-grained channels increases the permeability; since  $\delta_c \propto K^{1/2}$ ,  $\delta_c$  also increases. Brittle failure in the mantle, then, may only occur after melt has been localized to form veins and may not be an effective mechanism for vein formation.

## B. Effect of Reaction

Melt–rock reactions in the mantle not only may account for the compositions of erupted magmas and rocks through which melt has moved, but also may provide a mechanism for the focusing of melt flow into larger conduits. Geochemical data suggest that many dunites found in ophiolites and other mantle sections are replacive features formed by reaction between ascending basaltic melt and mantle peridotite. These dunites occur in a variety of shapes and sizes and have sharp boundaries in which pyroxene content changes  $<2\%$  to  $>15\%$  over distances of millimeters. In many mantle peridotites, these replacive dunites form an interconnected network of anastomosing channels. These dunite channels represent former conduits for focused melt flow through the mantle. Focusing of flow into dunite channels essentially isolates the melt from further interaction with the surrounding mantle, leading to the geochemical signatures for near fractional melting described above.

These dunite channels develop because mineral solubilities are dependent on pressure. For example, melt produced at depth in the mantle may become saturated in olivine, but undersaturated in pyroxene as it ascends through the overlying rock. At some critical depth or

degree of under saturation, melt will begin to dissolve the pyroxene in the rock through which it is moving. This reaction increases the melt fraction, which in turn enhances the permeability of the rock. The increased melt flow that results in turn enhances the rate of reaction, so that a positive feedback loop exists between reaction and melt flow. Although initially the reaction occurs throughout the rock, small differences in pyroxene content may cause an instability to develop. For example, an area with an initially larger proportion of pyroxene will have a higher melt fraction after all the pyroxene is dissolved. This higher melt fraction implies greater permeability; this effect focuses melt into the region. With continued reaction and focusing of flow, olivine-rich channels containing high melt fractions form and grow.

Numerical and laboratory experiments both indicate that this reaction instability could operate in the mantle. Figure 12 shows a typical channel developed during laboratory experiments in which melt undersaturated in pyroxene migrated into a fine-grained rock containing equal amounts of pyroxene and olivine. The initial melt migration-reaction front was planar; after several hours at high temperatures and pressures, several channel features developed. These channels had sharp boundaries defined by changes in melt and pyroxene content. Within the channel no pyroxene remained; outside the channel the initial pyroxene content was unchanged. Experiments in which water flowed through a mixture of glass balls and salt show very similar results.

Although these reaction channels seem likely to develop in the mantle, questions still remain about the time and length scales for this channeling process. For example, channels that develop by reaction during melt migration may have only a limited ability to focus flow in the mantle if the length of channel that develops is limited or if extensive branching of channels occurs. However, even with limited development, this process could provide a starting point for the melt focusing effects of deformation described earlier. For example, the high melt fractions developed in the reaction zones will cause these regions to be significantly weaker than the surrounding region. As discussed earlier, strength contrasts can cause melt to flow from strong to weak areas during deformation. Deformation would then draw more melt into the existing channels, increasing the length of these features beyond that obtained by reaction alone. If the channels become long enough, fracturing could occur as melt pressure at the top of the column of melt exceeds the rocks strength.

Although the relationship between aqueous fluid flow and reaction in crustal rocks has been examined, the

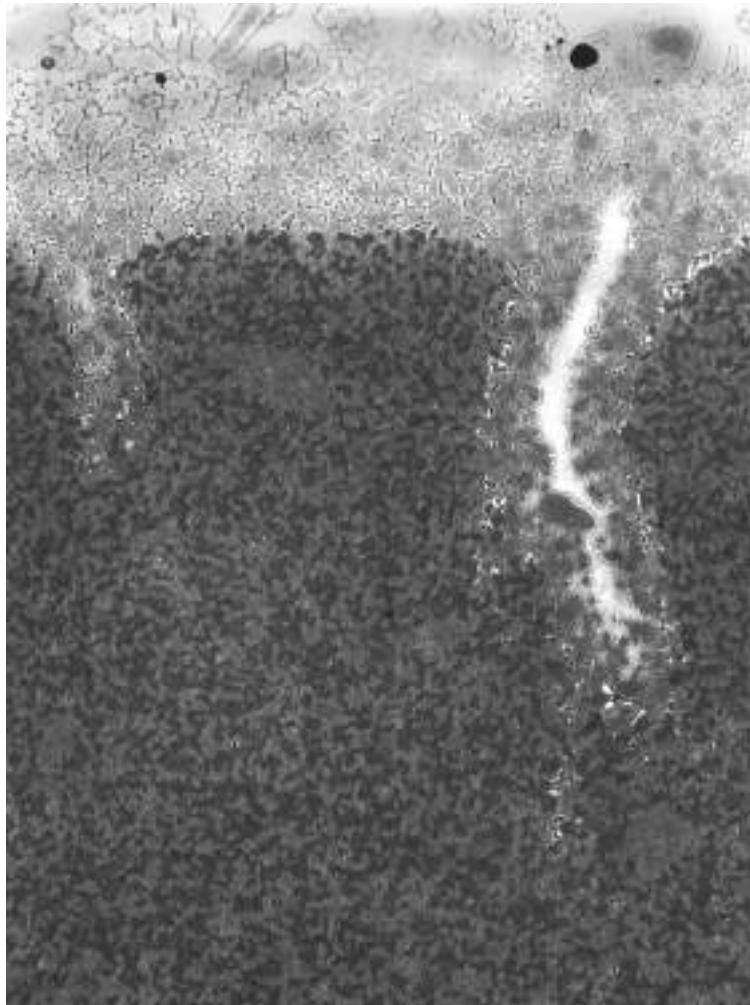

FIGURE 12 Backscatter electron micrographs of melt migration experiments in which the infiltrating melt was saturated in olivine, but undersaturated in Ca-poor pyroxene. Light gray mineral is olivine; medium gray mineral is pyroxene. The glass in these images is light gray to white to dark gray depending on location and degree of undersaturation in pyroxene. A distinct reaction zone is apparent at the top of the image. Within the reaction zone, all of the pyroxene has dissolved, the olivine grains are larger, and the glass is light gray to white. The instability of the reaction front during melt migration is indicated by the finger-like projections of the reaction front. These channel features indicate that melt is being focused due to reaction during melt migration. Field of view is  $\sim 600 \mu\text{m}$ .

effect of reaction on the focusing of melt flow in crustal rocks has not been considered in any detail.

#### VI. FUTURE DIRECTIONS

Melt migration in both the crust and mantle is a complicated process that requires an understanding of microscopic and macroscopic properties of partially molten rocks. Considerable progress has been made in the theo-

retical understanding of the extraction of melt, particularly when this separation is driven by density differences between melt and solid. Numerous models of large-scale melt migration have been developed based on gravity-driven compaction; many of these apply to melt migration beneath midocean ridges. Examination of these models, however, suggests that our understanding is still limited by our incomplete knowledge of the basic physical properties of partially molten systems. In particular, we need to know more about the permeability and viscosity of both mantle and crustal rocks.

Despite considerable work on the distribution of melt

in partially molten rocks, permeability estimates remain qualitative at best. Recent experiments that directly measure permeability hold a great deal of promise, but so far are limited to aqueous fluids rather than silica melts. Techniques to measure permeability at high pressures and temperatures need to be developed.

Most permeability models to date are based on two-dimensional analyses of melt networks; three-dimensional imaging techniques hold great promise for determining more accurate relationships among permeability, melt fraction, and grain size. In the past, three-dimensional imaging techniques were difficult due to lack of computational power for processing and storing images, poor resolution at which images could be attained, or time requirements for attaining images. Volumetric image data sets are extremely large and have been difficult to use effectively in the past. With recent advances, such as laser scanning confocal microscopy or high-resolution microtomography, three-dimensional images of melt networks should be obtainable. Images combined with flow simulations using Lattice-Boltzmann methods, for example, should resolve the relationship between melt network geometry and permeability in both undeformed and deformed rocks.

In the last 20 years, numerous laboratory studies have examined the mechanical properties of deforming partially molten rocks. In peridotites and other mantle analogues, detailed flow laws obtained through these experiments provide very good constraints on the effective viscosities of these rocks during melt migration. Despite the development of these flow laws, a fundamental understanding of the ongoing microscopic processes that result in these flow behaviors eludes us. This lack of understanding is compounded by recent discoveries of very thin melt films on grain boundaries in mantle samples. The effect these thin melt films have on macroscopic properties of the mantle and their relationship to melt migration processes is unclear. Future work on mantle rocks will undoubtedly focus on these issues.

Much work remains to be completed to constrain mechanical properties of partially molten crustal rocks. Experiments need to be performed at lower stresses and strain rates to examine deformation in the diffusion and dislocation creep regimes; current quantitative results apply only to deformation by cataclastic flow. Technological advances that allow for resolution of lower stresses and strain rates make these experiments possible. Not only will these experiments provide data to develop flow laws, but also they will provide insight into the role of deformation in the localization of melt and the focusing of melt flow in crustal rocks.

## GLOSSARY

- arc** A curved chain of volcanic islands or volcanic mountains located near the margins of continents that are formed as a consequence of magmatism related to subduction.
- asthenosphere** The plastic layer of the Earth's mantle below the lithosphere where most magmas are generated and in which seismic-wave velocities are attenuated and relatively low.
- axial graben** A linear, down-dropped section of a midocean ridge bounded by normal faults.
- crust** The outermost layer of the Earth above the mantle primarily comprised of basaltic igneous rocks in the oceans and a wide variety of more felsic igneous rocks, sedimentary rocks, and metamorphic rocks in the continents.
- flood basalts** Voluminous and thick sequences of mafic lavas erupted from fissures over relatively short periods of time; also known as *plateau basalts*.

**hot spot** A large volcanic center created by partial melting of the mantle due to the rise of deep, hot mantle material.

**incompatible trace element** An element with low concentration (<1000 ppm) that does not substitute for major elements in crystal lattices of minerals and instead is concentrated in the melt during the processes of melting or crystallization.

**isostasy** Mechanism whereby the crust (or lithosphere) rises or falls until its mass is buoyantly supported by the mantle (or asthenosphere) that lies below. Essentially, the less dense crust "floats" at a certain equilibrium level on the more dense, underlying mantle.

**lithosphere** The brittle 100-km-thick outer layer of the solid Earth overlying the asthenosphere, which consists of the crust and solid uppermost mantle.

**neovolcanic zone** Narrow region of focused magmatism and hydrothermal activity on midocean ridges

**petrogenesis** The study of the histories and origins of rocks.

**picritic basalt** A primitive, magnesium-rich lava, with abundant olivine phenocrysts, that may represent a primary mantle melt.

**plume** An elliptical or tail-down, drop-shaped mass of the mantle that ascends within the Earth's interior due to its relatively lower density and higher heat content compared to the surrounding mantle; associated with intraplate volcanism and rifting.

**primary magma** A melt generated by the direct partial melting of its source that is unmodified by crystallization or contamination before it erupts.

**slab** The subducted portion of oceanic lithosphere that undergoes dehydration and/or partial melting beneath arcs.

**subduction zone** Elongate region on the edges of an active continental margin or island arc where oceanic lithosphere sinks into the mantle; generally characterized by a deep-sea trench and landward dipping seismic belt.

**volatiles** Elements and compounds that are gases under normal atmospheric conditions or that readily vaporize when heated. During crystallization or eruption of magma, many of these elements come out of solution to form bubbles and escape.

PLATE TECTONICS IS the fundamental paradigm of the Earth sciences, enabling us to understand an overwhelming number of previously puzzling natural phenomena, including the origin and distribution of mountain belts, continents, earthquakes, and volcanoes. As far as we can tell, the Earth is unique among the planets of the solar system in having plate tectonics. Our planet is also unique in having abundant liquid water at the surface. Both of these factors strongly influence the formation of magma, the compositions of magmas, and the locations and behaviors of volcanoes. This in turn controls related aspects such as potential volcanic hazards and economic benefits, discussed later in this volume.

## I. INTRODUCTION

Plate tectonics is a simple consequence of the planet's loss of heat. The Earth's internal heat results from original or primordial heat that was accumulated during the processes of accretion and formation some 4.5 billion years ago, together with heat generated by natural radioactivity, as isotopes of elements such as K, U, and Th decay through time. The Earth was much hotter in the past, and has been cooling at a decreasing rate for most of its history. The consequences of an early hotter Earth, in terms of the vigor of convection, the intensity of volcanism, and whether liquid water could exist at the surface, are interesting aspects of Earth's history about which we continue to speculate. Certainly it is arguable whether plate tectonics as we know it today operated in Earth's early history.

The principal mechanism for transferring heat from the deep interior to the surface is by convection. As

material heats up at the base of the mantle, as much as 2900 km below the surface, it buoyantly rises because it expands slightly and becomes less dense than its immediate surroundings. At the top of the mantle, approximately 7–35 km below the surface, this material cools and becomes more dense, sinking back down in a return flow. This convection is similar to that observed in a pan of soup on a stove, although the mantle is a much more viscous fluid, and moves at rates of only millimeters to centimeters per year. As a result, over short timescales it behaves more like a plastic material than a liquid. This simple model is complicated by the existence of a rigid, brittle layer called the *lithosphere* that covers the surface of the Earth beneath the atmosphere and hydrosphere. The lithosphere, which includes the crust, is typically 70–120 km thick and is broken into a several large fragments called *lithospheric* or *tectonic plates*. The plates move relative to each other and relative to the underlying convecting mantle. The base of the lithosphere slides over a weak zone of upper mantle called the *asthenosphere*. The weakness of the asthenosphere is due to it being at, or near, the temperature at which it begins to melt. Consequently, some regions of the asthenosphere are partially molten although for the most part it is solid. This leads to an apparent paradox—the mantle flows (by convection) even though it is largely solid. The paradox is resolved only when it is realized that the behavior "fluid" versus "solid" is dependent on the timescales under consideration. For geophysical purposes the solid mantle can be considered a high viscosity fluid.

Note that the lithosphere is different from the crust. The lithosphere comprises both the crust and brittle uppermost part of the mantle. The crust is often erroneously referred to as a synonym for plates, but it is a physically and chemically distinct layer that forms just the uppermost part of the lithosphere. The crust is mainly formed by magmatic differentiation processes and is the underlying factor controlling the difference between continents and oceans. Continents are composed of a thicker (ca. 35-km), lower density crust with average ages of typically 1–2 billion years. In contrast, oceanic crust is thin (ca. 7 km), more dense, and with ages no greater than 200 million years old. The surface of the continents is largely above sea level because the thicker, less dense crust tends to "float" higher in the underlying mantle than the oceanic crust. The equilibrium level at which crust resides due to its density is controlled by a principle known as *isostasy*.

The lithosphere is a continuous layer at the surface to the Earth. The separate plates that comprise the lithosphere are always in contact with each other, but

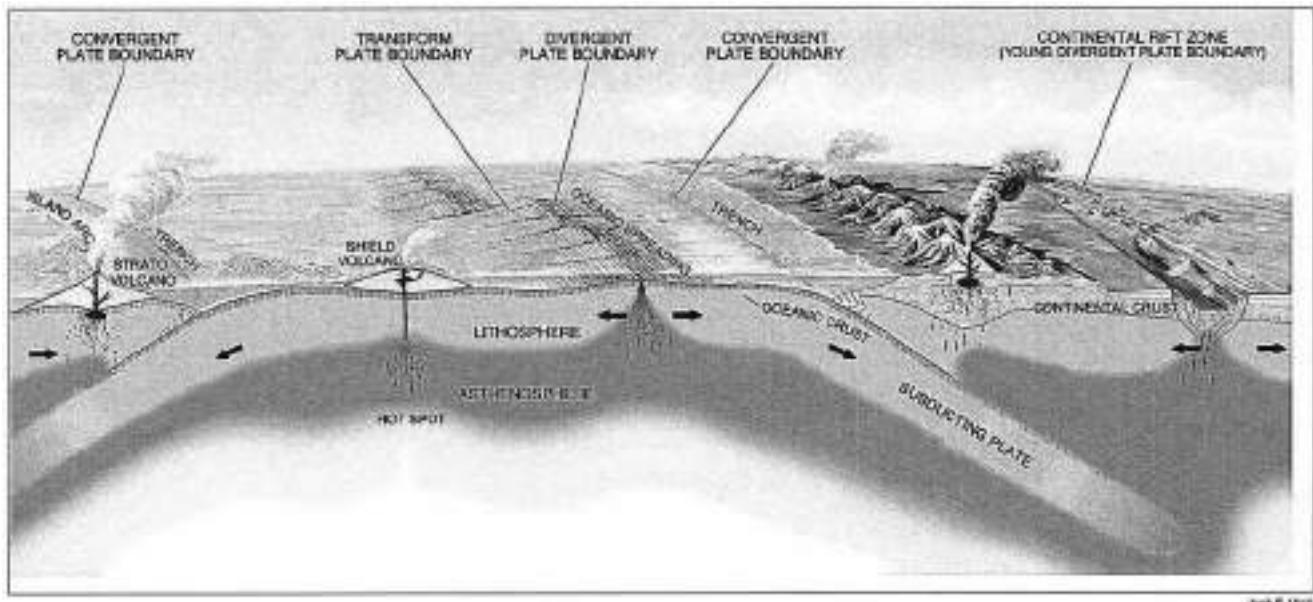

FIGURE 1 Schematic cross section depicting the main plate boundaries and their relation to volcanism. [Courtesy of USGS.]

meet in different configurations leading to three fundamentally different types of plate boundaries or margins (Fig. 1):

1. *Divergent (or constructive); plates move away from each other.* New lithosphere is formed by magmatic processes along the boundary. The feature formed by this is termed a *spreading center* or *rift zone*. Mid-ocean ridges characterize these plate boundaries.
2. *Convergent (or destructive); plates move toward each other and one sinks beneath the other.* The feature so formed is called a *subduction zone*. Subduction zones are characterized by deep oceanic trenches and chains of volcanoes on the overriding plate that parallel the trench. The amount of lithosphere cycled back into the mantle balances the amount created at divergent plate boundaries, keeping the surface area of the lithosphere constant.
3. *Transform (or conservative); plates slide horizontally against each other.* Transform boundaries are a geometrical requirement for a continuous system of moving plates on a globe, and typically link pairs of divergent and/or convergent plate boundaries. This type of boundary is defined by a transform fault, which is usually characterized by a linear fault(s) or fracture zone(s).

This system of plate boundaries is dynamic and evolving, so that a particular boundary may change location or

orientation through time, thus causing it to change morphology. They can also change from one boundary type to another or cease to function as a plate boundary while new ones appear elsewhere.

## II. DISTRIBUTION OF VOLCANISM

### A. Relationship of Volcanism to Plate Boundaries

A glance at Fig. 2 provides compelling support for the association of volcanism with plate tectonics. The distribution of most volcanoes and the locations of plate boundaries correspond very strongly. Rather than a random distribution, most volcanoes are arranged in narrow belts. Many of these exist along the edges of ocean basins—most notably the well-known circum-Pacific “Ring of Fire,” which runs around the Pacific Ocean from New Zealand to the Philippines, Japan, Kamchatka, the Aleutians, the Cascades, central America, and southward along the great chain of the Andes Mountains in South America. The association between volcanoes and the oceans was noted several hundred years ago, and volcanoes were thought to result from seawater getting into subterranean caverns. We now have a much

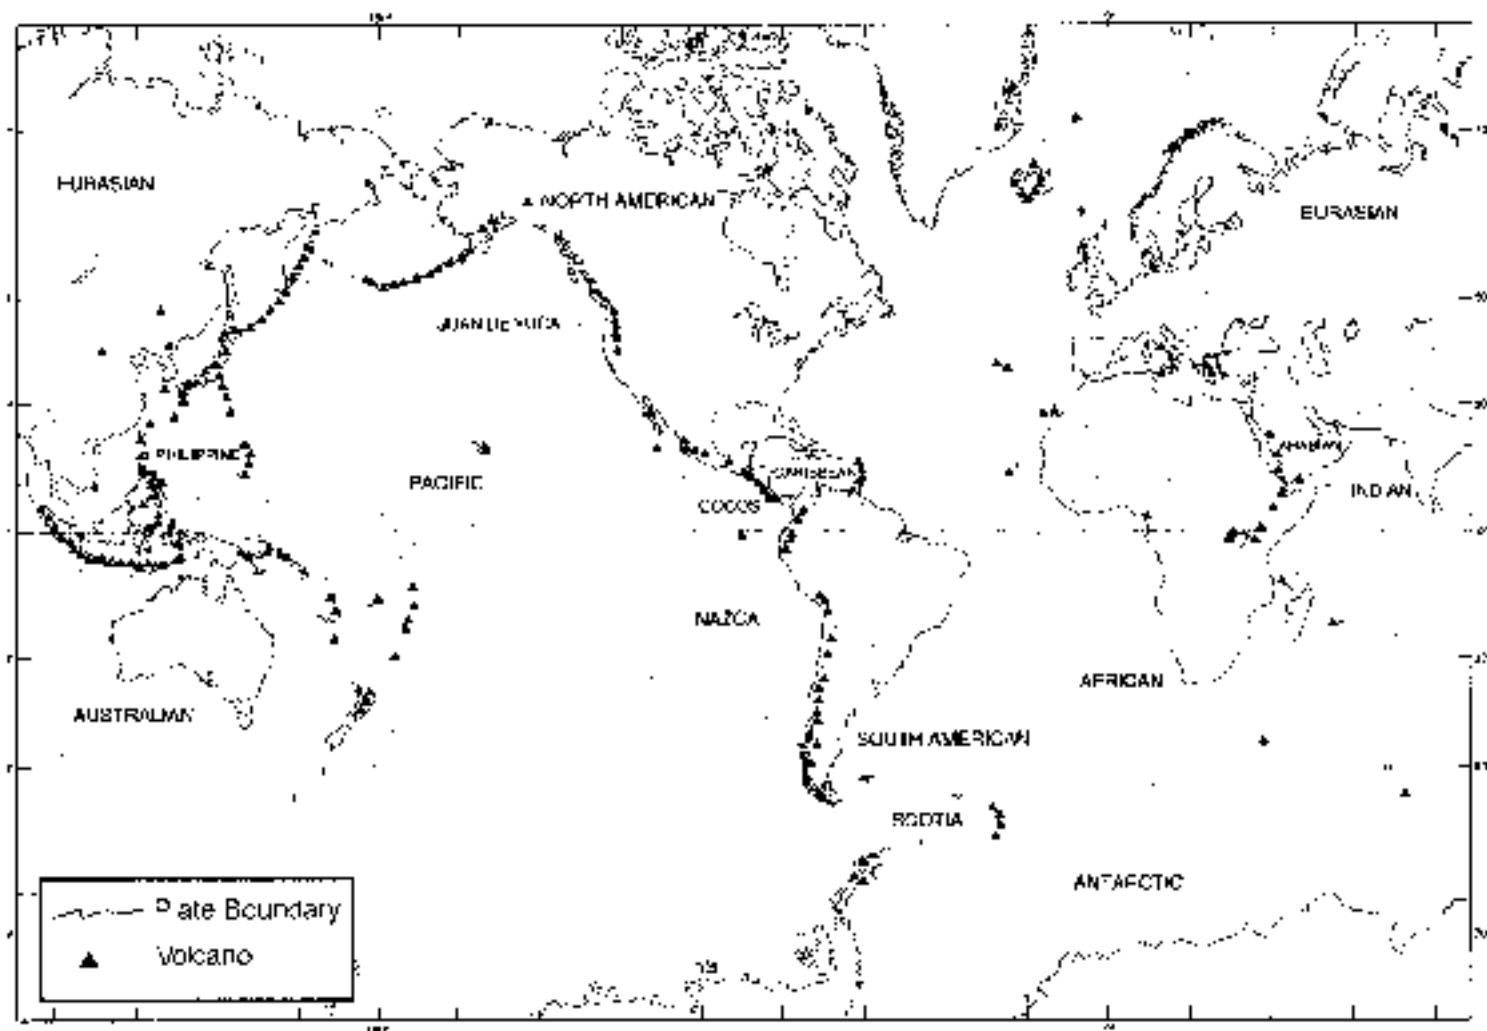

FIGURE 2 World map indicating locations of major active volcanoes and plate boundaries. [Courtesy of USGS.]

better understanding of the Ring of Fire, although interestingly, water does turn out to play an important role in the generation of magma. These volcanic chains are related to convergent plate boundaries.

Volcanism also occurs along divergent plate boundaries. This may not be as evident on Fig. 2 because (1) much of the volcanism occurs periodically along cracks or fissures and does not build volcanoes in the classical sense, and (2) most of the divergent plate margins are hidden from view, deep under the oceans. Although we have observed the effects of recent magmatic activity (young lavas, hot springs, hydrothermal vents) along divergent margins using manned submersibles and remotely operated vehicles (ROVs), we rarely actually record eruptions occurring.

The occurrence of volcanism along divergent and convergent plate boundaries or margins argues strongly for a causative mechanism. In contrast, volcanic activity rarely occurs along transform plate boundaries. There are exceptions to the association of volcanic chains with plate boundaries. Some volcanoes or small volcano groups are scattered, apparently randomly, far from plate margins. These are therefore referred to as *intratplate* or *hot spot* volcanoes. Even though they are not directly related to plate boundaries, they owe their origin to hot mantle plumes, which are related to the driving force behind plate tectonics.

## B. Influence of Plate Tectonics on Magma Generation

Magma is formed in two principal ways in the mantle (Fig. 3). The first involves simple decompression of hot, solid mantle material (from m to a on Figure 3), whereas the second involves lowering the melting temperature (solidus) of the mantle material by the addition of volatiles (especially H<sub>2</sub>O). The connection between plate tectonics and volcanism is in the ways in which plate tectonics can provide these melting mechanisms.

Mantle decompression is effected at mantle plumes and at divergent plate boundaries. In the case of plumes they are an integral part of the mantle convection system and are thought to originate near one of two major physical boundaries in the mantle; the 670-km discontinuity (boundary between the upper and lower mantle) and the core–mantle boundary (around 2900 km). Mantle plumes comprise buoyant mantle material that is solid until the pressure–temperature ascent path, which is typically thought to be adiabatic, crosses the solidus curve for mantle material of the composition repre-

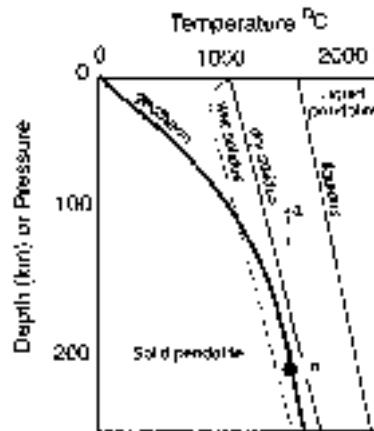

FIGURE 3 Melting mechanisms associated with the three major plate tectonic/magmatic environments. Intraplate and spreading center magmatism is represented by decompression melting, the former associated with deep-origin plumes, the latter with passive upwelling caused by lithospheric extension. Subduction zone magmatism is caused by fluid fluxing of the mantle in the wedge above the subducted slab, which lowers the melting point below the local geotherm temperature.

sented by the plume. This typically occurs at relatively shallow depths (<200 km), and leads to the production of some melt (magma) in the rising solid mantle. The mechanism and rapidity with which the melt segregates from the solid matrix is still hotly debated and very important because it is critical in determining the composition of the magma that leaves the mantle.

At divergent plate margins, mantle moves upward, in part, due to convection in the mantle but possibly more in response to the removal of the lithospheric lid above it, which is spreading laterally. The upwelling mantle partially melts in response to this process, exactly the same way as for plumes. Differences exist, however, in the compositions of the melts so formed. Such differences reflect differences in the segregation process, and in the composition of the mantle material that melts, which comes from deep within the mantle in the case of plumes, and from relatively shallow mantle depths at divergent plate margins.

The difference between plume and divergent margin magmatism is that the former is active upwelling while the latter is passive. The former is the fundamental upwelling that represents the heat advection driving plate tectonics. In principle, the location of plumes is not determined by the lithospheric geometry of the outer layer of the Earth. Divergent plate boundaries therefore may represent passive mantle upwelling—here it is the lithospheric geometry, specifically the loca-

tions of spreading centers, that are thought to largely control magmatism. Nevertheless, the distinction is not quite so clear-cut in space and time. Certainly a more careful examination of Fig. 2 might belie such a claim, particularly in the Atlantic where several hot spot volcanoes, believed to be related to plumes, are located close to the Mid-Atlantic Ridge. In fact, as explained later, it is the action of mantle plumes that, in many cases, leads to rifting of the lithosphere, making one plate into two and generating a spreading ridge as a consequence. Thus the association of plume-related volcanism with divergent plate margins is an artifact of the process of lithospheric rifting.

Melting due to lowering of the solidus (the temperature at which a solid begins to melt) is the principal cause of magmatism at convergent plate boundaries. Subduction of cold oceanic lithosphere would intuitively be expected to have a cooling effect on the mantle into which it sinks, so the occurrence of magmatism at subduction zones may be surprising. But the subducted lithosphere is not simply cold, but also water rich at its surface. The lithosphere has at its upper surface both a layer of waterlogged sediment and a layer of oceanic crust that has become hydrated as a result of seafloor alteration and hydrothermal processes that occur near spreading centers. As the oceanic lithospheric slab sinks to greater pressures and temperatures it undergoes metamorphism, which drives off the fluids into the overlying mantle wedge. The actual process of subduction may have an extra dynamic effect too. Subduction of the slab causes counterconvection in the wedge-shaped region between the slab and the upper plate, which draws hotter mantle into the region above the slab into which the volatiles are released. The overall effect is to cause melting, generating water-rich magmas, which ultimately predisposes them to become more explosive upon eruption than those erupted at other tectonic localities.

### C. Relative Volumes of Magma Fluxes

The flux of magma from the mantle to crust is concentrated along plate boundaries (Fig. 4). This magmatism is broadly correlated with heat flow. Sixty-two percent by volume of Earth's magma flux, amounting to ca. 21 km<sup>3</sup> per year, currently is found along divergent plate margins, and 26% along convergent plate margins; the remainder primarily occurs in intraplate settings. The flux is partitioned between extrusive (erupted at the surface) and intrusive, in a ratio of typically 1:9, although

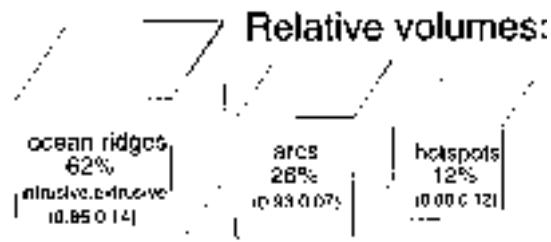

FIGURE 4 Relative volumes of magma produced at different environments. [Data from Fisher and Schmincke, 1984.]

this varies with environment. In particular, the ratio of intrusive to extrusive material is greater for the continents, where the thicker, lower density crust acts as a more efficient filter.

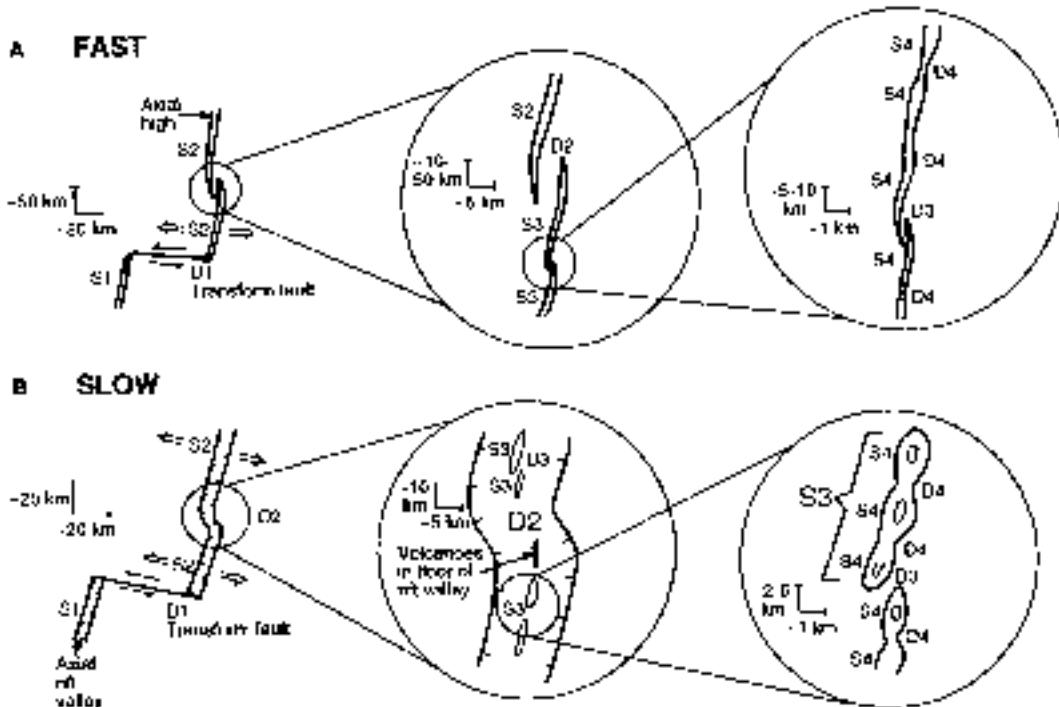

Although these averages may represent the current state of affairs, there is no reason to suppose that this is a constant steady state. The flux of plume-related volcanism in particular is highly variable over timescales of tens of millions of years. There have been specific periods in Earth history known as flood basalt events, when enormous volumes of intraplate basalts were erupted, believed to be a consequence of a large mantle plume head impinging on the base of the lithosphere. During such periods the flux of intraplate magmatism may actually dominate the overall flux, certainly exceeding the 4 km<sup>3</sup> currently erupted annually at intraplate locations.

---

## III. VOLCANISM AT DIVERGENT PLATE BOUNDARIES

### A. Structure and Tectonics at Midocean Ridges

Approximately 60% of the surface of the Earth can be considered "oceanic." Most of the oceanic crust has been formed by magmatic processes that occur at mid-ocean ridges (MORs), which form along divergent plate boundaries. These volcanic mountain ranges (which are not always in the middle of oceans) represent the largest, most continuous volcanic system on Earth. Although the ridge system is a globe encircling feature, it is broken up into segments that vary from long, first-order segments (~400–600 km) bounded by major transform faults, to short, fourth-order segments (~10 km) defined by bends or offsets in the linearity of the ridge crest (Figs. 1, 2, and 5). Ridge axis discontinuities that occur

**FIGURE 5** Diagrammatic representation of the hierarchy of MOR segmentation for (A) fast- and (B) slow-spreading ridges. S1–S4 are ridge segments of order 1–4 and D1–D4 are first- to fourth-order ridge axis discontinuities. The hierarchy of segmentation is likely a continuum and each order may develop into either higher or lower order segments with time. [From Macdonald, 1998.]

at local depth maxima along ridges can be long-lived, substantial tectonic features such as transform faults (first order), smaller (0.5–30 km) overlapping spreading centers (second and third order), or subtle (<1-km), short-lived and mobile deviations from axial linearity (Devals, fourth order). These discontinuities reflect breaks in the volcanic plumbing systems that feed the axial zone of magmatism. Recent hypotheses suggest that the shallowest and widest portions of ridge segments correspond to robust areas of magmatism, whereas deep, narrow zones are relatively magma starved. The unusually elevated segments of some MORs (e.g., south of Iceland, central portion of the Galapagos Rift, Mid-Atlantic Ridge near the Azores) are directly related to the influence of a nearby mantle plume.

Major differences in the morphology, structure, and temporal and spatial scales of magmatism along divergent boundaries vary with the rate of spreading (Figs. 6 and 7). Slowly diverging plate boundaries, which have low volcanic output, are dominated by faulting and tectonism whereas fast-spreading boundaries are controlled more by volcanism. Many of the morphologic differences observed along ridges can be explained in terms of

the competing interaction between volcanic and tectonic processes. While the balance between intrusion and extrusion at MOR axes, in general, has been difficult to constrain volumetrically, it appears that a significant amount of crustal construction occurs by intrusion at all spreading rates. The volumetric ratio of extrusive rock to intrusive rock in the oceanic crust is approximately 1:7.

The region along the plate boundary within which volcanic eruptions and high-temperature hydrothermal activity are concentrated is called the *neovolcanic zone*. It is the region where magmatism is focused at the ridge crest. The part of the ridge crest that encompasses the neovolcanic zone has variously been described as the axial valley, rift valley, inner valley floor, median valley, elongate summit depression, axial summit graben, and axial summit caldera. Differences in description are largely a result of the various morphologic expressions of the axis of the ridge crest (Fig. 6). The continuous spectrum of axial morphologies that are observed is a function of two competing processes that vary in time and space: volcanic activity, which results in the construction of relatively smooth features on the seafloor, and faulting/rifting, which results in the creation of

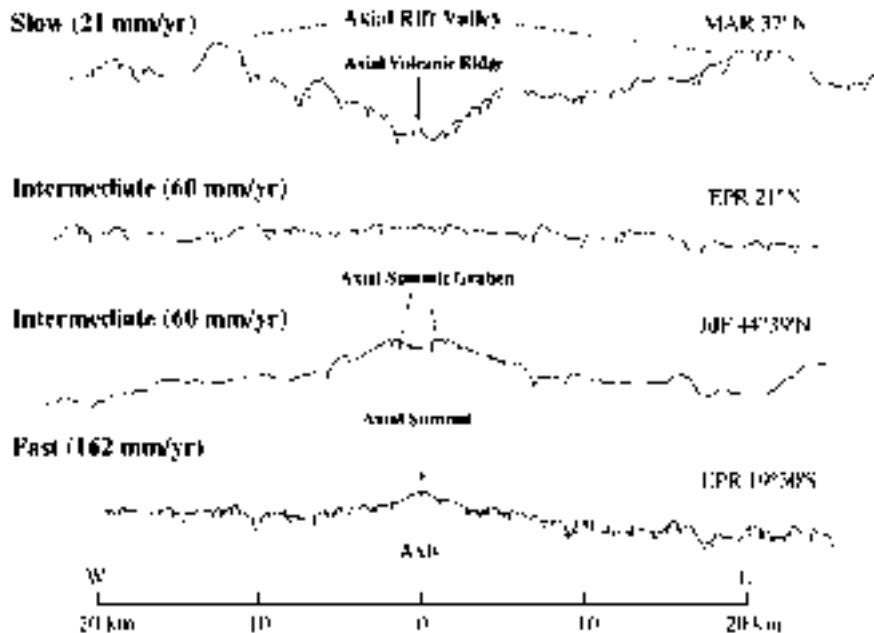

FIGURE 6 Cross-axis bathymetric profiles of selected MORs with different spreading rates. Profiles across fast-spreading (southern East Pacific Rise) and slow-spreading (northern Mid-Atlantic Ridge) ridges show the morphologic contrast between an axial high and a rift valley, whereas intermediate spreading rate ridges (Juan de Fuca Ridge) have transitional features.

rough, linear features at many scales. The width of the neovolcanic zone, its structure, and the style of volcanism within it vary considerably with spreading rate. In all cases, the neovolcanic zone on MORs is roughly linear, similar to rift zones in some subaerial volcanoes, but different than the circular craters and calderas associated with typical intraplate and convergent margin volcanoes. Not all MOR volcanism occurs along the neovolcanic zone. Relatively small, near-axis seamounts are common within a few tens of kilometers of fast and intermediate spreading ridges. Recent evidence also suggests that significant amounts of volcanism may occur up to 4 km from the axis off-axis mounds and ridges or associated with the formation of abyssal hills.

### 1. Slow-Spreading Ridges

Slow-spreading ridges (10–40 mm/yr), like the Mid-Atlantic Ridge, have large axial valleys (8–20 km wide and 1–2 km deep), and the neovolcanic zone can extend across the entire axial valley floor (5–12 km wide). The neovolcanic zone is more difficult to define because magmatism there is relatively unfocused, both across and along axis, and recent volcanic events are extremely rare. Commonly, a discontinuous axial volcanic ridge that can be up to 1–5 km wide, several hundred meters

high, and tens of kilometers wide lies at the center of the inner valley floor. Among slow-spreading ridges various axial morphologies are seen, probably related to differences in magma supply. Within single segments on slow-spreading ridges, the axial depth can vary by 1–2 km between the shallow axial highs at the center of the segments and the deeper segment ends (Fig. 7). Lava morphology on slow ridges is dominantly pillow lava, which tends to construct hummocks (<50 m high, <500 m diameter), hummocky ridges (1–2 km long), or small circular seamounts (tens to hundreds of meters high and hundreds to thousands of meters in diameter) that often coalesce to form axial volcanic ridges along the inner valley floor. The prevalence of small seamounts in the neovolcanic zone of slow-spreading ridges is in marked contrast with fast-spreading ridges where virtually no seamounts or large constructional edifices are found in the neovolcanic zone and at intermediate ridges where seamounts are only rarely associated with the neovolcanic zone.

Near-bottom observations on the Mid-Atlantic Ridge show that the inner valley floor is more faulted and fissured and large earthquakes (indicating major faulting events) are much more common than on faster spreading ridges. A high density of faults and fissures, larger earthquakes, and large axial valleys reflect the

dominance of tectonism over volcanism at slow ridges. In fact, the nature and scale of ridge segmentation on slow ridges may be primarily due to deformation processes rather than magmatic processes, which control segmentation on fast-spreading ridges. Lower magma supply, thicker crust, and deeper extent of hydrothermal cooling at slow ridges all lead to volcanic events being relatively infrequent.

## 2. Fast-Spreading Ridges

There is no axial valley on fast-spreading ridges (80–160 mm/yr full rate), but along most of an axial crest, there is

a narrow, linear depression or trough, which is typically 5–40 m deep, and 40–250 m wide that marks the locus of the neovolcanic zone (Fig. 6). The most striking characteristic of the neovolcanic zone at fast-spreading ridges is that it is very narrow (generally <2 km), indicating that most intrusions are focused beneath the ridge in a linear fashion (Fig. 8). This focusing of magmatism along the axial summit trough is apparently the direct consequence of the fast rate of plate spreading, greater magma supply, a shallower and more steady-state magma reservoir, and more frequent intrusive events than at slow-spreading centers. Lavas erupted within the trough are dominantly fluid sheet flows that vary

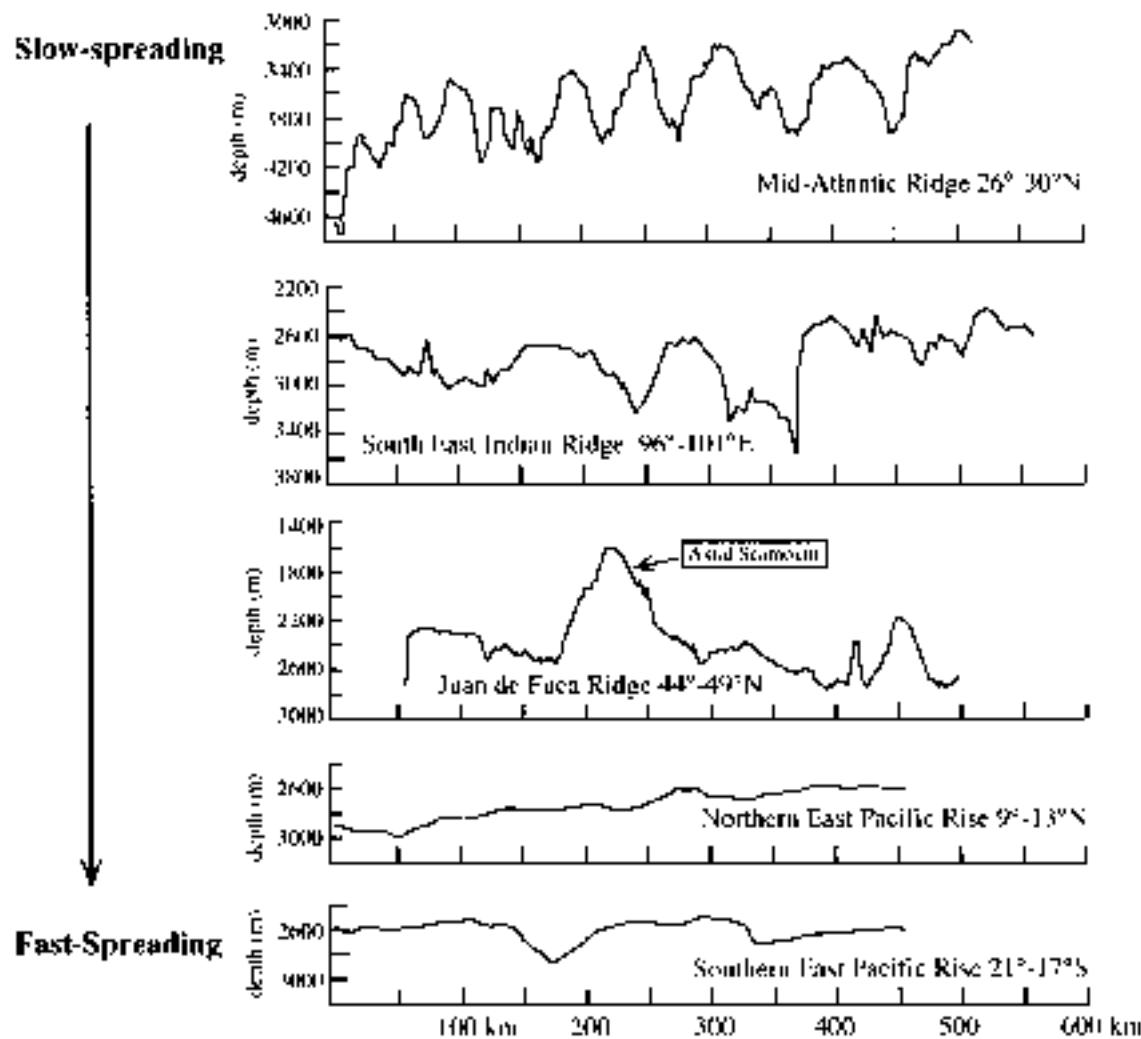

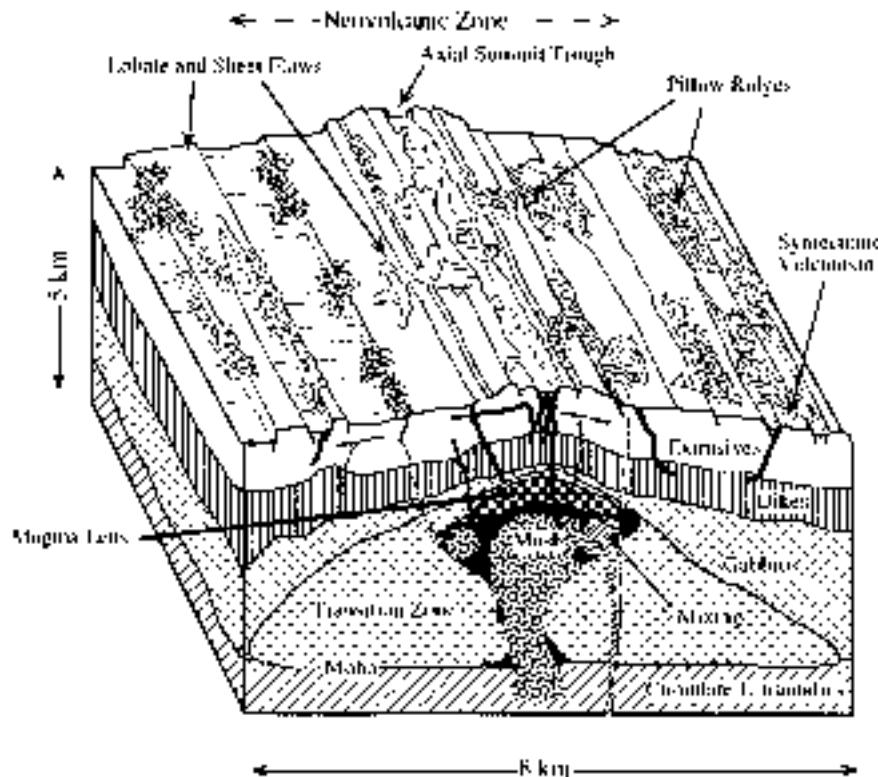

FIGURE 7 Along-axis, minimum depth bathymetric profiles of MORs with different spreading rates. The magnitude and wavelength of depth variations as well as the absolute depths change systematically with spreading rate. Note that the depth ranges differ for each ridge and the large excursion in the center of the Juan de Fuca Ridge profile is Axial Seamount, a hot spot volcano on the ridge axis. [From Perfit and Chadwick, 1998, and references therein.] Depth profile along the Southeast Indian Ridge illustrates the range of axial morphologies observed along this intermediate spreading ridge.

**FIGURE 8** Diagrammatic three-dimensional representation of oceanic crust formed along the northern East Pacific Rise [from Perfitt and Chadwick, 1998] based in part on the composite magma chamber model of Sinton and Detrick (1992). It can explain many of the chemical systematics observed in MOR basalt suites. The model proposes that there are melt-rich zones (magma lens) separate from crystal-rich zones (mush) that are variably affected by fractional crystallization, magma mixing, and crustal assimilation. Slow-spreading ridges, which do not have steady-state magma bodies, are dominated by mixing and processes such as *in situ* crystallization that occur in the mush zone, whereas magmatically robust fast-spreading ridges are most heavily influenced by fractional crystallization. The model explains why MOR basalts may vary with tectonomagmatic evolution at individual ridge segments, particularly at intermediate rates where magma lenses may be small and intermittent.

from remarkably flat and thin (<4 cm) to ropy and jumbled varieties with chaotically folded and deformed surfaces that can be tens of centimeters thick. These are in stark contrast to the bulbous, pillowed lavas that dominate slow-spreading ridges.

### 3. Intermediate-Spreading Ridges

The neovolcanic zone at intermediate rate spreading ridges (40–80 mm/yr) has morphologic characteristics that are transitional between those at fast and slow ridges (Fig. 6). However, individual ridge segments on an intermediate ridge can be significantly different in character from one another; some closer to one end member or the other. The morphology of intermediate ridges is variable, but generally consists of a small axial valley, 1–5 km wide, with bounding faults 50–1000 m high.

The neovolcanic zone is located within the floor of that valley. Well-studied intermediate ridges include the Juan de Fuca and Gorda Ridges, the Galapagos Ridge, the East Pacific Rise at 21°N, and the Southeast Indian Ridge.

The zone of focused accretion on intermediate rate ridges tends to be wider than at fast ridges but narrower than at slow ridges. There is evidence for episodic and spatially discontinuous magma supply to intermediate ridges, which helps explain the hydrothermal activity observed along intermediate ridges and the wide diversity of morphology (Fig. 6). The frequency of events is moderate, but probably variable and cyclic, more frequent during a magmatically robust phase and less frequent between such phases. The extrusive products of accretion events are also varied; both sheet flow and pillow lava eruptions are common.

Although the data are somewhat limited, calculated volumes of individual flow units that have been documented on MOR show an inverse exponential relationship to spreading rate, contrary to what might be expected. The largest eruptive units are cones in the axis of the northern Mid-Atlantic Ridge, whereas the smallest units are sheet/lobate flows on the East Pacific Rise. The data suggest that fast-spreading ridges erupt on yearly to decadal time scales; intermediate on 10- to 100-yr intervals; and slow-spreading ridges on 1000-yr to 10-ka intervals. This means that within a 10-ka time interval there may be thousands of small flows that build the crust out to ~500 m from the axes of fast-spreading ridges but only a few (<10) large flows near the axis of slow-spreading ridges. Morphologic, petrologic, and structural studies of many ridge segments suggest they evolve through cycles of accretion related to magmatic output followed by amagmatic periods dominated by faulting and extension.

### B. Types of Magmas at Divergent Boundaries

Volcanic rocks that comprise the oceanic crust primarily are low-K<sub>2</sub>O, tholeiitic basalts with very low abundances of incompatible trace elements such as Cs, Ba, Rb, U, Th, volatile elements, and the light rare Earth elements—all of which are considered to be incompatible in typical mantle mineral assemblages (see Composition of Magmas chapter). These incompatible element-depleted basalts are termed ocean floor tholeiites or, more commonly, normal midocean ridge basalts (N-MORBs). Some ridge basalts contain slightly greater concentrations of incompatible elements and are therefore termed enriched or E-MORBs. Although tholeiitic lavas occur in other tectonic localities (e.g., hot spots, island arcs), MORBs are distinctly more depleted in incompatible elements and have some of the least radiogenic isotope compositions of any terrestrial rock type. Very low abundances of volatile elements such as H<sub>2</sub>O and CO<sub>2</sub> in MORB magmas, coupled with the great hydrostatic pressures that exist on the seafloor, explain why explosive eruptions (and hence any pyroclastic rocks) on MOR are extremely rare.

Although MORB form a relatively homogeneous population of rock types when compared to lavas erupted at other tectonic localities, there are subtle, yet significant, chemical differences due to variability in source composition, extents of melting and mixing, and

processes that modify primary magmas in the shallow lithosphere (see Origin of Magmas chapter). Densely sampled sections of ridges show that quite a diversity of lava compositions can exist along individual ridge segments. Petrologic data suggest that magma is supplied from several centers of injection along axes that may correspond to second-, third-, and fourth-order ridge axis discontinuities. The melts from these magmatic focal points may coalesce to form continuous but incompletely mixed magma bodies over significant ridge lengths. Mixing of melts from depleted and enriched mantle sources in subaxial magma chambers (Fig. 8) is partly responsible for the spectrum of MORB compositions observed.

MORBs from normal, robust ridge segments typically exhibit only minor compositional variation due to relatively frequent magma recharge and mixing. However, in environments proximal to transforms, propagating rift tips and overlapping spreading centers highly differentiated FeTi basalts (basalts that are particularly enriched in iron and titanium) are common and iron-rich andesites and rhyodacites are often found. This is due to extensive fractional crystallization in crustal magma chambers as a consequence of the relatively cooler thermal regimes and the magmatic processes associated with rift propagation. In general, the paucity of primitive MORBs and the variety of evolved lava types primarily results from shallow-level fractional crystallization although deeper crystallization, magma mixing, and crustal assimilation can also play important roles. Greater estimated depths of crystallization at slower spreading ridges are consistent with observations of increased depths of magma lens or fault rupture depth with decreasing spreading rate.

MORB chemistry of individual ridge segments is, in general, controlled by the relative balance between tectonic and magmatic activity, which in turn may determine whether a steady-state magma chamber exists and for how long. Ultimately, the tectonomagmatic evolution is controlled by temporal variations in input of melt from the mantle. Global correlation of abyssal peridotite and MORB geochemical data suggest that the extent of mantle melting beneath normal ridge segments increases with increasing spreading rate and that both ridge morphology and composition are related to spreading rate.

The depths at which primary MORB melts form and equilibrate with surrounding mantle remain controversial, as does the mechanism(s) of flow of magma and solid mantle beneath divergent plate boundaries. The debate is critical for understanding the dynamics of plate

spreading and is focused on whether flow is “passive” plate-driven flow or “active” buoyantly driven solid convection. At present, geologic and geophysical observations support passive flow, which causes melts from a broad region of upwelling and melting to converge in a narrow zone (neovolcanic?) at ridge crests.

down to the brittle–ductile transition zone in the oceanic lithosphere. The associated large-scale stretching and thinning of the lithosphere results in the formation of *megamullions*—similar to core complexes in highly extended continental rift zones where deep-level crustal rocks are exposed.

### C. Faulting Associated with Volcanism

It is clear in many places on MORs that volcanism is related to faulting and fissuring of the crust (hence the concept of a “rift zone”). Graben (extensional rift valleys) often form above intruding dikes in volcanic rift zones because a dike creates two zones of maximum tensional strain at the surface, parallel to the dike axis but offset to either side. In the tectonic environment of a spreading ridge, a dike intrusion releases horizontal tensional stress that has built up by divergent plate motion since the last rifting (intrusion or faulting) event. When a dike-induced graben forms above a dike, the faulting occurs before the dike reaches the surface and once an eruption begins, lava may then fill or partially bury the graben.

Distinct graben, 10–100 m wide and 5–15 m deep, are associated with recent eruptive sites on the Juan de Fuca Ridge. These graben are interpreted to have formed directly over the dike that fed the eruptions as it was intruding. Similar, but wider, graben formation has been documented during dike intrusions in Iceland. Along fast-spreading ridges, dike-induced graben subsidence is questionable because there is little direct evidence for structural control of the axial summit trough which appears more related to volcanic drainout.

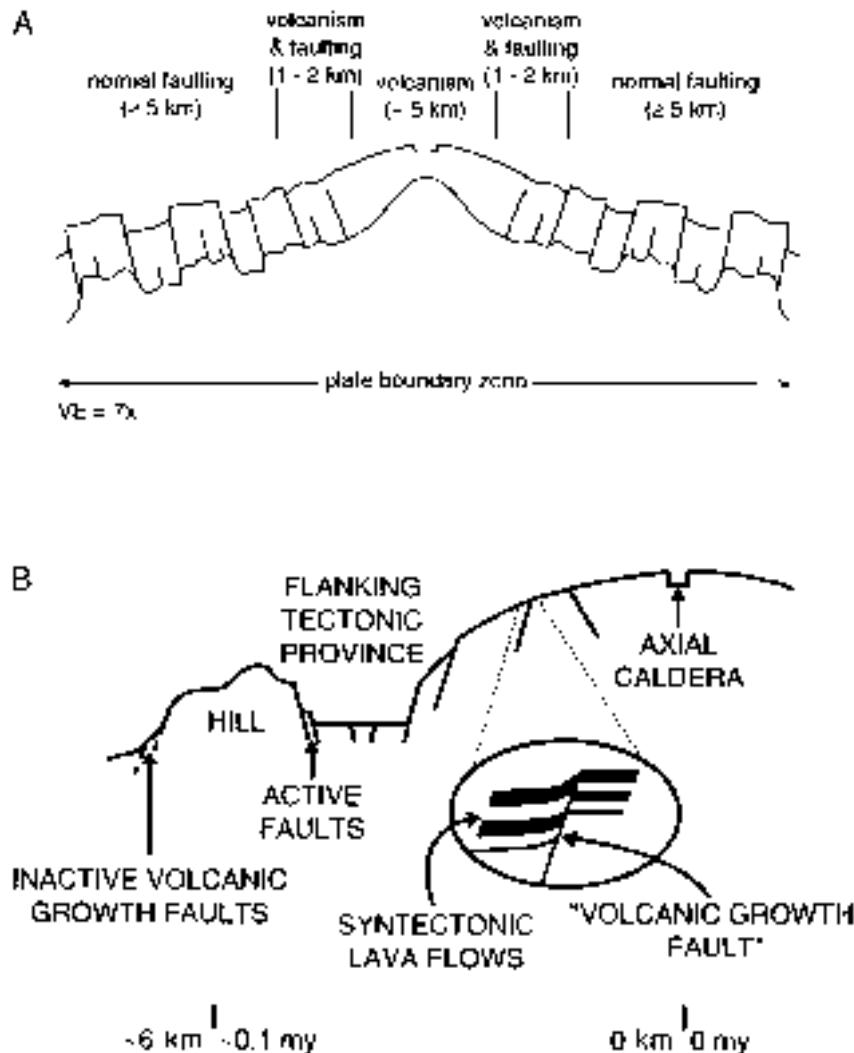

The narrow dike-induced graben observed on intermediate and fast-spreading ridges imply that a relatively low level of ambient horizontal tensional stress exists perpendicular to the ridges, whereas the wide graben that characterize slow-spreading centers suggest high levels of horizontal tensional stress. The differences in tensional regimes may be a consequence of more frequent eruptions at fast-spreading ridges (magmatically robust) compared to the infrequent eruptions at slow-spreading ridges (tectonically dominated). Horizontal extension without magmatism has led to the exposure of mafic plutonic rocks and peridotites that must come from the deep oceanic crust, and the development of strong geologic and structural asymmetry in the axes at some slow-spreading ridges. During amagmatic periods, tectonic stretching creates numerous normal faults and low-angle, listric, or detachment faults that extend

### D. Off-Axis Volcanism

Although most of the magma delivered to a MOR is focused within the neovolcanic zone, off-axis volcanism and near-axis seamount formation add significant volumes of material to the oceanic crust formed along ridge crests. Detailed sampling and U-series dating of lavas from the crestal region of fast- and intermediate-spreading rate MORs have shown that some lavas have been erupted up to 4 km outside the axial summit trough on the crestal plateau (Fig. 8). This recent off-axis volcanism is expressed as young-looking lava fields and prominent pillow ridges up to 20 m high that have a larger and more complex range of compositions than the lavas on-axis and show significant chemical variations over small spatial scales. Observational and chemical data suggest that these off-axis eruptions may be fed from different magma plumbing systems than the ones at the axis or from the distal edges of subaxial magma bodies.

In some portions of fast-spreading MORs, off-axis eruptions are related to the syntectonic volcanism and the formation of abyssal hills (Fig. 9). Volcanic growth faults form in a flanking tectonic province 2–6 km from the ridge axis, and are repeatedly covered by lava flows associated with ridge parallel faults. The lavas are interpreted to have been erupted either from the ridge axis itself or from a zone 2–3 km off-axis, consistent with the geochemical studies discussed earlier. This model for abyssal hills is specific to fast-spreading ridges, and other processes may be important at intermediate and slow ridges. On segments of slow- and intermediate-spreading MORs that are magma-starved, abyssal hill faults may rarely get covered with lava.

Some models for volcanism on MORs suggest that there is a bimodal distribution of lava flows: frequent short flows confined to the axis and occasional voluminous flows that spill out of the axial trough and flow for considerable distances. Only a few examples of extremely large (10–200 km<sup>2</sup>) lava flows or lava fields have been found on or near some sections of the MOR in the northeast Pacific and the southern East Pacific Rise. These types of flows represent tremendous volumes of lava, but it is unknown how often these kinds of events

**FIGURE 9** (A) Diagrammatic crustal cross section showing the various tectonic and volcanic zones associated with a fast-spreading ridge. The volcanic layer develops in the first 5 km and then normal faults begin to develop. These faults may be partially buried by the off-axis eruptions shown below. Abyssal hills are formed by large-scale faulting beyond the neovolcanic zone. (B) Depiction of the development of growth faults and their association with syntectonic volcanism on fast-spreading ridges. These are common off-axis features and have been proposed to explain the morphology and origin of most abyssal hills on fast-spreading centers. The cross section below shows the tectonic and volcanic zones that develop near the axis of fast-spreading ridges. [From Macdonald, 1998.]

occur, if they are the result of single or multiple eruptions, and what combination of regional tectonic and/or magmatic processes provokes such large-scale outpourings of lava near spreading axes.

### 1. Off-Axis Seamounts

Another aspect of infrequent but volumetrically significant off-axis volcanism is the formation of near-axis seamounts. These consist of small (typically <500-m-

high), singular circular volcanoes, or slightly larger (<1-km-high) cones in chains, that appear to have developed above point sources near, but off of the ridge axis. (Here we are not considering the few cases where a hot spot is centered on a ridge axis.) Off-axis volcanism is best documented on intermediate and fast-spreading ridges where the neovolcanic zone is relatively narrow. On fast-spreading ridges, seamounts do not form on the ridge crest at all, but apparently form within a zone 5–15 km from the axis. There are greater numbers of

near-axis seamounts adjacent to parts of the MOR that have a larger cross-sectional area, suggesting that more magma is available for off-axis volcanism where the axial supply is larger. On intermediate- and slow-spreading ridges, increasing numbers of seamounts are found in the neovolcanic zone with decreasing spreading rate. This dependence on spreading rate as to whether or not seamounts are excluded from the neovolcanic zone is related to the relative continuity of magma supply and the focusing of melt beneath the ridge axis. At fast-spreading ridges, seamounts do not form on axis because most of the eruptable melt generated in the mantle directly beneath the ridge is focused upward into a thin magma lens and associated crystal mush zone directly beneath the axis. Consequently, these near-axis seamounts can only form by melt diapirs that occasionally segregate from the mantle and rise outside this zone of focused upwelling. As spreading rates decrease, the zone of upwelling beneath the ridge axis is less focused and the lateral continuity of the subaxial magma lens breaks down, allowing the possibility of individual melt diapirs to rise directly beneath the ridge to form seamounts on axis. Abundant small seamounts observed on the axial valley floor of the Mid-Atlantic Ridge may result from more focused eruptions from many individual magma bodies that reside in the crust.

Craters or calderas in some chains tend to be offset from the center of the seamount in the direction toward the ridge axis. This is consistent with a model of formation in which early, rapid, voluminous extrusion is followed by a long waning stage of growth, culminating in magma withdrawal and collapse. The duration of seamount growth is a few tens of ka—long enough for plate motion to move the seamount off its relatively stationary subplate source before collapse. Many off-axis seamounts form relatively short, linear chains that are subparallel to absolute plate motions, suggesting that melting is somehow fixed in the mantle. It is not clear what deep-seated processes are involved in generating these chains of volcanoes and why they erupt from point sources over long periods of time to form distinct voluminous cones. Geometrical and geochemical arguments suggest that small thermal anomalies cause episodic melting of depleted but heterogeneous mantle sources up to 50 km away from ridge axes and rapid transport of melt via dikes to central vents. Both enriched and depleted basalts have erupted at some near-ridge seamounts in the eastern equatorial Pacific, suggesting derivation from heterogeneous mantle sources consisting of a very depleted component and one that is more enriched in incompatible elements than average ocean island basalts.

## 2. *Transform Fault Volcanism*

Although transform faults are supposed to be plate boundaries where no crust is created or destroyed, recent evidence suggests that volcanism occurs in some transform domains that offset first-order segments of fast-spreading MORs. Volcanism occurs in these locales either at small intratransform spreading centers where seafloor spreading takes place or at localized eruptive centers within the shear zones or relay zones between spreading centers. Spreading has been documented in three transform faults in the eastern Pacific: Blanco (Juan de Fuca Ridge), Siqueiros (northern East Pacific Rise) and Garrett (southern East Pacific Rise). Unlike their adjacent ridge segments, they contain a variety of basalt types that range from very depleted picritic types to highly fractionated ferrobasalts and some enriched MORBs. The diversity of magma types may simply reflect a lack of steady-state magma chambers in these magma-starved regions, which allows distinct melts to erupt without being homogenized in crustal magma chambers.

Many features on the MOR that vary with spreading rate—the width of the neovolcanic zone, the overall morphology of the ridge crest, the size and frequency of eruptions, the morphology of lava flows—appear to be fundamentally related to whether or not a steady-state magma reservoir can be sustained at a given spreading rate. This single factor has tremendous control over the volcanic output over time. Where a steady-state magma reservoir exists, volcanism can keep pace with or dominate over tectonism; where magma reservoirs are intermittent, tectonism tends to dominate. This variation in the degree of magma input also has a profound influence on the resulting structure of the upper oceanic crust, both in terms of the character of volcanic constructs and the degree of subsequent structural reorganization. The critical spreading rate, above which a steady-state magma reservoir can form and below which one cannot, appears to be about 50 mm/yr.

## IV. VOLCANISM AT CONVERGENT PLATE BOUNDARIES

### A. Architecture of Convergent Margins: Island Arcs, and Continental Margin Arcs

Magmatism at a convergent plate margin is most obviously manifest as a linear or curved chain of volcanoes

called a *volcanic arc*. The chain is broadly parallel to the trench—the deep topographic feature on the seafloor that reflects the surface trace of the plate boundary (Fig. 1). The arc can be constructed on oceanic or continental lithosphere. In the former case, since the oceanic lithosphere lies underwater, the volcanic cones are required to build up a considerable volume before the tops of the edifices rise above the surface to form islands. The chain of volcanoes so formed is accordingly referred to as an *island arc*. Several classic island arcs of this type are found around the western Pacific Ocean Basin (the Aleutians, Kuriles, Izu-Bonins, Marianas, New Hebrides, and Tonga-Kermadec arcs). These regions, known as supra-subduction zone (SSZ) settings, are very active tectonic environments where mantle-derived magmas erupt in the forearc, arc, and backarc; sediments are metamorphosed and accreted to the arc; and fragments of oceanic-like crust (ophiolites) are thrust upon the arc crust. Given a sufficiently large accumulation of magmatic material and sediment deposition and metamorphism over time, island arcs can amalgamate to form extensive land areas underlain by young arc crust, intermediate between true island arcs built directly on the oceanic lithosphere, and continental margin arcs built on old continental lithospheric basement. Examples of such intermediate character arcs include New Zealand, Japan, Kamchatka, the Cascades (northwestern United States) and Java. Volcanoes constructed on “true” (old) continental lithosphere, to form a continental margin arc, are typically wholly subaerial. The volcanic chain of the Andes Mountains along the western edge of South America is probably the best developed example of a continental margin arc today.

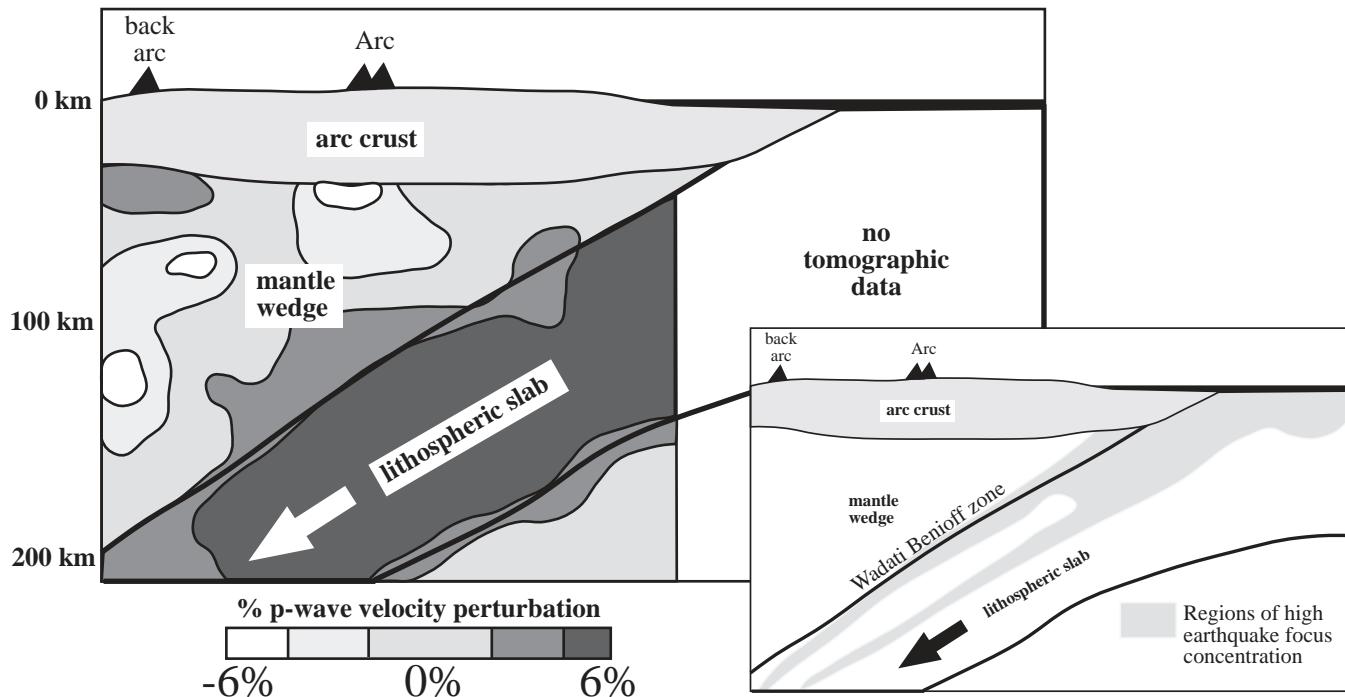

Although arcs are characterized principally by a chain of volcanoes subparallel to the trench, this chain may be broken in places (segmented) and may have superimposed cross-arc volcano chains. Segmentation may reflect structures in the subducted plate, such as transform faults, or may be largely controlled by structures in the upper plate. Careful structural analysis can commonly relate the distribution of volcanoes and their orientations to features in the lithosphere immediately underlying the arc, suggesting that local stress distribution dictates the capacity for ascending magma to reach the surface. In places, subduction may not produce volcanism on the overriding plate. The Andes, for example, exhibits a major segmentation into three currently active zones of volcanism (with second-order segmentation imposed on them) separated by nonvolcanic zones, despite continuous subduction along the entire western margin of South America. Absence of magmatism appears to accompany particularly shallow slab dips, and

changes in magmatic behavior through time at specific arcs can commonly be traced through plate tectonic reconstructions to variations in slab dip.

Subduction is a transient condition. The subducted lithosphere is always oceanic—continental lithosphere is thicker and more buoyant, and cannot be effectively subducted. Consequently, if subduction results in the convergence of two fragments of continental (or intermediate) lithosphere, the interaction between them produces deformation, and uplift—in its most dramatic manifestation producing mountain ranges such as the Himalayas, which resulted from the collision of India with Asia, following subduction of the oceanic part of the Indian Plate. Such collisions terminate subduction at that location—although new subduction zones may be initiated in response to the new plate organization and changes in stress.

## B. Types of Magmas and Volcanoes at Convergent Plate Boundaries

The mechanism of mantle melting, as alluded to earlier, is generally thought to be due to hydration of the mantle by volatiles released from the subducted slab into the mantle wedge (the corner of mantle material between the subducted slab and the upper plate) with consequent lowering of the mantle solidus (Fig. 3). This is consistent with thermal models of subduction zones, which conclude that in most cases the subducted slab is below its solidus at depths corresponding to those beneath the volcanic arc (100–150 km). There is a remarkably consistent relationship between the location of the volcanic arc front (the trench-ward limit of volcanism, along which most volcanoes are concentrated in a given subduction system) and the depth to the Wadati-Benioff zone (the inclined zone of seismicity, which corresponds roughly to the top of the slab). This depth of 100–150 km implies that the trigger for magmatism is pressure sensitive. Pressure-dependent breakdown of a hydrous phase (such as amphibole or mica) is commonly invoked as a way to release volatiles into the overlying mantle wedge. Detailed tomographic investigations of mantle structure, such as in Japan are consistent with this model (Fig. 10). It is of interest to note that where the subducted slab is present beneath an arc (or portions of one) but moving in a lateral sense rather than deeper within the mantle (e.g., Greater Antilles, western Aleutian Islands), the arc is not volcanically active. This presumably reflects the lack of continued dehydration that is required to instigate melting in the mantle. By the

**FIGURE 10** Seismic tomography of the mantle beneath Japan, from Hasegawa et al., (1991; figure courtesy of Academic Press). Fast velocities are characteristic of the slab, whereas slow velocities, which may indicate hot and/or partially molten mantle, are found in the mantle wedge above the slab.

same token, the correlation between shallow slab dips and absence of magmatism alluded to earlier probably also reflects an impediment to melting via hydration. In this case, the fluids derived by slab dehydration are introduced into the cooler, shallower lithospheric mantle—which, unlike the convecting asthenospheric wedge, is unable to melt.

The general geochemical characteristics of subduction-related magmas are discussed later. However, it is worth noting here that there are compositional variations in magmas through both time and space. Early magmatism at oceanic arcs is typically basaltic and tholeiitic in composition, while later magmatism tends to be more calc-alkaline in composition with a greater predominance of more differentiated andesitic magmas. Indeed the common occurrence of andesites (so named after the Andes Mountains) at convergent plate margins led to early suggestions that this was a primary magma composition. This broad, general (and not inviolate) trend may simply reflect the thickening maturation of the arc crust through time, leading to an increasing depth and extent of differentiation for the magmas. In the early stages of magmatism at some arcs, and toward the trench (at depths  $\ll 100$  km above the Wadati-

Benioff zone), unusual types of magmas called *boninites* are formed. These comprise high-magnesium, high-silica lavas with very low concentrations of all but the most fluid mobile incompatible trace elements. Overall, there is commonly a trend (again general and not ubiquitous) of increasing incompatible element concentrations at volcanic centers across the strike of an arc. This is expressed as the “K-*b* relationship,” which claims that potassium concentrations at a given degree of differentiation increase with depth (*b*) to the Wadati-Benioff zone. In some well-established arcs with magmatism significantly behind the arc front (large depths to the slab), K-rich and alkaline magmas (shoshonites) are erupted. This is particularly true at continental arcs (such as the Andes) although the effects of crustal contamination increasing incompatible element contents may complicate the issue here. The K-*b* relationship may be largely a reflection of the decreasing degree of partial melting with distance behind the volcanic front/depth to the top of the slab. The degree of partial melting may, in turn, be controlled by the flux of volatiles (principally  $H_2O$ ) from the subducted slab, which is high beneath the arc front—leading to high degrees of melting—but decreases as depth increases.

There are a few subduction zones in which the subducted slab appears to attain unusually high temperatures and actually melt. The slabs in these cases typically comprise very young oceanic lithosphere, which is consequently anomalously warm as it enters the trench (see Ridge Subduction section later). The compositions of magmas produced in such systems are distinct from those at “normal” arcs (high SiO<sub>2</sub>, low K), and resemble in many ways the compositions of ancient continental crust, leading to the suggestion that early crust was actually formed by high-pressure melting of basaltic crust—either deep under the continents or subducted much like today’s convergent plate boundaries. These unusual subduction-related magma compositions are referred to as *adakites*.

Volcanoes at convergent margins are diverse in their types and in their distribution. The principal type of volcano is the composite cone (see Composite Volcanoes chapter), composed of blocky lavas and pyroclastics, although most other volcano types can also be found, ranging from shieldlike volcanoes through many varieties of smaller, commonly monogenetic types such as cinder cones, lava domes, and maars. Explosive volcanism is more typical than the effusive basaltic outpourings that characterize both intraplate and divergent margin volcanism. This produces a wide range of pyroclastic deposits accompanying lava flows that are basalt through rhyolite in composition. The tendency toward more explosive eruptions is primarily a function of higher water contents in the primary magmas at arcs. The relatively protracted differentiation of primary magmas to produce andesites through rhyolites that are erupted at arc volcanoes exacerbates the explosivity by concentrating the volatiles into progressively more viscous magma.

### C. Extensional versus Compressional Arcs

Perhaps because of our perspective of living on the “horizontal” surface of the Earth, there is a tendency to imagine subduction zones as regions of compression where one plate is thrust beneath another. Indeed this prejudice is underscored by using terms like *plate collision*. In fact, subduction may be driven by the simple negative buoyancy of dense cold oceanic lithosphere, which can sink back into the mantle under its own weight. Having said this, the actual origination of subduction zones is still an area of debate and beyond the scope of this chapter.

The state of stress across the arc is actually controlled by the relative motion of both the subducting plate and

the upper plate. Sinking of oceanic lithosphere is driven by the magnitude of the density difference between it and the underlying mantle. Density of the lithosphere is, in turn, largely a function of age. When formed at a spreading center, oceanic lithosphere is hot, thin, and therefore buoyant. As it ages and moves farther away from the spreading center, it progressively cools, thickens, and becomes denser. In cases where the slab sinks rapidly, it will sweep back through the mantle like a paddle, subsiding at a steeper angle and causing the hinge line to migrate away from the arc in a process known as *slab rollback*. Despite their relative movement the two plates are in continuous contact with each other and cannot part company and leave a gap. The upper plate is, therefore, pulled along in the direction of rollback and may be extended in the process leading to backarc spreading (Figs. 11 and 12).

The age (and therefore density) of the lithosphere entering the trench may not be constant though. If the slab entering the trench becomes progressively younger, for instance as a ridge moves toward the subduction zone, it will become more buoyant. The effect will be to impede subduction. The angle of subduction will decrease, leading to a greater area of contact between

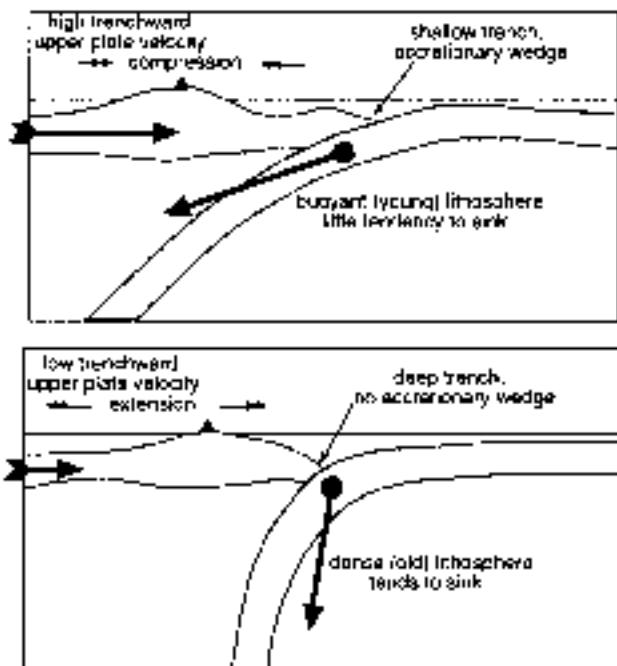

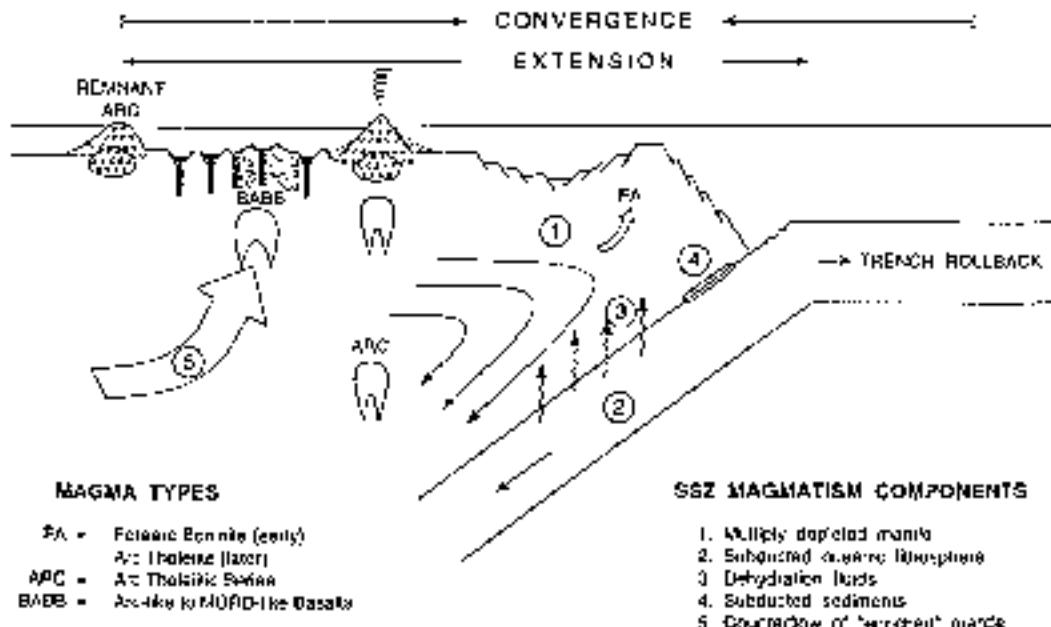

FIGURE 11 Variations in the state of stress in the arc crust as a function of relative plate velocities. If the upper plate moves rapidly trenchward the angle of subduction shallows and compression occurs. If the slab sinks rapidly and rolls back away from the trench it extends the upper plate.

**FIGURE 12** Diagrammatic cross section of an intraoceanic convergent margin showing the salient tectonic and volcanic features. The arrows and shaded areas represent sites of magma formation in different tectonic environments beneath the forearc, active arc, and backarc basin. Potential components that contribute to SSZ magmatism are numbered 1–5. [From Hawkins, 1995].

the two plates along higher viscosity lithosphere. This will cause compressional stresses to be transmitted into the upper plate and may lead to deformation such as folding and thrust faulting in the crust. It can be appreciated that the relative velocity of the upper plate is important in controlling the stress field—if the plate moves rapidly toward the trench it may lead to a shallowing of subduction and more compressive stresses (Fig. 11). The velocity of the upper plate, while controlled in part by interaction at the subduction zone, will also be affected by forces acting on any other plate boundaries surrounding it.

Volcanism is more prevalent along convergent plate margins undergoing extension than those suffering compression. Extensional stresses tend to promote magma ascent through the crust, commonly providing conduits. Compression inhibits ascent, and any additional obliquity in convergence may also lead to arc-parallel strike-slip deformation. Furthermore, the shallow angles of subduction, which are typically associated with compressional stresses in the upper plate, may actually prevent the production of magma. For example, it is fairly certain that melting at subduction zones is the result of releasing fluids from the subducted slab into the hot overlying mantle. If the slab dip is shallow, fluids are likely to be released into cooler, overlying mantle of either the lithosphere, or asthenosphere, which is impeded from

convecting by the restricted geometry of the narrow mantle wedge. Evidence for this control has been seen along the Andes today, where there are zones along which recent volcanism is absent despite ongoing subduction. These zones correspond to unusually shallow slab dips compared with the regions of active volcanism along the arc.

The different geodynamic architectures of subduction zones led to the definition of end member types—a Mariana type and a Chilean type. The former, typical of the western Pacific, involves extension and the development of backarc basins, associated with steep subduction of old lithospheric slabs. The Chilean-type margins involve shallower subduction, on occasion accompanied by compression, but in any case, generally lacking back-arc extension.

#### D. Backarc Basins

The ultimate consequence of extension in arc environments is that the upper plate riffs apart. When this happens, rifting will occur along the line of greatest weakness, which typically corresponds to the volcanic arc where the crust has been heated by magmatism. The first stages of extension may be amagmatic but continued

ripping has the effect of inducing passive upwelling in the subjacent lithosphere, which leads to magmatism and the generation of new lithosphere—effectively producing a spreading center in the SSZ setting, which is geodynamically analogous to a divergent plate boundary. The relatively deep sea that contains this spreading center is known as a *backarc basin*. As new lithosphere forms, the spreading center migrates away from the trench and the arc may be able to reestablish itself at the subduction zone. A diagrammatic representation of some of the magmatic and tectonic aspects of arc and backarc volcanism are shown in Fig. 12. Western Pacific arcs are commonly characterized by backarc basins, an observation that likely reflects the very old age of the Pacific seafloor in this region, and the consequent tendency for this dense lithosphere to sink easily.

Lavas erupted in backarc basins (backarc basin basalts, BABBs) range in composition from island arc tholeiites to MORB-like basalts that have some arclike traits (e.g., depletions in high field strength elements and slight enrichments in large ion lithophile elements and volatiles). These common transitional characteristics are a consequence of melting a multiply depleted MORB-source mantle that has been enriched by subduction-derived fluids/melts. Lesser amounts of FeTi basalts and low-K andesites recovered from backarc spreading centers are related to BABB by fractional crystallization and crustal assimilation. In some cases, these fractionated suites are associated with rift propagation in the backarc.

### E. Ridge Subduction

A consequence of plate tectonics is that ridges (and associated transforms) will, on occasion, intersect subduction zones in a configuration known as a ridge-trench *triple junction* and when this happens, divergent ridges may be consumed along the convergent margin. Theoretically, volcanism in the overlying arc may be related to (1) the subduction of “normal,” but hotter oceanic lithosphere, (2) segments where the oceanic lithosphere is missing and consequently so would any slab-derived fluids/melt, or (3) the subduction of transform faults that may allow the lithosphere to “tear” as it descends beneath the arc. There are many cases in the geologic record where triple junction migration is known to have occurred (e.g., Kula-Farallon spreading center beneath the Aleutian Islands; Kula-Pacific Ridge beneath Japan) and others that are occurring at the present time (e.g., Mendocino Triple Junction, northwest United States;

Woodlark Basin, Solomon Islands; Chile Triple Junction; Rivera Triple Junction, Mexico).

As a triple junction migrates along a convergent margin, the subducted young oceanic lithosphere is relatively hot and the divergent plate boundary may create a gap or “slab window” beneath the overlying arc (Fig. 13). A diverse group of geological effects has been ascribed to the effects of a slab window and the increased thermal input associated with it, but little consensus identifying the distinctive structural and petrologic characteristics directly related to ridge subduction. Some of the magmatic and tectonic manifestations of triple junction interactions along a convergent plate boundary include anomalous forearc volcanism, cessation of volcanism, increased volcanism, accretion of oceanic crustal sections (ophiolites) in the forearc, rapid uplift of the forearc, and intrusion of near-trench granitic rocks. Small degrees of melting of the hot, subducted oceanic slab prior to the opening of a slab window may produce adakite magmas.

The compositional variety of volcanic rocks associated with ridge subduction appears to be great—dominated

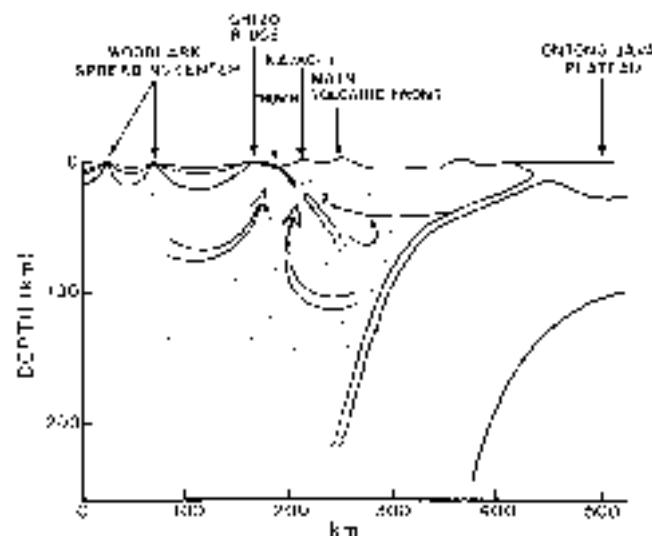

FIGURE 13 Diagrammatic cross section across the Woodlark Basin, Solomon Islands, and Ontong Java Plateau that shows the possible relationships between thickened Pacific lithosphere that is no longer subducting and young, thin lithosphere formed at the active Woodlark spreading center that is currently being subducted beneath the arc. Openings in the Woodlark lithosphere represent asthenospheric windows. Arrows represent regions where mantle sources or magmas may mix. Kavachi is an active tholeiitic volcano and Ghizo Ridge (in the Woodlark Basin) is comprised of both MORB-like and arclike lavas. Basalts erupted from the Woodlark spreading center primarily are normal MORB. [From Perfit et al., 1987.]

by arc tholeiitic and calcalkaline assemblages but also including rare boninites and sodium- and titanium-enriched basalts (NaTi basalts). The tholeiitic and calcalkaline rock types vary from picritic basalts to quite fractionated dacites. In at least two locations (Woodlark spreading center and Chile Rise), submarine volcanic rocks with oceanic, arc, or transitional chemical characteristics have been erupted along the divergent zone on the oceanic side of the plate boundary. Because of the many possible plate configurations at triple junctions, it has been difficult to make generalized statements regarding how volcanism is related to tectonics in these complex regions.

## V. INTRAPLATE VOLCANISM

### A. Plumes and Their Distribution

While the distribution of magmatism by and large coincides with the locations of plate boundaries (divergent and convergent), examination of Fig. 2 shows that there are important exceptions. The Hawaiian islands, for instance, one of the most familiar regions of volcanism, lie thousands of kilometers from the nearest plate boundary in the midst of the Pacific Plate. And there are numerous other examples of intraplate volcanoes—most of the islands in the Atlantic are not located at plate boundaries. They may be close to the Mid-Atlantic Ridge, such as the Azores and Ascension Islands, or may be at the edges of the ocean such as the Canary and Cape Verde Islands. Intraplate magmatism is scattered throughout the continents too, represented, for instance, by the Snake River Plain (Idaho, USA) and Yellowstone (Montana, USA) or the many volcanic centers on the African continent. Recent investigations indicate there may be many hundred currently active intraplate volcanoes.

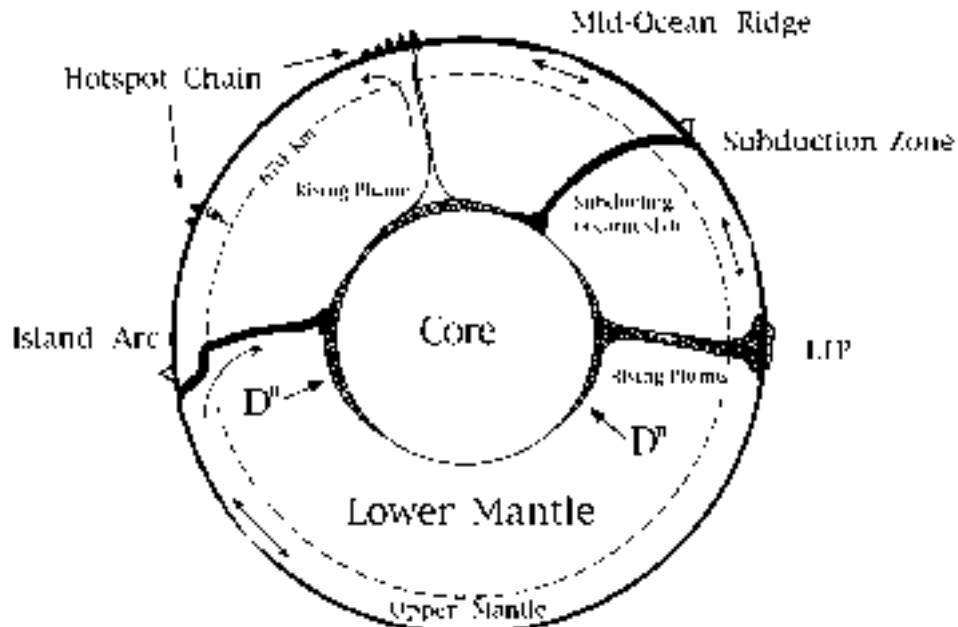

The foci of intraplate magmatism are commonly referred to as *hot spots*—an obvious reference to the high heat flow advected to the surface with the magmas. Recent geodetic surveys have correlated the locations of many hot spots with geoid highs—a rise in the gravitational potential surface—which in turn are believed to reflect the buoyancy of warmed lithosphere. Tomographic analyses of the mantle also commonly correlate the surface location of hot spots with decreases in seismic-wave velocity in the subjacent mantle. The interpretation is again that the lower velocity mantle is warmer, perhaps incorporating a small fraction of molten material (although the observation of decreased ve-

locities might also be explained by alternative mechanisms such as a greater content of H<sub>2</sub>O or CO<sub>2</sub>).

These observations, taken together, suggest that hot, low-density material is advected from depth in the mantle toward the surface. Melting occurs as the rising material undergoes decompression which takes the *P-T* trajectory across the peridotite solidus (Fig. 3). The rising material is generally referred to as a *plume*, and is considered an integral part of the Earth's mantle convection system—the principal mechanism by which heat is lost from the interior. In fact, spherical convection models representing a simple core–mantle system develop a radial convection system in which plumes (narrow axisymmetric upflow domains) rise from the lower thermal boundary layer and spread out near the upper thermal boundary layer (Fig. 14). The head of the plume displaces denser, normal asthenosphere and heats the base of the lithosphere, which leads to regional uplift, lithospheric thinning, and magmatism. Complementary zones of downflow comprise sheets or curtains of material, which to a first order seem to resemble subducted slabs, although the more sophisticated models currently under development incorporate an upper mechanical boundary layer to more realistically represent the lithosphere.

The initiation of plume ascent occurs episodically—although apparently not regularly through time. The plume begins as an instability at a deep thermal (and possibly compositional) boundary layer known as seismic layer D'', which is typically taken to be the core–mantle boundary (Fig. 14). Similar arguments have also been made for plumes initially forming at the upper/lower mantle boundary at 670 km. Fluid dynamic experiments that attempt to reproduce appropriate viscosity contrasts suggest that a plume is characterized by a voluminous plume head, which is able to entrain the ambient mantle through which it rises, followed by a thin plume tail. If plumes in the Earth are similar, we would predict that the temporal pattern of magmatism would be characterized by a voluminous outpouring as the large volume plume head reaches the depth at which it crosses the solidus, followed by a prolonged period of less voluminous but sustained magmatism. The record for much intraplate volcanism, where preserved, is consistent with this prediction.

The period of sustained magmatism produces a mass flux at the surface. Since the location of the plume is independent of preexisting plate boundaries, a hot spot trail will form on the crust as a lithospheric plate moves over the locus of the plume. The track of the hot spot is represented by a series of volcanoes aligned in the direction of plate motion that become progressively younger toward the presumed present-day location of

**FIGURE 14** Schematic cartoon showing hypothesized recycling of oceanic lithosphere into the mantle and the origin of mantle plumes from the D'' seismic layer at the core–mantle boundary. This model is based on tomographic images of the interior of the Earth based on seismic studies. Features shown and depths are not to scale. The thickness of the D'' layer is greatly exaggerated for illustrative purposes. Large igneous provinces (LIP) may form by voluminous volcanism associated with the impingement of the head of a rising plume on the base of the lithosphere. Hot spot chains may result from either shallow plumes from the 670-km discontinuity or continued upwelling of the tail of deep mantle plumes.

the plume (Fig. 14). The Hawaiian Islands are commonly cited as the classic example of such a hot spot trail. Other island chains or groups, such as the Galapagos Islands and Canary Islands, do not conform to a simple linear pattern but seem to reflect interaction of the plume head with structural features in the lithosphere. The complex distribution and timing of voluminous Cenozoic volcanism in east and central Africa may also reflect the effects of a single large plume ponding and flowing in preexisting zones of lithospheric thinning.

### B. Flood Basalts and Continental Rifting

While the distribution of lithospheric plates may have no influence on the distribution of plumes, the reverse may not be true. The burst of magmatism accompanying the ascent of a substantial-sized plume head to shallow depths may have a profound effect on the superjacent lithosphere. The specific effects depend on whether the lithosphere is continental or oceanic. If the lithosphere is continental, it may be uplifted and domed and eventually rift apart (e.g., East African Rift Valley). Voluminous outpouring of magma forms a flood basalt province or

large igneous province (LIP)—of the order of 100,000 km<sup>3</sup> or more of basalt may be erupted within a few million years. Less voluminous, more steady-state volcanism may follow as the plume tail rises to the surface. If rifting of the continental lithosphere continues to completion, new oceanic lithosphere is formed and a new divergent plate boundary is initiated. At this stage the plume and divergent plate boundary are coincident and will remain so until the plate boundary migrates in response to lithospheric processes. Many hot spots in the Atlantic are found close to the midocean ridge, reflecting their earlier role in the rifting apart of continental landmasses now located either side of the basin. The island of Iceland is actually located on the divergent plate boundary marked by the Mid-Atlantic Ridge, and chemical tracers in Icelandic lavas confirm that the magmatism is related to a deep-seated plume, believed to be the same plume responsible for initiating rifting in the north Atlantic region 60 Ma ago. Thousands of meters of flood basalts in east Greenland reflect the earliest stages of plume-related magmatism in the North Atlantic. Flood basalt records of rift initiation are commonly preserved along the margins of the ocean basin, which are now passive continental. The Parana and Etendeka basalts, now located in South America and

southern Africa, respectively, formed 130 Ma ago during the rifting event that formed the South Atlantic Ocean. Paired aseismic ridges like the Rio Grande Rise and Walvis Ridge in the south Atlantic represent traces of the plume as oceanic lithosphere was created after the continents rifted apart.

If, on the other hand, the lithosphere above the plume head is oceanic, the result is an oceanic LIP—an oceanic plateau. Plateaus such as the Ontong Java and Manihiki, in the western Pacific Ocean, represent some of the largest outpourings of basalt in the geological record (the Ontong Java Plateau is estimated to have a volume on the order of 15–18 million km<sup>3</sup>). In such cases the oceanic lithosphere, which apparently is stronger than its continental counterpart, does not rift apart. The magmas formed from decompression melting of the plume head are simply transferred into (as intrusions) or onto the surface of (as eruptions) the oceanic crust causing it to become anomalously thick (20 km thick in comparison to 7 km). The consequence of such lithospheric thickening is that it is isostatically compensated—even after the additional thermal buoyancy has waned as the plume's influence diminishes—such that its surface stands much higher than the surrounding seafloor. In this way the characteristic extensive submarine plateaus are formed. The plateaus may be topographically connected, via a hot spot chain to active plume-related regions of volcanism. The plateaus also, by virtue of their thickness and consequent buoyancy, are resistant to subduction. Upon encountering a convergent plate boundary the plateau will typically collide with material of the upper plate, whether it be continental or oceanic arc, and will terminate the subduction process at that location (e.g., Solomon Islands, Fig. 13). In this fashion, oceanic plateaus may be permanent residua of oceanic magmatism and, like arcs, may be accreted laterally to the continents. Some terranes along the northwest margin of North America and much of the Caribbean Sea, for instance, are interpreted to be oceanic plateaus that have been rafted in from their sites of origin in the Pacific Ocean Basin.

From the preceding discussion it is clear that plumes may initiate and drive rifting of the continental lithosphere. Nevertheless, not all continental rifts are convincingly associated with plumes. In some cases it appears that the magmatism is a response to lithospheric extension that is driven by plate interactions. The interior of a plate may fail if subjected to pulls from plate edge forces, such as subduction. As the lithosphere is attenuated, hot underlying asthenosphere must inevitably move up into the region beneath the rift. This decompression may then lead to melting (Fig. 3). The

relative roles of active upwelling of deep mantle plumes versus passive upwelling of shallow asthenosphere and thinned lithosphere in producing continental rift zones and their associated magmatism vary significantly. In instances such as the East African Rift the signatures of a deep mantle plume are clear—uplift and magmatism occur early in rifting and, among the volcanic rocks, the chemical characteristics associated with the deep mantle are unmistakable. The origin of rifts such as Baikal in Russia are, however, less well constrained. The paucity of magmatism here may reflect a modest passive response to rifting driven by lateral forces.

---

## VI. GEOCHEMICAL AND PETROGRAPHIC ASSOCIATIONS

### A. Processes Related to Plate Tectonics

It will become clear, as the reader progresses through this volume, that volcanoes from different plate tectonic environments are distinct in terms of their behavior, the morphology of landforms associated with volcanism, the compositions of magmas and associated volatiles, and the characteristics (textures, mineralogy, composition) of related volcanic deposits. It is the purpose of subsequent chapters to examine the petrography (mineral types, compositions, and textures) and geochemistry of volcanic rocks. By means of introduction, though, it is important to point out that these characteristics are closely related to tectonic environment since ultimately the chemistry of magmas is related to plate tectonic processes.

The two diagrams (selected from many) of Fig. 15 show compositional distinctions between rocks from different plate tectonic environments. The geochemical principles needed to understand the differences are explored more fully in the chapter titled Composition of Magma. Suffice to say that plate tectonic control is clear. Most magmas generated at spreading centers are depleted in elements considered incompatible in mantle peridotite. In particular, large ion lithophile elements such as Cs, Ba, Rb, and K have very low concentrations in MORBs (Fig. 15). This incompatible element depletion is likely a consequence of the suboceanic mantle having been previously melted to form the continental crust during the history of the Earth. In addition, most of the subridge mantle—in particular away from hot spots—has not been reenriched in these elements by secondary processes.

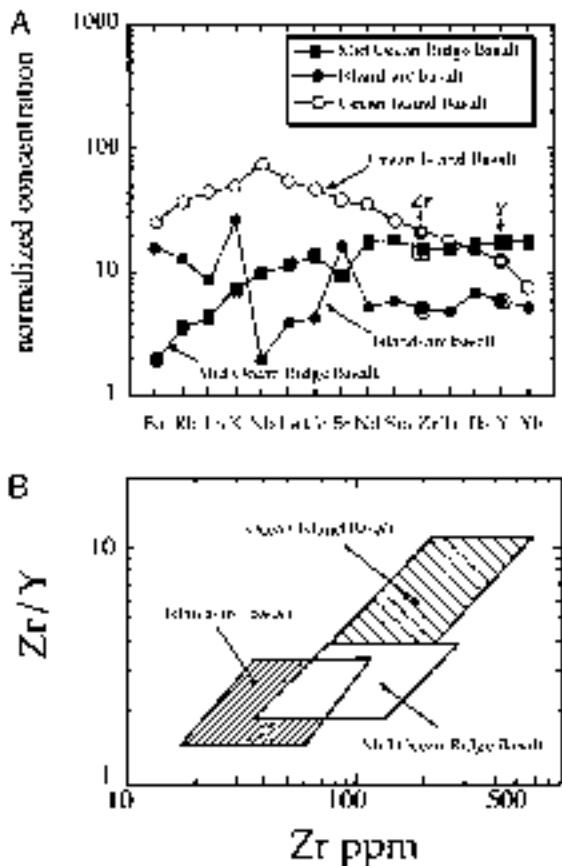

FIGURE 15 Diagrams illustrating the control that plate tectonic association has on magma composition. (A) Distribution of incompatible trace elements (incompatibility increases to the left). (B)  $Zr/Y$  versus  $Zr$  ppm discriminant diagram. [After Pearce and Cann, 1973.] The elements  $Zr$  and  $Y$  are highlighted in Part (A) to illustrate how the slope of the “spidergram” pattern relates to ratio, and to emphasize how specific ratios may be selected to provide a suitable means of discrimination among tectonic environments. Note the relatively low normalized abundances of the most incompatible elements in MORBs; hence it is believed to have been derived from a “depleted” source.

Perhaps the most distinct characteristic of the convergent margin magmas is their low abundance of a group of elements known as high-field strength elements, which includes Nb, Ta, Ti, Zr and Hf. These elements are notable in that they are highly insoluble in  $H_2O$ -dominated fluids. The mechanism of magma generation at subduction zones, by addition of fluid from the slab to the mantle, is consistent with this observation—the fluid causes a relative enrichment in most of the trace elements (including the large ion lithophiles) but not the fluid insoluble ones. The differences between divergent margin magmas and intraplate magmas are less obvious,

but the latter clearly have much higher concentrations of the most incompatible trace elements. This is consistent with derivation of intraplate magmas from a different source (mantle that has been carried from deeper levels within a plume or enriched continental mantle lithosphere), perhaps coupled with differences in the process of melt generation and the extent of partial melting—lower amounts of melting lead to more enriched magmas. The principal differences in the distribution of trace elements among magmas from different tectonic environments are emphasized in the representative patterns of Fig. 15A. Diagrams such as this, comparing the incompatible trace element concentrations (normalized to some nominal reference composition—typically an estimated composition for the primitive mantle) are colloquially referred to as “spidergrams,” emphasizing the irregular trace of the pattern—as if a spider has tracked ink over the paper! These diagrams can serve to highlight differences in behavior between specific elements or element pairs, but are limited in the number of actual samples that can be plotted before they become messy and indecipherable. Diagrams such as Fig. 15B make use of only those elements that are most distinctive in comparison—for our purposes we have selected  $Zr$  and  $Y$ . Because each sample only plots as a point, large numbers of analyses can be compiled on these types of plots.

Despite these clear distinctions there are spectra of magma compositions between the end member compositions illustrated. To a large extent this reflects concurrent variations in plate tectonic environment. Despite the clear-cut instances of magma generation introduced earlier (mantle plume, divergent plate boundary, convergent plate boundary) there are actually intermediate cases. For instance, backarc basins share properties in common with subduction zones and spreading centers—and backarc lavas are typically geochemically intermediate between MORB and arc lavas. Similarly, where mantle plumes and spreading centers are roughly coincident, such as at Iceland, the magmas are chemically intermediate between those of hot spots and those of spreading centers. The connections are illustrated in Fig. 16.

The link between magma chemistry and plate tectonic environment is sufficiently strong that it can be applied as an investigative tool for ancient rocks. In instances where the original environment in which a suite of magmatic rocks formed is unclear, as is commonly the case in deformed, ancient rock series, plotting their compositions onto discriminant diagrams, for which plate tectonic fields have been empirically defined on the basis of modern data (such as Fig. 15B), can serve to indicate the tectonic environment in which the ancient rocks most likely formed. These observations together with

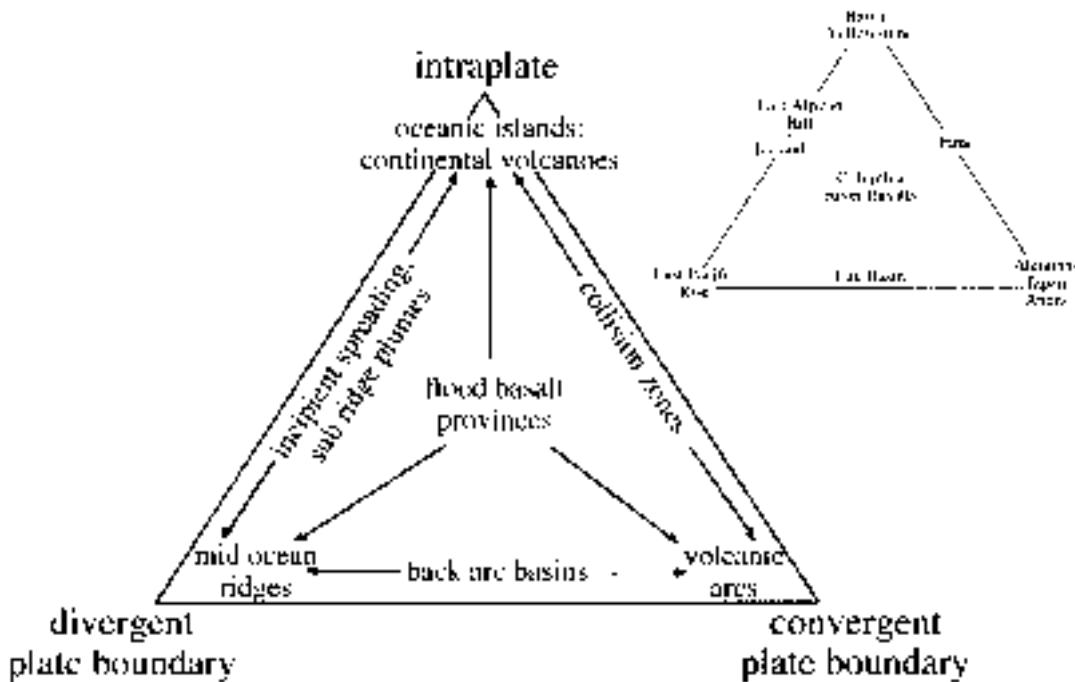

FIGURE 16 Diagram illustrating the variations that occur between the three main magma associations, which are reflected in variations in the chemistry of lavas from different tectonic environments [Figure modified after Pearce, 1996.] Some specific examples are shown in inset.

careful field mapping and integration with observations from associated rock types can enable geologists to unravel the geological history of a region.

### B. Effects of the Lithosphere on Volcanism

It was suggested earlier that the lithosphere is a fundamental product of the plate tectonic process. The crust, the chemically distinct upper layer of the lithosphere, is the product of plate tectonic-related processes in the shallow Earth, the most important of which is magmatism. The lithosphere plays an important role in modulating the character of volcanism. It acts as a filter, modifying the compositions of magmas from the time that they are generated (mostly in the asthenosphere) to eruption at the surface. The thicker and lower density the filter, the greater its effect at impeding the ascent of mantle-derived magmas, which are largely basaltic. These basaltic magmas can pond in the lower continental crust in some instances due to their greater density. As a consequence, this leads to fractional crystallization coupled with assimilation of country rock to produce less dense, more evolved and crustally contaminated

magmas that erupt on the surface. In addition, heat added to the lower continental crust may be great enough to partially melt large volumes of crust to form viscous and volatile-rich rhyolitic melts that may crystallize to form granites at depth or rise to the surface to violently erupt. This type of volcanism creates large intracontinental caldera complexes like Long Valley Caldera in California, and Valles Caldera in New Mexico, which are associated with voluminous outpourings of rhyolitic pyroclastics. In many continental regions, rhyolitic volcanics are temporally and spatially related to voluminous basaltic lavas—an association known as *bimodal volcanism*. The bimodal distribution of compositions is a consequence of both mantle-derived basalts and the rhyolites they create by partially melting the lower crust, erupting during the same volcanic episode. In some cases, the basaltic volcanism is plume related (e.g., Snake River Plain–Yellowstone) while in others (e.g., Rio Grande Rift–Jemez Volcanic Field, New Mexico) it may be due to rift-related decompression melting of the upper mantle.

It is important not to overlook the connection between magma composition and many of the volcanological and hazard-related aspects of volcanoes that will be

discussed at length later in this volume. As magmas evolve to more silica-rich compositions and concentrate water, they have an increased propensity to erupt explosively and produce pyroclastic deposits rather than effusive lavas. The evolution to silica-rich magmas is typically promoted by residence in (and partial melting of) crust. Volatile concentration occurs inevitably during evolution, but is further controlled by the original water content, which is a function of source and plate tectonic environment. Subduction-related magmas typically have higher water contents than those from other environments. It is, therefore, hardly surprising that some of the more infamous violent eruptions are associated with subduction-related volcanoes built on continental or intermediate lithosphere (Katmai, 1910; Taupo, 1800 years before present; Crater Lake 6850 years before present)

The processes of magma ponding, fractional crystallization, crustal assimilation and melting, and magma mixing in the lithosphere result in a great variety of volcanic rocks being generated. They also explain why the proportion of basalts, relative to more evolved rock types, is greater in the ocean basins than on the continents. Thus, the character of the lithosphere together with the plate tectonic environment determine many of the important characteristics of a given volcano.

## GLOSSARY

**accessory mineral** Accessory minerals are not an essential component of a rock and are often rich in a trace element. For example, sphene, a calcium titanate, is found in many granites and diorites but is not ubiquitous and is not an essential component of all granites and diorites. Other common accessory minerals include zircon (Zr), monazite (Th), rutile (Ti), allanite (REE), apatite (P), and garnet. They are usually present in small quantities (<1%).

**CFB** Continental flood basalt provinces are large volumes of dominantly tholeiitic basalt, in the form of sheet flows with few intervening sedimentary or other beds. They are thought to have been erupted in geologically short periods of time at high extrusion rates.

**compatible element** A compatible element has a high partition coefficient (*D*-value) between a mineral and a coexisting melt.

**felsic** Felsic rocks have high proportions of quartz, feldspars, and feldspathoid minerals. Granite is a felsic rock.  
**geotherm** The geotherm is defined by the variation of temperature with depth within the earth.

**HFSE** High field strength elements are those with a high ionic charge (+3, +4, +5) and a small ionic radius. Examples include Y and the heavy REE, Yb and Lu (+3); Zr, Hf, Ti, Th (+4); Nb, Ta (+5).

**incompatible element** An incompatible element has a low partition coefficient (*D*-value) between a mineral and a coexisting melt.

**LILE** Large ion lithophile elements are those trace elements with low ionic charge (+1, +2) and relatively large ionic radii. Examples include the alkali elements K, Rb, Cs (+1), and the alkaline earth elements, Sr, Ba (+2).

**mafic** Mafic rocks have high proportions of minerals rich in MgO, FeO, and CaO, that is, olivine, pyroxene, amphibole and mica. Basalt is a mafic rock. Mafic is the opposite of felsic.

**metaluminous** Metaluminous rocks are poor in aluminium ( $\text{Al}_2\text{O}_3$ ) relative to the total of calcium, sodium, and potassium ( $\text{Al}_2\text{O}_3 < \text{CaO} + \text{Na}_2\text{O} + \text{K}_2\text{O}$  expressed as molecular %). They are also rich in feldspars and aluminous mafic minerals such as biotite, hornblende, and melilite.

**MORB** Mid-ocean ridge basalts are produced at a mid-ocean ridge and are tholeiitic.

**OIB** Ocean island basalts are generated away from plate boundaries and are commonly alkaline but also tholeiitic. Generally produced from a mantle plume.

**partition coefficient (*D*-value)** This is the ratio of the concentration of a trace element in a mineral to its concentration in a coexisting liquid or melt.

**pegmatite** Pegmatites are coarse-grained, mineralogically complex veins, commonly associated with granitic rocks, containing unusual minerals of often economic significance. They are often dominated by unusual minerals, enriched in elements that are only present in trace quantities in the associated granites.

**peralkaline** Peralkaline rocks are depleted in aluminum ( $\text{Al}_2\text{O}_3$ ) relative to the alkali elements  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  ( $\text{Al}_2\text{O}_3 < \text{Na}_2\text{O} + \text{K}_2\text{O}$ , expressed as molecular %). Peralkaline rocks are rich in feldspars and feldspathoids (if  $\text{SiO}_2$  is also low) and contain Na-rich pyroxenes and amphiboles such as aegerine, riebeckite, and richterite.

**peraluminous** Peraluminous rocks are rich in aluminum ( $\text{Al}_2\text{O}_3$ ) relative to the total of calcium, sodium, and potassium ( $\text{Al}_2\text{O}_3 > \text{CaO} + \text{Na}_2\text{O} + \text{K}_2\text{O}$  expressed as molecular %). They are rich in feldspars and the excess aluminum is accommodated by minerals such as muscovite, topaz, tourmaline, garnet, and corundum.

**petrogenesis** Petrogenesis is the collective noun used to describe all those processes that contribute to the production of an igneous rock, including melt production, segregation and transport, fractional crystallization, magma mixing and contamination, degassing, and eruption or emplacement.

**radiogenic isotope** A radiogenic isotope is a stable isotope produced by the radioactive decay of an isotope of another element. For example, in the decay scheme  $^{87}\text{Rb}$  to  $^{87}\text{Sr}$ ,  $^{87}\text{Sr}$  is the radiogenic isotope produced by the beta decay of  $^{87}\text{Rb}$ .

**REE** The rare earth elements are the 15 4f series elements between La (atomic number 57) and Lu (atomic number 71). They generally have +3 ionic charge and their ionic radii decrease systematically from La–Lu.

**solidus** The solidus is the melting temperature of a rock and it varies with pressure and volatile content.

toward the surface and while some may crystallize at depth, many reach the surface at active volcanoes. Thus, volcanoes are located above zones of partial melting within the earth, but the compositions of the volcanic products depend on the causes of melting, the nature of the source material, and the processes that have affected the melt en route from its source to the surface.

Molten rocks are very rarely erupted on the surface as pure liquids. Rather they are complex mixtures of silicate liquid and crystals that may have either crystallized from the same liquid or been picked up by the melts as they moved toward the Earth's surface. *Magma* is the term given to these mobile, largely molten mixtures of liquid and solid material generated in the Earth and, probably, other planets. On Earth the liquids are generally of complex silicates complete with a range of dissolved gases including water, carbon dioxide, and other more exotic compounds. When it approaches the surface, magma generates volcanic activity during which mobile silicate lava may be erupted and solidify to form volcanic rocks. Alternatively, magma may be trapped at depth and cool more slowly to form plutonic igneous rocks that may eventually be revealed by erosion. Thus it is tempting to equate the composition of magmas with the composition of igneous rocks. However, because the processes of eruption and solidification allow volatiles to be released to the atmosphere, often explosively, and crystals to separate from the liquid, igneous rocks typically have different compositions from the magmas generated within the Earth. Despite this, great progress has been made in our understanding of the processes that lead to the compositional diversity of magmas through the study of igneous rocks, and that is the subject of this chapter.

## II. ROCK NAMES AND COMPOSITIONS

### I. INTRODUCTION

The generation of melts, and the movement and crystallization of those melts, is the primary mechanism whereby planet Earth has evolved into a core, its mantle, and the continental and oceanic crust. At the present time melting is limited to the outer 200 km of the Earth, within the crust and the uppermost layers of the mantle. Because melts are generally less dense than the source regions from which they are derived, they tend to rise

Igneous rock compositions are conventionally expressed in terms of major, minor, and trace elements. Major and minor elements are expressed as oxides:  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{FeO}$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{MgO}$ , and  $\text{Na}_2\text{O}$  (major elements) and  $\text{K}_2\text{O}$ ,  $\text{TiO}_2$ ,  $\text{MnO}$ , and  $\text{P}_2\text{O}_5$  (minor elements). Major elements are, by definition, those with oxide abundances above 1 wt%, whereas minor elements are those between 0.1 and 1 wt%. Some elements, such as potassium and titanium, are present in minor element abundances in some rocks but attain major element proportions in others. Below 0.1 wt% we enter the realm of trace ele-

ments, the concentrations of which are conventionally expressed in terms of ppm (parts per million, or  $\mu\text{g g}^{-1}$ ) of the element alone. Thus conventional chemical analyses of igneous rocks appear as in Table I, which lists the compositions of a variety of igneous rocks from selected geological environments. Volatile elements and oxides are less frequently reported but can be added to the list as  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{SO}_2$ ,  $\text{F}$ ,  $\text{Cl}$ , etc.

Two points are clear from Table I. First, igneous rock compositions vary considerably, from those with, for example, very low  $\text{SiO}_2$  to others dominated by  $\text{SiO}_2$  almost to the exclusion of other elements. The second point is that it is very difficult to assimilate such geochemical information from a list of numbers alone and igneous petrologists have devised a number of graphical methods for summarizing such data that render them more easily understood. Indeed the so-called "variation diagram" is a standard tool of modern igneous petrology, and one of the most commonly used in the definition of igneous rocks is a plot of  $\text{SiO}_2$  abundance against the total alkali content,  $(\text{Na}_2\text{O} + \text{K}_2\text{O})$ . An example of this plot is shown in Fig. 1, in which a large number of analyses of volcanic rocks are plotted and a grid superimposed to demonstrate how chemical composition can be used to define rock names.

Rock names also depend on mineralogy and grain size and, to a lesser extent, on the presence or absence of specific minerals, resulting in an even greater variety of

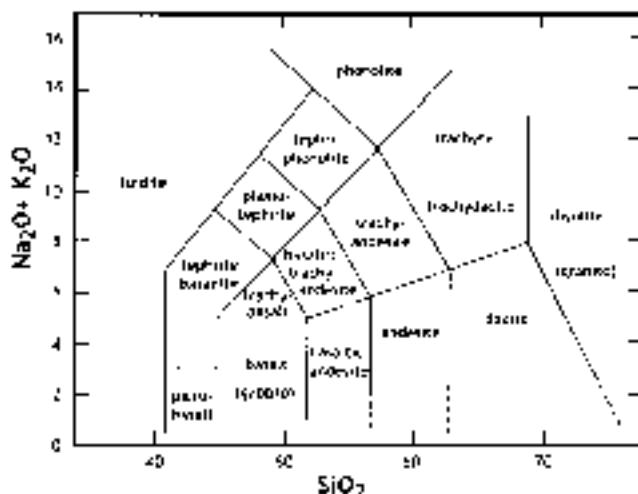

FIGURE 1 Total alkalis versus silica diagram with  $\sim 100$  volcanic rock analyses illustrating the enormous variation in rock compositions. Superimposed are the boundaries that delineate different rock types with examples of extrusive (volcanic) and intrusive (plutonic) names superimposed. (Plutonic rock names are given in parentheses.)

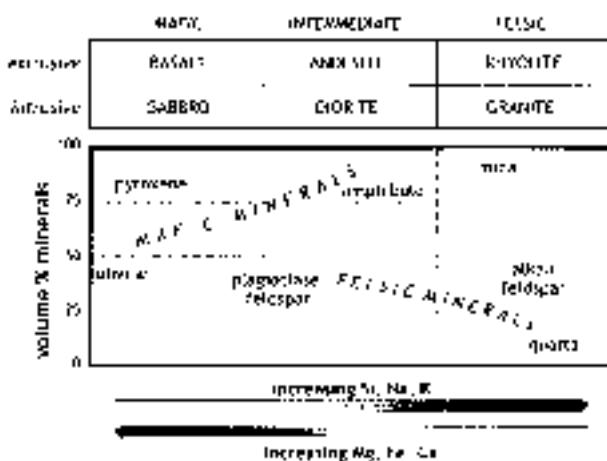

FIGURE 2 This chart summarizes the mineralogy and the general compositional characteristics of the most common igneous rock types.

names than those given in Fig. 1. In Fig. 2 the mineralogical variations of some of the more common rock types are illustrated graphically as a function of bulk composition. Thus, basalt is the name given to a volcanic rock with low Si, Na, and K; high Mg, Fe, and Ca; and a mineralogy of pyroxene, olivine, and plagioclase. However if a basaltic magma cooled slowly beneath the surface, a coarse-grained rock called gabbro would be formed. Similarly rhyolite is a volcanic rock with high Si, Na, and K; low Ca, Mg, and Fe; and is dominated by quartz and feldspar with small amounts of mica or amphibole. Its coarse-grained equivalent is granite.

The origins of the names of the commonest rock types, such as basalt and granite, are diverse and rather obscure. Others rock types recognized more recently are named after the locality where they were first identified; hence, icelandite, hawaiite, and andesite. Others record the presence or dominance of a specific mineral; for example, nephelinite (nepheline), leucite (leucite), and carbonatite (carbonate), all of which add to the complexity of igneous taxonomy. Despite this plethora of specific names, igneous rocks are dominated by two compositional types: basalts and granites. Rocks of basaltic composition dominate the crust beneath the world's oceans, whereas granitic rocks and their volcanic equivalents (rhyolite) are the most abundant igneous rock types of the continents. Indeed, the higher silica and lower iron content of granitic rocks makes them less dense than basalt and this difference is the reason why the continents are on average 5 km higher in elevation than the ocean basins. In the following two sections these two dominant magma types are described in relation to the places where they are found.

Key: MORB, midocean ridge basalt; OIB, ocean island basalt.

### III. BASALTIC MAGMAS

#### A. Major Elements and Formation

##### 1. Ocean Floor Basalts

Basalts dominate the floor of the oceans, forming the oceanic crust, which is generated at constructive plate margins at midocean ridges. Magma is produced in response to the separation of two plates, which allows the underlying mantle to rise up and melt as a result of decompression. Decompression melting is one of the major mechanisms of melt generation within the Earth and occurs when hot mantle material (peridotite) rises from depth (high pressure) to shallower levels (lower pressures) as a result of thinning of the overlying crust and lithosphere. This process is illustrated schematically in Fig. 3. As pressure is reduced, the temperature of the mantle decreases slightly (adiabatically). This decrease in temperature is less than the decrease in the melting point of the mantle (which also decreases with decreasing pressure) so that eventually the rising mantle moves from conditions of pressure and temperature in which it is solid to  $P-T$  conditions that produce a melt.

A key feature of melting in the Earth is that rocks melt over a range of temperatures, even while the pressure is kept constant. One consequence is that the composition

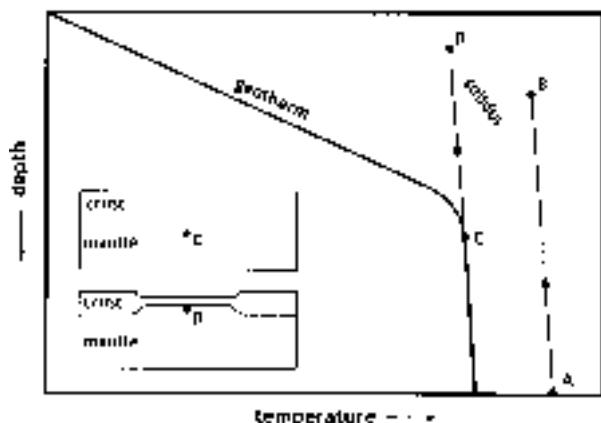

FIGURE 3 Illustration of the principles of decompression melting. A parcel of mantle lies on the geotherm at point C. If the overlying crust is rifted or extended, then that parcel of mantle rises to point D at a lower pressure but with a minimal drop in temperature. Point D is above the solidus and so the mantle melts. The vector A-B shows the trajectory of a similar parcel of mantle with a higher temperature, for example, as in a rising mantle plume. Decompression of this parcel induces melting at a greater depth and a higher degree of melting overall.

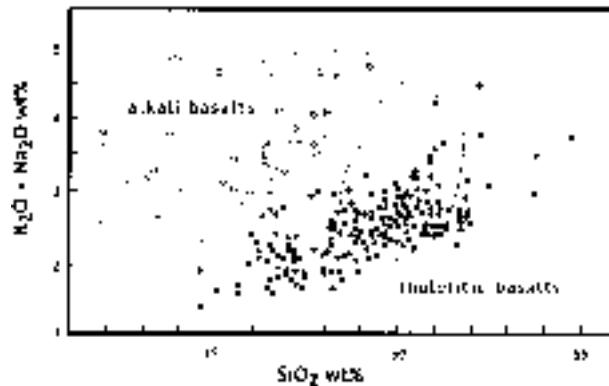

FIGURE 4 A diagram showing the variation in total alkalis and silica in basalts from Hawaii and the compositional differences between alkali and tholeiitic basalts. The outlined field represents the region in which most midocean ridge basalts plot.

of a partial melt is different from that of the initial source rock, because the different minerals within the source rock melt at different rates. In the case of the Earth's mantle, the common rock is peridotite, which is composed of four minerals: olivine, orthopyroxene, clinopyroxene, and an aluminous phase (plagioclase, spinel, or garnet). (On Fig. 2 peridotite falls to the left of basalt, having even lower Si, Na, and K and higher Mg.) These four minerals contribute to the melt in different proportions, and it is clinopyroxene and the aluminous phase that melt first—hence, the melts have higher  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  contents than peridotite, and also higher  $\text{SiO}_2$  and lower  $\text{MgO}$  contents. Such melts of peridotite are called *basalts* (Fig. 1).

Melting beneath ocean ridges occurs over a range of depths depending on the ambient temperature of the mantle (Fig. 3), and the melt that is emplaced in the crust or erupted on the ocean floor is called *tholeiitic basalt* (after the type locality in Germany). This type of basalt is poor in sodium and potassium and contains about 50%  $\text{SiO}_2$  (Fig. 4). Once emplaced within the crust, the basalt cools and starts to crystallize. However, just as melts differ in composition from their parent rocks, the material that crystallizes first has a different composition from the basaltic liquid—it is the  $\text{MgO}$ -rich mineral olivine. Olivine is denser than the basalt melt and the two are physically separated by, for example, crystal settling due to gravity. This separation leaves the basaltic melt poorer in  $\text{MgO}$  but richer in those elements not included in olivine (e.g.,  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$ , alkali elements), and so changes the composition of the liquid. As this process continues, the liquid becomes depleted in  $\text{MgO}$  and enriched in  $\text{CaO}$ ,  $\text{Na}_2\text{O}$ , and  $\text{Al}_2\text{O}_3$  and, eventually, a second mineral phase crystallizes which

is rich in these elements. This mineral is plagioclase feldspar, and it too separates from the melt, depleting the latter in CaO and Al<sub>2</sub>O<sub>3</sub>. This process is called *fractional crystallization*, and it is one of the most important magmatic processes, after partial melting, for generating the wide range in the compositions of magmas and igneous rocks (Fig. 5).

The effects of fractional crystallization on lavas erupted on the ocean floor are illustrated in the variation diagram in Fig. 6. The diagram shows how the Na<sub>2</sub>O contents vary in basaltic lavas dredged from three different regions of the midocean ridge system that encircles the earth. The diagrams show how Na<sub>2</sub>O increases as MgO decreases in each of the three examples, consistent with the removal of MgO-rich and Na<sub>2</sub>O-poor phases such as olivine, clinopyroxene, and calcic plagioclase. In fact, the samples shown in Fig. 6 are all tholeiitic basalts and the inflection in, for example, the trend labeled AAd at ~8 wt% MgO is caused by the crystallization of calcic plagioclase in addition to olivine, which is the only phase crystallizing at MgO contents above 8 wt%.

A second important feature emerges from this diagram, and that is that the basalts from the three different ridge regions lie along separate trends that do not converge on a single Na<sub>2</sub>O content at high MgO abundances. This discrepancy suggests that there is a range of different parental magma compositions with different Na<sub>2</sub>O contents for midocean ridge basalts (MORB), and debate continues as to the underlying causes of these differences. In the case of Na<sub>2</sub>O, which is an incompatible element in the mantle (see later discussion), its abundance is probably related to the amount of melting in

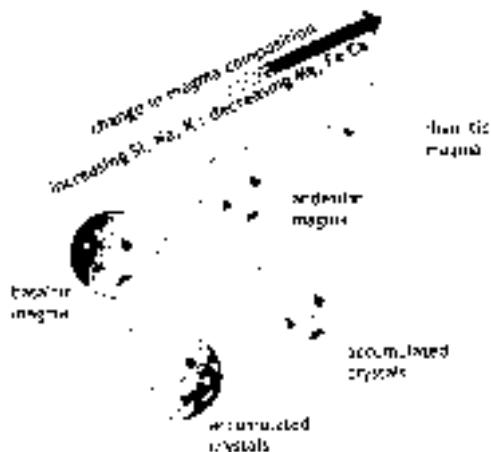

FIGURE 5 Illustration of the evolution of progressively more silica-rich magma as a result of repeated fractional crystallization. The process may be continuous or occur in a number of stages.

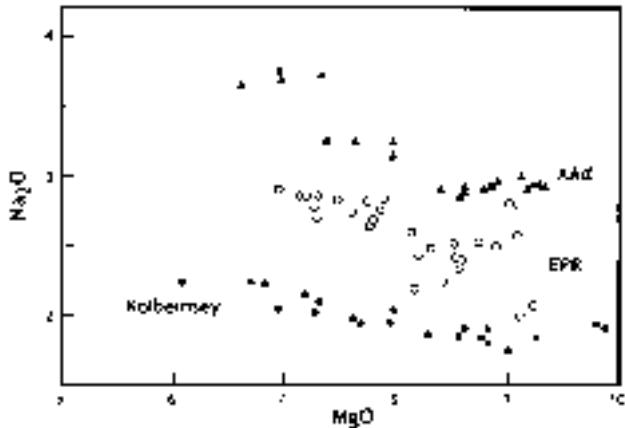

FIGURE 6 The variation of sodium with magnesium (both expressed as wt% oxides) in basalts from three segments of the midocean ridge system. The Kolbeinsey Ridge is the extension of the Mid-Atlantic Ridge, north of Iceland, the EPR is the East Pacific Rise, and the AAd lavas are from a segment of ocean ridge south of Australia (the Australia Antarctic discordance). Each region shows an increase in sodium as magnesium decreases, but the trends start at different sodium concentrations at high magnesium abundances.

the mantle. Thus for the parent of the AAd trend, melt fractions in the mantle would be small and their Na<sub>2</sub>O contents would be high, whereas for the parent of the Kolbeinsey trend they would be higher.

## 2. Ocean Island Basalts

A second important location where basalts are found is in ocean islands, such as Hawaii, Tahiti, Easter, Reunion, the Azores, and the Canary Islands, to name but a few. These active basaltic volcanoes are located away from the midocean ridges in an intraplate or within-plate setting. In these locations there is no crustal or lithospheric extension and melting is induced by the active upwelling of hot mantle, popularly known as *mantle plumes*, beneath the moving oceanic plates.

Mantle plumes can occur beneath continents as well as oceans and are an integral part of the convective overturn of the Earth's mantle. They have their origin at great depth, in some cases possibly at the boundary between the core and the lower mantle, and because the mantle within a plume is intrinsically hotter than the mantle through which it is rising, it can start melting as a consequence of decompression at a greater depth than occurs beneath the ocean ridges (Fig. 3). However, unlike the ocean ridge setting, the top of the melting regime is limited by the thickness of the overlying plate or lithosphere. Thus the average depth from which

ocean island basalts are derived is greater than that for MORB, and the amount of melt that is produced from a given parcel of mantle is less. As a result, ocean island basalts (OIB) tend to be richer in alkalis and iron and poorer in silica than MORB. Despite this change in the melting regime, larger ocean islands above large mantle plumes (e.g., Hawaii) and mantle plumes that upwell beneath constructive plate margins (e.g., Iceland) both produce tholeiites. By contrast, islands situated above smaller plumes and/or located on old and thick ocean lithosphere are characterized by a variety of basalt that has lower  $\text{SiO}_2$  but higher  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  contents than tholeiites. Such basalts are termed *alkaline olivine basalts* or *alkali basalts*. Both varieties occur on Hawaii and the total alkalis versus silica diagram can be used to discriminate between them (Fig. 4).

The mineralogical variety of alkali basalts is considerable and is a result of both a reduction in  $\text{SiO}_2$  and an increase in the alkali elements, particularly  $\text{Na}_2\text{O}$ , and other minor and trace elements. This trend toward increasing alkalinity also produces magma compositions outside the field of alkali basalts, which are generally known as *basanites* and *foildites* (Fig. 1). These tend to be the result of yet smaller degrees of partial melting than are responsible for alkali basalts and in extreme cases, also reflect the effects of  $\text{CO}_2$  on mantle melting at great depths. Rock types produced in this way include basanites, nephelinites, leucitites, and melilitites and are frequently found on smaller ocean islands, or in the final stages of volcanic activity on larger islands, such as Hawaii.

### 3. Island Arc Basalts

The third oceanic location where basalts are generated is above subduction zones where old, cold oceanic lithosphere descends back into the mantle. Subduction zones are consequently regions of generally low heat flow and at first glance it is surprising that melt should be produced in regions where the mantle is cold. However, the subducting lithosphere carries water back into the mantle temporarily trapped in sediments and in seafloor basalts that were hydrothermally altered at midocean ridges. This water is released as the subducting plate warms up and it is the fluxing of the mantle wedge overlying the subduction zone by this water that induces melting by lowering the solidus of peridotite by 2–300°C. The basalts produced in this environment tend to be tholeiitic and have a crystal fractionation assemblage similar to that of MORB.

In regions where subduction takes place beneath continents, such as beneath the Andes, the basaltic magma

may be trapped within the thick, low-density continental crust. Basaltic magma is denser than the continental crust and can only rise to a level of neutral buoyancy, often at the junction between layers of contrasting density such as the boundary between the crust and mantle (the Moho), or at boundaries within the crust. In addition the magma is richer in water, derived from the subducting lithosphere, than either ocean ridge or ocean island basalts. These differences in composition and the higher pressure of crystal fractionation have a profound effect on the composition of the crystallizing minerals and as a result basaltic magma crystallizes along a different path, producing magmas with lower iron contents (Fig. 7). Such trends are termed calcalkaline and lead to the production of an intermediate rock known as *andesite*. This rock type is named after the Andes where it is one of the dominant volcanic rock types. Calcalkaline fractionation trends and andesites result from a number of different processes, such as mixing between basalts and granitic melts, fractional crystallization of Fe-rich minerals, and complex reactions between crystallizing phases and coexisting liquid.

Further fractional crystallization of andesitic magma, possibly combined with the assimilation of crustal material, leads to the production of even more silica-rich compositions such as dacites and rhyolites. As fractionation proceeds, the concentration of water builds up in the magma because the crystallizing minerals are essentially anhydrous. The end product is a silica-rich magma charged with water, and the explosive release of water when such magma reaches the surface produces the violent volcanic eruptions that can prove so hazardous to

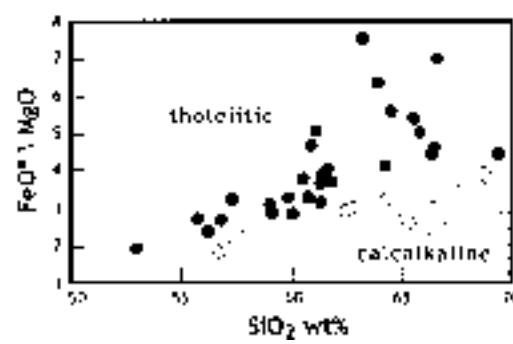

FIGURE 7 Contrasting  $\text{FeO}/\text{MgO}$  ratios in calcalkaline and tholeiitic rocks from Aso, a Japanese volcano. Fractionation of olivine and plagioclase in the tholeiitic suite produces iron enrichment and hence high  $\text{FeO}/\text{MgO}$  ratios for a given increase in  $\text{SiO}_2$ , whereas early fractionation of clinopyroxene and olivine in the calcalkaline trend produces less iron enrichment and a more rapid increase in  $\text{SiO}_2$ .

property and life close to destructive plate margins (e.g., Mount St. Helens, Pinatubo, Montserrat).

#### 4. Continental Basalts

As in the oceans, both tholeiitic basalts and alkaline basalts erupt on the continents. Rift zones, such as the East African Rift system, the Baikal Rift in Siberia, the Rhine Graben and the Rio Grande Rift in the United States are dominated by alkali basalts, basanites, and nephelinites. These are regions where the crust and lithosphere are under extension, leading to fracture and the development of rift valleys. However, the amounts of crustal and lithospheric extension are small, and so mantle melting is restricted to depths similar to that beneath ocean islands, albeit in the presence of a lithosphere that may be thicker than that in the oceans (Fig. 8). Consequently, the basalts and associated lavas from such regions broadly resemble those from the ocean islands and are dominated by alkaline compositions and their evolved derivatives, such as trachytes and phonolites (Fig. 1).

By contrast, continental flood basalt (CFB) provinces contain large volumes of tholeiitic basalts (perhaps  $>10^6$  km $^3$ ) that may have been erupted in geologically short periods of time (1–2 My). They represent vast catastrophic events, and in a number of cases it is speculated that they were linked with major mass extinctions in the fossil record, such as the eruption of the Deccan CFB, 65 Ma ago, broadly coincident with the extinction of the dinosaurs. Such flood basalt provinces are often, but not exclusively, associated with continental breakup and the development of a new ocean. Moreover, many CFB occur at the end of hot spot traces on the adjacent ocean floor, and so they are linked in some way to the presence

of a mantle plume. In general, the large volumes require the presence of anomalously high mantle temperatures, as in a plume, and an association between CFB provinces and the initiation of a mantle plume is often invoked.

As more data become available it appears that there are differences in major and trace element compositions (see later discussion), and also perhaps in the average eruption rates of different CFB. These differences may in turn reflect differences in the source regions, and in the causes of partial melting in the different CFB provinces, and an alternative view to the plume initiation theories relates CFB to the conductive heating and melting of source regions within the mantle section of the continental lithosphere.

The mantle lithosphere is the cool and relatively rigid part of the mantle immediately below the continental crust that extends to depths in excess of 100 km, and beneath the oldest continental nuclei, perhaps to 200 km. As in the oceans the mantle lithosphere beneath the continents is widely regarded as being the residue after partial melting and therefore incapable of generating further magmas. However, if it contains a small percentage of water locked up in the form of hydrous mineral phases, such as amphibole or mica, then these phases reduce the mantle solidus so that melt can be generated if the lithosphere is heated. A mantle plume impinging on the base of the lithosphere could supply the necessary heat by conduction while the release of volatiles, particularly water, would ensure the generation of a tholeiitic magma. Thus flood basalts may be produced both by a process of conductive heating prior to extension and continental breakup, by adiabatic melting within mantle plumes where they coincide with areas of extension and hence thinner lithosphere, or by melt-

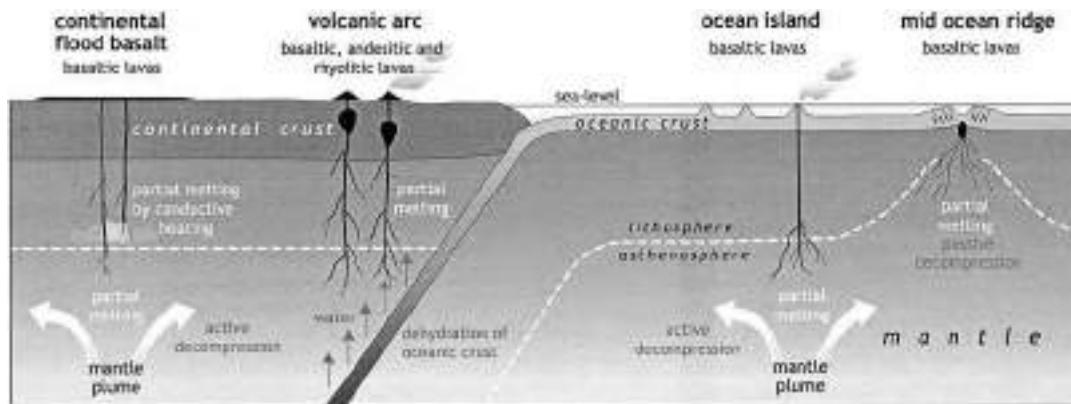

FIGURE 8 A diagrammatic section through the continent and ocean showing crust and mantle lithosphere and melting mechanisms for MORB, OIB, island arcs, and continental flood basalts.

ing of the anomalously hot regions of mantle associated with the initiation of new mantle plumes.

### 5. Summary

Basaltic magmas are generated by partial melting of the peridotite mantle by adiabatic decompression beneath midocean ridges (tholeiitic MORB), by adiabatic decompression in mantle plumes (alkalic and locally tholeiitic OIB), and by depression of the melting point by the addition of volatiles in subduction zones (tholeiitic and calc-alkaline basalts). In continental regions, basalts are also produced by adiabatic melting within mantle plumes in regions of extension although they may also be generated in response to conductive heating of lithospheric mantle that contains a small amount of volatile elements. These different mechanisms for generating melting within the mantle are summarized in Fig. 8.

## B. Trace Elements

By definition the major elements dominate the bulk composition of an igneous rock, and their relative abundances reflect the depths at which melting took place, and the amount of differentiation which has subsequently taken place. However, minor and trace elements are widely used in the study of volcanic rocks to understand the processes that produce igneous rocks because they are very much more sensitive to the amounts of melting, the residual minerals present during melting, and the element abundances in the original source rock. As an example, the major element composition of a melt changes only gradually with increases in the degree of melting, while the same residual minerals are present, and yet the abundances of some trace elements in the melt may change by two orders of magnitude between 0.05 and 5% melting. Similarly, the minor and trace element abundances of mantle peridotites vary much more than their major elements. Consequently, trace element variations in basaltic rocks are critical in assessing the origins and the scale of chemical variations in the Earth's mantle and whether different suites of igneous rocks might have been derived from similar source regions.

The distribution of trace elements in a melting or crystallizing magmatic system is often described in terms of partition coefficients, which are defined as the concentration of the element in the mineral or solid divided by its concentration in the coexisting liquid. Partition coefficients vary enormously and depend on the size and charge of the trace element cation and the size of the

crystallographic site in the coexisting mineral into which the element substitutes. In general those elements with  $D$ -values of  $<1$  are described as incompatible elements, whereas those with values of  $>1$  are described as compatible. Examples of elements that are compatible during mantle melting include Ni in olivine, Cr in pyroxene, and Yb (one of the rare earth elements) in garnet. Others, such as Zr, Nb, and the light rare earth elements, are incompatible because they do not easily fit into the structure of any common mantle mineral. Other elements become compatible within the crust. Sr and Eu, for example, fit easily into plagioclase and alkali feldspar, which are common minerals within the crust, but they are generally incompatible elements in the mantle. The relative abundances of such trace elements can therefore be used to identify the minerals that were present, either during melting or fractional crystallization. Moreover, because certain minerals are stable over particular pressure ranges, critical trace element ratios can in turn be used to infer the depths at which melting or fractional crystallization took place.

A convenient way for comparing trace element abundances in basaltic rocks is via the use of mantle or chondrite (meteorite) normalized abundance diagrams, such as those illustrated in Fig. 9. The elements are ordered in their approximate sequence of compatibility in the mantle, with the most incompatible element at the left. The elements conventionally illustrated this way include the incompatible trace elements and the minor elements, K, P and Ti. These three minor elements generally behave incompletely in the mantle, and only rarely form discrete silicate phases during mantle melting. It is only their intrinsically high natural abundances that allowed them to be recognized traditionally as minor elements.

The analyses shown in Fig. 9 include an average MORB and an average OIB. A striking feature of such diagrams is that for rocks which represent more than a few percent of partial melting, the shape of the pattern of incompatible elements in the basalts will be similar to that in their source—albeit at different abundances. Note, therefore, how the abundance pattern for the MORB has a convex upward curve, and that the more incompatible elements have lower concentrations than the less incompatible. This pattern is characteristic of MORB worldwide and reflects the broad pattern of the trace elements in their mantle source regions. The fact that there are relatively low concentrations of the more incompatible elements indicates that those elements have been preferentially removed in a previous partial melting event. In most models this depletion of the most incompatible elements in the source of MORB is attributed to a previous melting episode(s) including the

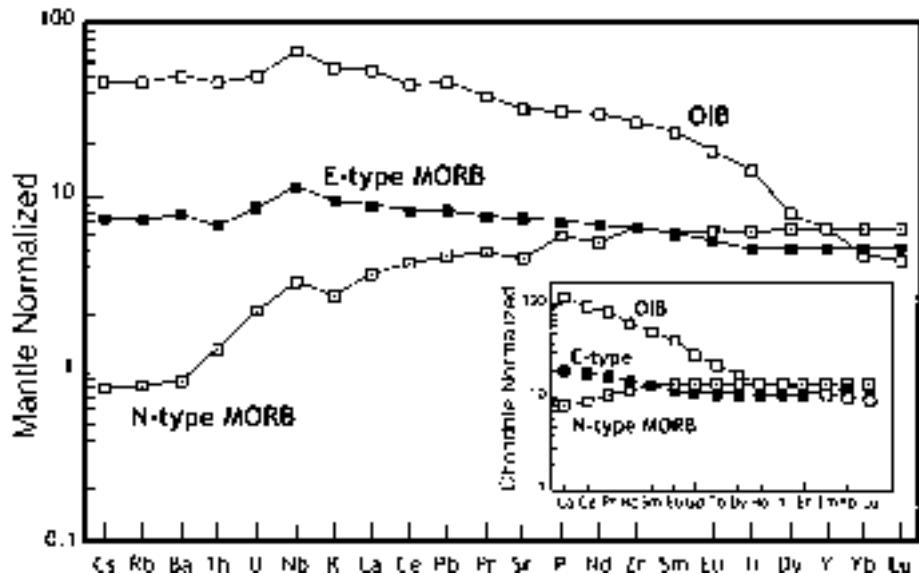

FIGURE 9 The variation of incompatible trace elements in a typical MORB and OIB. Trace elements are normalized to their concentrations in the upper mantle and arranged in order of their incompatibility, the most incompatible elements to the left of the diagram. The inset shows the rare earth elements (REE) normalized to their abundances in chondritic meteorites. Note the depletion of the most incompatible elements in N-MORBs and the low abundances of the most compatible in OIB. E-type MORBs are found in areas of the midocean ridge system close to ocean islands and imply interaction between an actively upwelling mantle plume and the MORB source; hence, their intermediate abundances of trace elements.

progressive extraction of the continental crust throughout Earth history.

In comparison to MORB, OIB have higher abundances of the more incompatible elements and slightly lower abundances of the less incompatible elements such as Y, Yb, and Lu. This difference reflects two aspects of the generation of OIB. The higher abundances of the incompatible elements are due to the smaller overall melt fraction in the generation of OIB compared with MORB, since highly incompatible elements are concentrated in the first small amount of melt to form, and simply diluted as the degree of melting increases. The lower abundances of Y, Yb, and Lu reflect their compatibility in the mineral garnet. Garnet is the stable aluminous phase in peridotite at pressures  $>25-30$  Kb, and so this evidence for the presence of residual garnet during the generation of OIB indicates that they were generated at relatively high pressures. A final point is that the trace element patterns for both MORB and OIB are relatively smooth on Fig. 9. Since the order of the elements plotted is that of increasing compatibility in common mantle minerals from left to right, the smooth patterns are indicative of partial melting of a peridotite source which itself had a relatively smooth pattern. Other basaltic rocks do not have smooth patterns (see later discussion) and show the development

of minor and trace element anomalies, which are highly diagnostic of the processes involved in their formation.

Figure 10 illustrates four analyses of basalts from the Marianas island arc on a diagram normalized to abundances in N-MORB. The differences between these

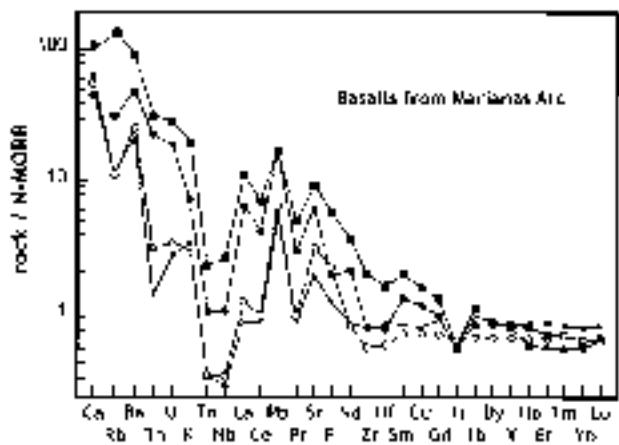

FIGURE 10 Incompatible trace element abundances of basalts from the Mariana arc, western Pacific, normalized to abundances in N-MORB (cf. Fig. 9). Note the low abundances of Nb and Ta and the high abundances of elements such as Cs, Ba, K, Pb, and Sr.

profiles and the profiles for MORB and OIB in Fig. 9 are very clear, in that the island arc basalts have high abundances of elements such as K, Rb, Ba, and Sr (large ion lithophile elements, LILE) relative to the rare Earth elements (REE), and low abundances of Nb and Ta. These latter elements, along with Zr, Hf, and Ti are referred to as the high field strength elements (HFSE), having high ionic charges but small ionic radii, and their depletion is frequently referred to as the *niobium* (or *tantalum*) *anomaly*. It may be expressed as high values of trace element ratios such as Ba/Nb, Ba/Ta, La/Nb, or La/Ta, and high values of these ratios have long been regarded as distinctive characteristics of subduction-related igneous rocks.

In detail, basalts from different arcs show a wide variety of trace element abundances with varying amounts of enrichment of the light REE and the large ion lithophile elements (LILE) and varying depletions of Nb and Ta, and sometimes Ti. What is unique about island arc rocks is that they are thought to be derived by melting of peridotite triggered by the introduction of water-rich fluids from the subducted oceanic crust. Thus, some models invoke the effect of residual Ti-rich minerals, stabilized during hydrous melting, as the cause of the Nb anomaly, while others relate element abundances in arc rocks to the differing mobilities of elements in fluids and melts derived from the material within the subducted oceanic crust. Hydrous fluids will preferentially contain the more mobile LILE, and if the slab is heated sufficiently for sediments to melt they will contribute a full range of elements, but with relative abundances distinct from those generated during anhydrous melting of peridotite. Consequently, most island arc rocks are modeled as some mixture of MORB-like melts of the mantle above the subduction zone, and both hydrous fluids and melts of sediment from the subducted crust.

In addition to subduction-related basalts, some continental basalts also have incompatible element profiles with positive and negative anomalies. Figure 11 illustrates the trace element abundances in some lavas from the Parana continental flood basalt province. Some have smooth trace element profiles similar to those from Hawaii (cf. Fig. 9, OIB), suggesting that they too were probably derived from partial melting within an upwelling mantle plume. By contrast, others show uneven trace element patterns and anomalies strikingly different from the smooth patterns seen in MORB and OIB. These CFB would therefore appear to have been derived from source regions different from those commonly present in the convecting upper mantle, and one model is that they were derived not from the convecting upper mantle, but from the mantle part of the continental litho-

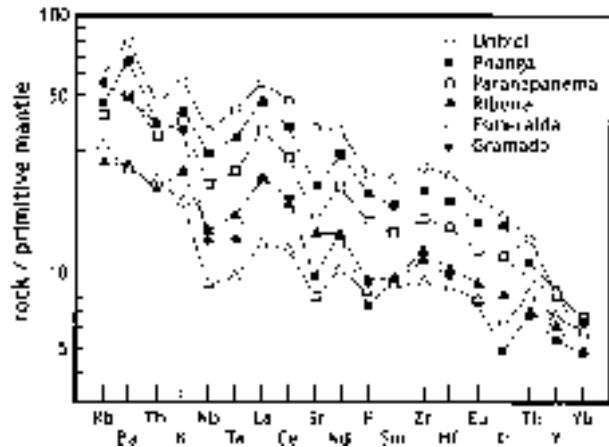

FIGURE 11 Mantle normalized trace element diagram of basalts from the Paraná continental flood basalt province. Note the negative Nb, Ta, and, in some cases, Ti anomalies and the high abundances of the LILEs, Rb, Sr, and Ba.

sphere. A second feature is that the uneven patterns of these anomalous CFB are similar to those seen in subduction-related basalts.

Much of the continental crust is thought to have been generated along destructive plate margins, and it certainly preserves a lengthy record of repeated subduction-related magmatic and tectonic events. Thus it may be that aspects of continental flood basalts reflect interaction with the continental crust. Alternatively, it is likely that during crust generation segments of the underlying mantle become isolated from the convecting interior and become incorporated into the lithosphere, which may then preserve geochemical features similar to those of island arc magmas. These enriched zones of mantle lithosphere can subsequently be melted if heated when a mantle plume impinges on the base of a continental plate, provided they contain small amounts of volatiles to lower the peridotite solidus, and would impart these characteristics to the magmas so generated.

#### IV. SILICIC MAGMAS: GRANITES AND RHYOLITES

Silicic magmas have a more restricted major element compositional range than basalts, a feature that results from the processes that lead to their production, namely, partial melting of crustal rocks and fractional crystallization of silicate melts. As their name implies, silicic magmas have high SiO<sub>2</sub> and total alkalis and low MgO and

FeO contents (Fig. 1 and 2) and their compositions lie close to the lowest melting fraction of crustal silicate systems. If, for example, a basalt is melted, then the first melt that forms has a silica-rich composition. Likewise, during fractional crystallization of a basalt, the progressive loss of minerals such as olivine, pyroxenes, and calcic-plagioclase feldspar enriches the liquid phase in silica, sodic plagioclase, and alkali feldspar. Thus two possible routes to silicic magmas exist, one by extensive fractional crystallization of basaltic magma, the other by partial melting of pre-existing crustal rocks.

As with basaltic magmas, silicic magmas can crystallize at depth to form coarse-grained intrusive rocks known as *granites* and this is the most common fate of silicic magmas. Sometimes, however, they erupt at the surface to form fine-grained or glassy volcanic rocks known as *dacites* and *rhyolite*. When this happens, the magma rapidly releases its dissolved volatiles (mainly water), resulting in a violently explosive eruption. Such events capture the public imagination because of their destructive power. Indeed, the largest and most violent volcanic eruptions in both historic and prehistoric times are related to the eruption of silicic magmas [e.g., Mt. St. Helens, Crater Lake, Yellowstone, Long Valley (United States), Santorini (Greece), Toba, Krakatoa, Tambora (Indonesia), Taupo (New Zealand)]. In the following text, for convenience silicic magmas are referred to as granites, but it should be remembered that rhyolites and dacites are chemically equivalent although their fine-grained or glassy texture often renders mineralogical classification difficult or impossible.

All granites contain alkali feldspar, plagioclase feldspar, and at least 20% quartz, and classification schemes for granitic rocks depend on a combination of mineralogy and bulk composition. The detailed nomenclature of plutonic rocks, summarized in Fig. 12, is based on the relative proportions of alkali feldspar to plagioclase. Of these different rock types, granites and granodiorites are the most abundant in the continents, closely followed by diorites and gabbros, whereas gabbros dominate the deeper sections of the oceanic crust. Syenites and monzonites are somewhat less abundant and generally restricted to the continents.

Chemical classifications add further complexity to this system but reveal important differences, possibly related to the processes of magma formation. The primary classification depends on the molecular ratio  $\text{Al}_2\text{O}_3/(\text{Na}_2\text{O} + \text{K}_2\text{O} + \text{CaO})$ . If this is less than 1, then the granite is defined as metaluminous; whereas if it is greater than 1, it is peraluminous. Metaluminous granites tend to be rich in sodium and are often associated with a broad range of other igneous rocks. Peralumi-

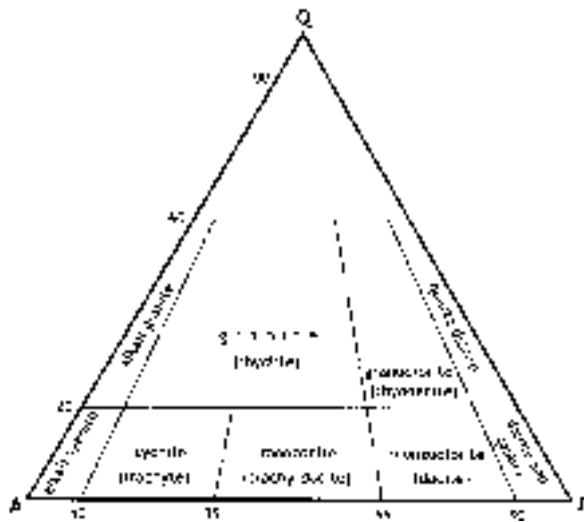

FIGURE 12 The mineralogical classification of plutonic rocks. Q refers to the amount of quartz in the rock, P the amount of plagioclase, and A alkali feldspar. Granites (*sensu lato*) include all those rock types with more than 20% quartz, whereas those rocks with less than 20% quartz are classified as intermediate. Note that on this diagram basaltic and andesitic rocks are restricted to a small region close to the P apex because they are dominated by plagioclase feldspar, pyroxenes, and olivine.

nous granites have lower sodium contents, but are richer in potassium and tend to be restricted in their association to high-silica magmas. An alternative classification divides granites at value of the  $\text{Al}_2\text{O}_3/(\text{Na}_2\text{O} + \text{K}_2\text{O} + \text{CaO})$  ratio of 1.1. Above this ratio (i.e., highly peraluminous) granites are classed as "S-type," while below a value of 1.1 they are "I-type." It is generally thought that I-type granites are derived, either by fractionation or partial melting, from igneous precursors, whereas S-type granites are derived from melting of pre-existing sedimentary rocks. The value of such classifications based on petrogenetic theories remains debatable.

A subcategory of I-type granites is the peralkaline or A-type granites, in which the critical compositional parameter is the molecular ratio  $\text{Na}_2\text{O} + \text{K}_2\text{O}/\text{Al}_2\text{O}_3 > 1$ . Such granites tend to be associated with alkaline basalts in within-plate or continental rift environments and they are often rich in volatiles such as  $\text{F}_2$  and  $\text{CO}_2$ .

The trace element contents of granites are considerably more variable than those in basalts, largely because of the effect of small amounts of accessory minerals such as zircon, monazite, allanite, and titanite that can accommodate high concentrations of many trace elements. However, the abundances of critical trace ele-

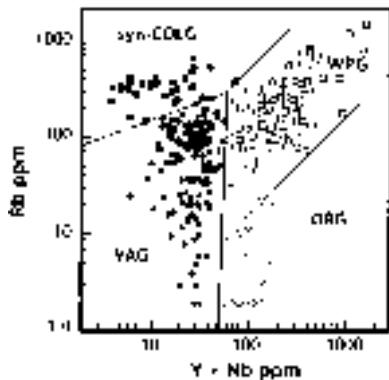

FIGURE 13 Trace element discriminant diagram for granites from contrasting geological environments. VAG, granites from volcanic island arcs (I-type); ORG, granites from ocean ridges; WPG, granites from within-plate environments (A-type); syn-COLG, granites produced in continental collision zones (S-type).

ments can be used to discriminate between granites formed in different geological environments, in the same way that characteristic interelement ratios in basalts can be used to indicate different geological regimes. One example is shown in Fig. 13, which illustrates that granites from oceanic environments have particularly low Rb contents but high Nb+Y, whereas those from volcanic arcs have low values of both. Peralkaline granites from within-plate environments have moderate to high Rb and Nb+Y, whereas granites in continental collision zones have high Rb and generally low Nb+Y.

These differences in trace element contents mirror those of basalts in the same environments, such that within-plate basalts are enriched in Nb and Y, whereas these elements are less abundant in arc or midocean ridge environments. To a greater or lesser extent, these similarities are the result of the processes that are unique to different geologic settings and the controlling effect of critical phases during basalt and granite melt generation.

Volatile, particularly water, play an important role in crustal melting. Water decreases the melting temperature of crustal rocks, in much the same way it does in the mantle, and it is the dehydration of water-bearing minerals, such as biotite, muscovite, and amphibole, that allows the production of large volumes of granitic melt at moderate temperatures within the crust. Furthermore, magmas rich in SiO<sub>2</sub> are very viscous because the Si–O bonds link to form chains and complex three-dimensional structures within the melts. In general the higher the silica content of a magma, the more highly structured the magma is and the higher its viscosity. Volatiles,

particularly water, break the Si–O bonds and so reduce the viscosity, enabling the melt to move through the crust more readily. Thus water has a dual role in granite formation, first by reducing the melting temperature of crustal rocks and, second, by reducing the viscosity and enabling the magma to rise to shallower levels in the crust.

As a final emphasis on the importance of water in the evolution of silicic magmas, it is instructive to explore the effect water has on the melting point of granite (Fig. 14). The ability of a granite to dissolve water increases as pressure increases, thereby reducing its melting point considerably. However, hydrous minerals are stable within the crust to higher temperatures than the water-saturated granite solidus, and if the temperature is increased and the hydrous mineral breaks down, the ensuing release of water will induce melting. The water-bearing granitic magma produced by this reaction can then rise to a shallower depth (lower pressure) within the crust, as shown by the downward pointing arrow on Fig. 14. However, it can only rise as far as the water-saturated liquidus curve because at pressures below this, even silicic magmas saturated with water solidify. This is the primary reason why most silicic magmas stall at depth and solidify as granites rather than reaching the surface to erupt as rhyolite.

During solidification of granite magma, the volatiles are released from the magma in the form of a high-temperature fluid. This fluid is highly reactive and mobile and transports elements that do not easily fit into the feldspar-rich granite in the rocks surrounding the

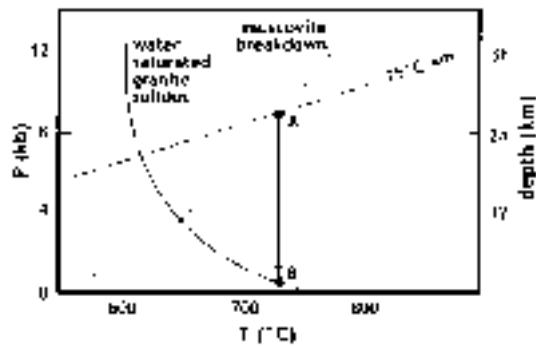

FIGURE 14 A graph of pressure against temperature showing the water-saturated solidus of granite, that is, the temperature at which granite melts in the presence of excess water. Water released by the breakdown of a water-bearing mineral, such as mica or amphibole, induces melting at point A. This melt rises along the line A–B until it intersects the water-saturated solidus at B, at which point the granite solidifies and moves no further.

granite. Thus granites are commonly associated with economic deposits of metal-rich minerals and the differences in the volatile phases associated with different types of granites leads to variations in the style of mineralization and their economic importance. For example, metaluminous granites, such as those in the Andes, are often characterized by Cu-Mo mineralization in the well-known "copper porphyry" association. Peraluminous granites, as for example in the Cornubian batholith of southwest England, have a range of mineralization that includes Sn and W-greisens, tourmaline (boron) mineralization, and veins of Pb and Zn sulfides. This variety in part reflects the heterogeneous crustal source regions of peraluminous granites. Finally, peralkaline granites often include rare metal pegmatites, rich in Nb, Ta, P, Cs, the rare Earth elements, and Y.

In summary, silicic magmas are produced by partial melting in the crust and the details of their compositions are controlled by the nature of their source regions (i.e., igneous or sedimentary). Their production, mobility, and final crystallization are controlled by volatiles, particularly water, and on those occasions when they do reach the surface they produce the most violent volcanic eruptions. If, however, they freeze at depth they are responsible for many of our important economic mineral deposits.

## V. IGNEOUS ROCKS AND RADIogenic ISOTOPES

One of the major goals of terrestrial geochemistry is to determine how and when the Earth differentiated into the core, the mantle, and the crust. Such problems require information on the age of the crust and the complementary residual portions in the upper mantle, and the continuing fluxes of elements between the different reservoirs in the crust and the mantle. To determine *when* chemical changes took place, it is necessary to use *radiogenic isotopes*, that is, those produced by the decay of long-lived radioactive parent isotopes. Their increasingly routine application since the 1960s has revolutionized many areas of the Earth sciences. They are also widely used as tracers for the different materials that may have contributed to the generation of different magmas, and their application has revealed the hybrid nature of many of the igneous rock types that occur at the Earth's surface.

Isotope abundances are extremely difficult to mea-

sure, and so radiogenic isotopes are presented normalized to a stable isotope the abundance of which is not changed by the processes of radioactive decay. The most widely used isotopes are those of strontium, among which  $^{87}\text{Sr}$  is generated by radioactive decay from  $^{87}\text{Rb}$  with a half-life of  $4.88 \times 10^{10}$  yr. A measured  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio then depends on the  $^{87}\text{Rb}/^{86}\text{Sr}$  ratio (and hence the Rb/Sr ratio) of the sample, the time since the  $^{87}\text{Rb}/^{86}\text{Sr}$  ratio was last changed and the  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio at the time of that change. The ages that are determined by such systems are the time since the last change in ratio of the parent to the daughter element, in this case Rb/Sr, and so it is important to have established independently just what geologic processes were responsible for element fractionation. Similarly the isotope ratio of Nd,  $^{143}\text{Nd}/^{144}\text{Nd}$ , depends on the Sm/Nd (parent/daughter) ratio of the rock. However, because in general Sm is less incompatible during melting than Nd, but Rb is more incompatible than Sr, rocks with low  $^{87}\text{Sr}/^{86}\text{Sr}$  tend to have high  $^{143}\text{Nd}/^{144}\text{Nd}$  and vice versa.

Figure 15 summarizes variations in  $^{87}\text{Sr}/^{86}\text{Sr}$  and  $^{143}\text{Nd}/^{144}\text{Nd}$  ratios in MORB and OIB and reveals the differences between these two types of basaltic magma. The lines at  $^{87}\text{Sr}/^{86}\text{Sr} = 0.705$  and  $^{143}\text{Nd}/^{144}\text{Nd} = 0.51264$  represent estimates of the composition of the

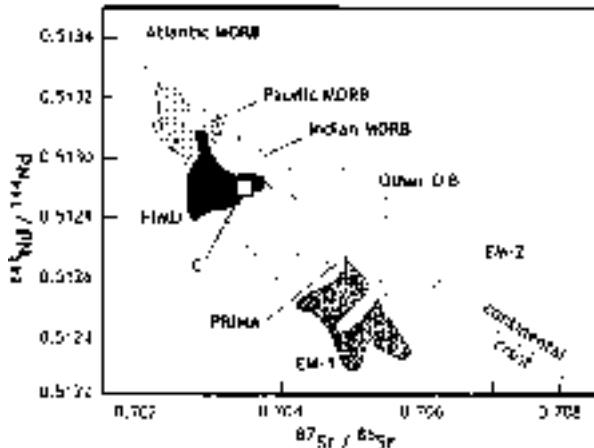

FIGURE 15 Nd-Sr isotope diagram, showing fields for MORB and different groups of OIB. PRIMA, an abbreviation for primitive mantle, and C are different estimates of the composition of the deep mantle. PRIMA is based on the composition of meteorites, whereas C is derived from the inferred composition of mantle plumes. Abbreviations HIMU, EM1, EM2 denote those OIB with particular isotopic characteristics. They are thought to represent distinct components within the mantle and there is much heated debate concerning their origins.

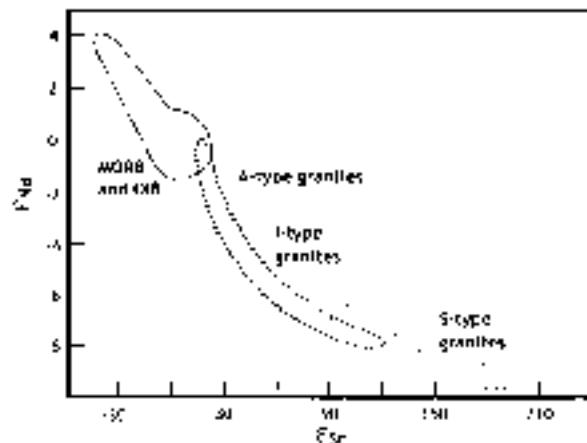

FIGURE 16 Nd-Sr isotope diagram for I-, S-, and A-type granites from southeastern Australia. Isotope ratios are expressed as  $\epsilon$  units, the difference between the isotope ratio of the granite and that for the bulk Earth composition at the time of granite formation, in parts per 10,000.

bulk Earth. In Fig. 16 similar isotope data for granites from southern Australia fall in a different part of the diagram that is complementary to MORB and bulk Earth and many granites from other continents have isotopic compositions similar to those shown here. The isotope ratios are corrected to the time of emplacement and are expressed as differences from the bulk Earth value in parts per 10,000 ( $\epsilon$  unit). Thus they are a reflection of the composition of the source region of the parent magma. The differences in isotope ratio suggest that the mantle source of MORB has high  $^{143}\text{Nd}/^{144}\text{Nd}$  and low  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios, which reflect the high Sm/Nd and low Rb/Sr ratios of their source regions relative to these ratios in the bulk Earth. By contrast, the crustal source regions of S-type granites have complementary isotopic and, hence, trace element characteristics to the mantle source of MORB and OIB that is, higher Rb/Sr and lower Sm/Nd ratios than the bulk earth. Such observations have led to models of crust generation and evolution as a result of the progressive depletion of the convecting upper mantle by the extraction of basaltic magmas throughout geologic time.

Radiogenic isotope data from OIB generally lie between MORB and bulk Earth (sometimes denoted by the acronym PRIMA) and have been classified into a number of groups (labeled EM1, EM2, HIMU etc., on Fig. 15). The origins of these different isotope signatures remain speculative although models involving recycling of sediments and oceanic crust via subduction are popu-

lar, linking mantle composition with the plate tectonic cycle and current models of mantle convection. However, the generation and migration of mafic melts within the mantle can lead to the fractionation of parent/daughter trace element ratios, which, with time, can produce anomalous isotope ratios. The possibility remains that isotope heterogeneity may be generated entirely within the mantle as a result of magmatic processes.

Notable exceptions to the general rules on the trace element and isotope compositions of basalts and granites are basalts from some CFB provinces and continental subduction zones. Many continental flood basalts that have incompatible element abundances and ratios similar to OIB have Nd and Sr isotope ratios that are also similar to those found in OIB and other mantle plume-related basalts. However, those CFB with anomalous incompatible element abundances and ratios, as discussed earlier, also have high  $^{87}\text{Sr}/^{86}\text{Sr}$  and low  $^{143}\text{Nd}/^{144}\text{Nd}$ , plotting in the same region of the isotope diagram as granites and the continental crust. These deviations from the composition of the convecting mantle have been attributed to the effects of crustal contamination, but in many cases mass balance calculations show that addition of crustal material to a typical plume basalt cannot reproduce critical aspects of the CFB composition. The alternative proposal is that the compositions of these basalts in part reflect that of their mantle source regions, which may be located within the mantle lithosphere.

The other location in which basalts may take on the isotopic characteristics of crustal rocks is above subduction zones. Once again the lithosphere (either crust or mantle) may play a role where a plate is being subducted beneath a continent (e.g., the Andes). Elsewhere, where the overlying crust is more youthful, such as in the Philippines, or even oceanic, high  $^{87}\text{Sr}/^{86}\text{Sr}$  and low  $^{143}\text{Nd}/^{144}\text{Nd}$  ratios cannot be derived from the mantle. Rather they indicate a contribution from subducted sedimentary material, itself derived from ancient continents. Such a situation is apparent in parts of the Lesser Antilles where sediment derived from the South American crust, an area dominated by ancient rocks, is being recycled into the mantle by the subducting Atlantic plate (Fig. 17). In this case, isotope ratios can be used to constrain the amount of sediment in the mantle source region of the erupted basalts and hence the amount of sediment being recycled back into the mantle. In general, the amount of sediment required to give arc basalts their distinctive characteristics is very small (<5%), implying that much of the material being subducted is recycled back into the mantle.

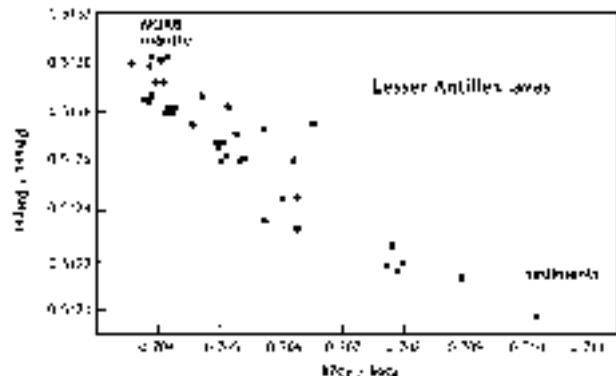

FIGURE 17 Nd-Sr isotope diagram for basalts and andesites from the Lesser Antilles island arc in the Caribbean. Many of the analyses plot close to those of MORB (see Fig. 15), whereas others define a trend toward lower  $^{143}\text{Nd}/^{144}\text{Nd}$  and higher  $^{87}\text{Sr}/^{86}\text{Sr}$ . This is a particularly good example of mixing subducted crust into the source of arc magmas, displacing their Nd and Sr isotope composition toward that of sediment derived from the continents.

In Fig. 16, the isotope ratios of granites appear to vary systematically with granite type. Thus peraluminous, S-type granites have low  $\epsilon_{\text{Nd}}$  values and high  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios, reflecting their crustal source regions as discussed earlier. Peralkaline granites tend to plot closer to mantle-derived rocks, supporting the notion that they are derived from mafic material in the deep crust, whereas the intermediate position of metaluminous, I-type granites reflects the complex interplay between mantle and crustal source regions in their evolution.

## VI. CRUSTAL EVOLUTION

The continental crust is dominated by igneous rocks and their metamorphic equivalents and it is clear that magmatism has played an important role in the evolution of the crust over the 4.6-Ga history of the Earth. The bulk composition of the present-day continental crust is andesitic (dioritic), and its low density makes it difficult to recycle it back into the mantle via subduction. Thus the continents survive on the surface of the Earth and record the effects of geologic processes that have affected them over the past 3.9 Ga. The generation of the continental crust is therefore considered to be the result of melting in the mantle and a largely irreversible process. Such a notion is supported by the complemen-

tary nature of radiogenic isotopes in the crust and the convecting mantle and the overall abundances of trace elements in the continental crust (Fig. 18). These are, with a few exceptions, similar to those in OIB, which are, in essence, small melt fractions of the upper mantle.

One of the exceptions is the element Nb and the continental crust is thought to be characterized by a negative Nb anomaly, very similar to those seen in island arc magmas. Thus a popular model for the evolution of the continental crust is as a result of subduction-related magmatism throughout Earth history. However, while the estimated composition of the continental crust is andesitic, melts of the mantle are generally basaltic and the present-day flux of material from the mantle to the crust, whether at destructive plate margins or in intraplate settings, is basaltic. Moreover, basalt has been the dominant mantle-derived magma throughout much of the history of the Earth. Andesitic (dioritic) magma can only be produced by fractionational crystallization of basaltic magma (or possibly partial melting of basalts) within the crust, but because any crystals separated during fractional crystallization would remain in the crust, the latter would retain a bulk composition similar to basalt. We are therefore left with the apparent contradiction that while the crust has the trace element characteristics of a melt derived from the mantle, its bulk composition is that of a magma that has experienced fractionation. This contradiction remains as

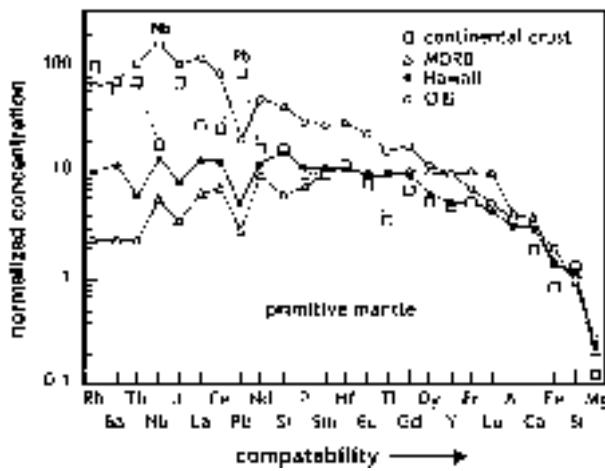

FIGURE 18 Mantle-normalized trace and selected major element abundances in MORB, OIB (Hawaii and Tristan da Cunha), and the average continental crust. Note the overall similarity between the element abundances of OIB and the continental crust and the anomalous behavior of elements such as Nb, Ti (depleted in the crust), and Pb (enriched in the crust).

yet unresolved. It may be that our estimates of the composition of the bulk crust are incorrect and that it is closer to basalt than andesite. Alternatively, crustal generation may not be a one-way process and may involve transport of mafic material from the crust back into the mantle.

In summary, the outer portions of the Earth differentiated into the continental crust, the oceanic crust, and enriched and depleted portions of the mantle primarily by the processes of melt generation, melt extraction, and the movement of those melts. The mantle source regions for MORB are depleted in incompatible elements relative to estimates for the bulk Earth, and the compositions of the MORB-type mantle and the continental crust are thought to be complementary such that the depletion of the MORB-type mantle is attributed to the formation of the continental crust throughout the history of the earth. The bulk composition of the continental crust represents, on average, just a few percent of partial melting of the upper mantle, but the details of the processes by which the continental crust was formed and their timing remain the subject of lively debate.

## GLOSSARY

- adiabatic** The thermodynamic process of expanding or compressing a substance without allowing it to exchange heat with its surroundings.
- amphibole** Rock-forming silicate mineral that contains Fe, Mg, Al, Ca, Na, Al, Ti, and ~1.5 wt% H<sub>2</sub>O.
- assimilation** The incorporation of material originally present in surrounding wallrock into a magma. If the wallrock is incorporated into the liquid, thermal energy is required to heat and melt the solid rock.
- asthenosphere** The part of the upper mantle beneath the lithosphere that deforms by plastic flow as a result of high temperatures at depth in the Earth.
- clinopyroxene (cpx)** Rock-forming silicate mineral with the general formula Ca(Mg,Fe)Si<sub>2</sub>O<sub>6</sub>. In mantle peridotite

most of the Na<sub>2</sub>O, TiO<sub>2</sub>, and Al<sub>2</sub>O<sub>3</sub> in the rock is contained in this mineral.

**crust** The part of the Earth lying above the Mohorovicic discontinuity. Continental crust varies from 30 to 80 km in thickness and oceanic crust ranges from 6 to 20 km in thickness.

**fractional crystallization** Crystallization of minerals from a silicate liquid (magma) during cooling causes the liquid to change composition. The possible compositional variations that can occur through this process are governed by thermodynamic state functions for the crystals and melt.

**latent heat of melting or latent heat of crystallization** Heat of reaction required to accomplish the phase change from solid to liquid form.

**liquidus** Temperature above which a magma is completely liquid, or the temperature below which a melt begins to crystallize.

**liquidus volume** The range of composition for a liquid solution over which a particular solid is the liquidus phase.

**lithosphere** The portion of the earth's crust and upper mantle above the asthenosphere that is rigid and deforms by brittle fracture as a result of lower temperature.

**magma** Molten rock that consists of up to three components: liquid silicate melt, suspended crystalline solids, and gas bubbles. Lavas are magmas that solidify at the surface to crystalline or glassy igneous rocks that are referred to as volcanic rocks. When magma cools in the interior of the earth, the resulting igneous rocks are referred to as intrusive or plutonic rocks.

**magma mixing** The mixing of two magmas to form a hybrid.

Such a process presents the immediate problems of how the two magmas were produced and what caused them to remain separate and then mix.

**mantle** Portion of the Earth's interior lying below the Mohorovicic discontinuity and above the outer core. Divided into an upper mantle that extends to a depth of ~400 km, a transition zone that extends to ~670 km, and a lower mantle that extends to the core-mantle boundary at ~2900 km.

**melt reaction coefficient** The proportion of a crystalline phase that is reacted during melting. Positive reaction coefficients indicate that the solid is consumed during melting. Negative reaction coefficients indicate that the solid is produced along with the melt phase.

**olivine (ol)** Rock-forming silicate mineral in the crust and mantle with the composition  $(\text{Mg}, \text{Fe})_2\text{SiO}_4$ .

**orthopyroxene (opx)** Rock-forming silicate mineral in the crust and mantle with the general composition  $(\text{Mg}, \text{Fe})\text{SiO}_3$ .

**peridotite** A crystalline rock consisting dominantly of olivine and pyroxenes. The principal rock type present in the Earth's upper mantle.

**plagioclase** Rock-forming silicate of crust with the composition  $(\text{Ca}_{1-x}, \text{Na}_x)\text{Al}_{2-x}\text{Si}_{2+x}\text{O}_8$ .

**primary magma** A liquid produced by partial melting of a source region and unmodified by any postsegregation process.

**solidus** Temperature below which a magma is completely crystallized, or temperature at which a solid begins to melt.

**spinel** Rock-forming oxide mineral. In the mantle the composition is  $(\text{Mg}, \text{Fe})(\text{Al}, \text{Cr})_2\text{O}_4$ . In the crust the composition is  $\text{Fe}_2\text{TiO}_4 - \text{Fe}_3\text{O}_4$ .

## I. INTRODUCTION

The chapter describes the processes that lead to the compositional diversity in magmas in active volcanic regions. The chapter focuses on midocean ridge and subduction zone volcanoes—the two dominant melt production regimes operating on the modern Earth (see chapter on Plate Tectonics and Volcanism). The chapter introduces the methods that are used to determine the conditions of and controls on compositional diversity in magmas. The influence of partial melting on magma generation is discussed for active midocean ridge spreading centers. The next section describes the processes that control compositional diversity after a melt has migrated from its source region into the oceanic lithosphere.

For each of these processes, the physical and chemical controls are described. A similar approach is used to discuss magma generation and magma modification processes in subduction zone environments.

---

## II. MAGMATIC PROCESSES AS CONTROLS ON THE COMPOSITION OF THE CRUST AND DEEP INTERIOR

### A. Magmatic Processes throughout Geologic Time

The Earth is a dynamic and active planet. It formed from crystalline solids that had condensed from the solar nebula 4.5 billion years ago. These solids were swept up by gravitational attraction to form the Earth and the inner terrestrial planets. During this process magmas were created by impacting planetesimals. Some of the impactors may have been as large as Mars, and their collision with the early Earth supplied enormous amounts of energy. These early giant impacts led to heating and melting on a large scale. Giant magma oceans covered the surface of the early Earth, and the early Earth may have melted entirely. The most obvious consequence of these early processes is the presence of a metal-rich core. Evidence of the nature, timing, and extent of the early magma ocean phase has been largely erased from the solid silicate portion of the Earth's interior by continued magmatic activity on Earth. There exists little direct evidence of when this phase of Earth history came to an end. The magmatic processes that occur today have been operating for a significant part of the Earth's history. The oldest rocks found on Earth, the 4.0-billion-year-old Acasta gneisses in the Northwest Territories in Canada, record magmatic processes much like the ones that take place in subduction zone and convergent margins today.

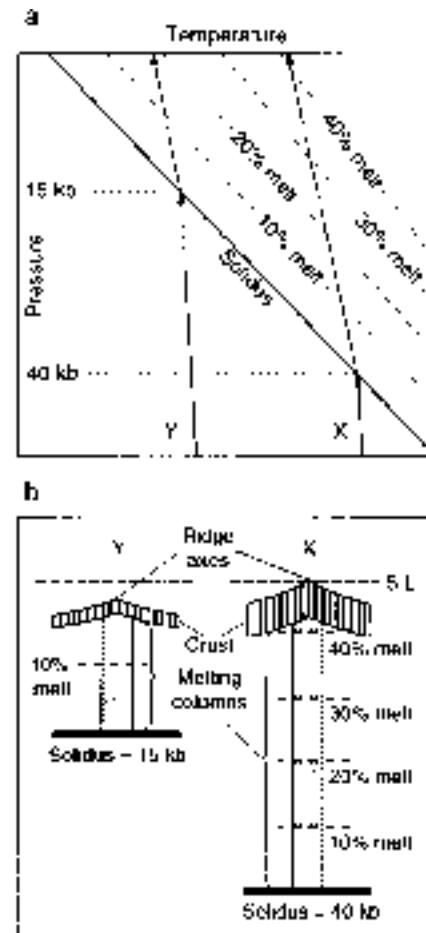

The most active sites of melt generation on the Earth occur at midocean ridges, and the products of this volcanism form oceanic crust. Oceanic crust, overlying sediments, and other volcanic rocks that occur in the oceans are recycled back into the mantle on time scale of 0.1 billion years or less and are blended back into the solid interior. However, ancient ocean floor crust is sometimes preserved in the Earth's continental crust, and these rock associations are called *ophiolites*. Examples are found in Cyprus and Oman. Thus, the geologic record contains evidence that the processes that are occurring in active volcanic centers today have been taking place for a large portion of Earth history.

## B. Tectonic Controls on Magma Generation

Magma generation and tectonic setting are closely linked and this topic is discussed in the Plate Tectonics and Volcanism chapter. The current global annual rate of magma production of volcanic and plutonic igneous rocks is about 30 km<sup>3</sup>/yr (Crisp, 1984). Magma generation at midocean ridges (divergent margins) accounts for 75% of the volume, and 20% occurs in subduction zone environments (convergent margins). The remaining 5% occurs as intraplate magmatic activity within either oceanic or continental plates (intraplate volcanism). Magma generation in these environments probably occurs through the same mechanism that leads to midocean ridge magmatism. The following discussion focuses on the midocean ridge and subduction zone environments because they dominate the global magma production rate. Melting processes in these two environments lead to a broad spectrum of compositional variation in magmatic products.

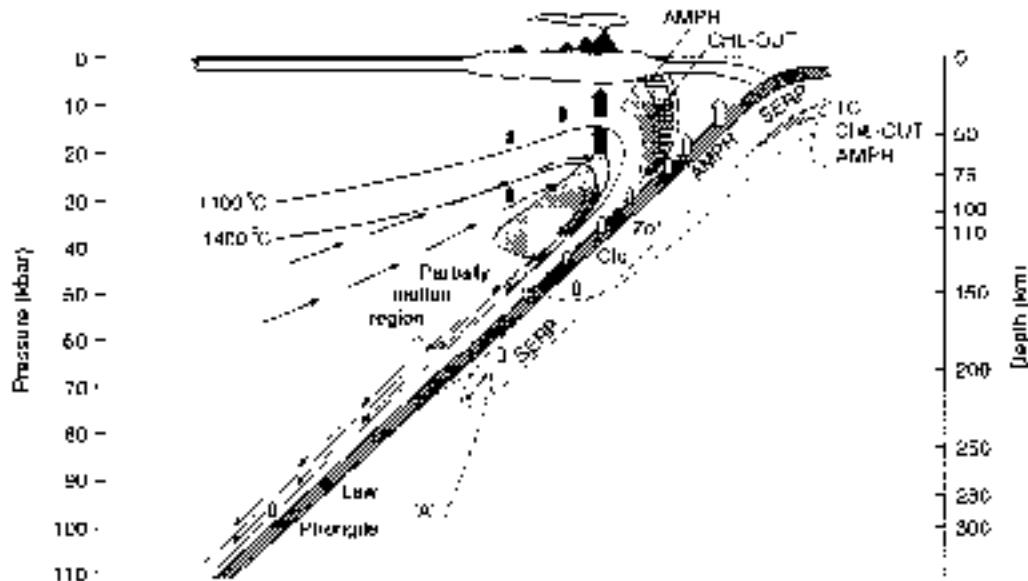

At midocean ridges the production of magma is dominated by passive convective upwelling of mantle asthenosphere. As the solid mantle ascends, its temperature follows that of an adiabat, and the mantle peridotite will begin to melt at a depth where the peridotite encounters its solidus (see chapter titled Melting the Mantle). The magmas produced by this melting process are basaltic in composition (see chapter titled Composition of Magmas). The primary controls on melt generation are the temperature of the upwelling mantle and mantle composition. The control of temperature on melting is illustrated in Fig. 1 for two different adiabatic paths. Magma is produced by cooling the solid mantle after it crosses its solidus, and using the heat derived from cooling to melt solid rock. Melting continues until the cold, shallow oceanic lithosphere is encountered. At this depth magmas may cool below their liquidus and undergo fractional crystallization.

In subduction zones (convergent margins), magma generation is controlled by a process that involves the interaction of fluid released by the subducted slab with overlying mantle. Fluid that has been transported into the mantle by the subducted slab is released when hydrous minerals decompose and release their H<sub>2</sub>O. This H<sub>2</sub>O dissolves some of the silicate components in the subducted slab and the resulting fluid ascends into hotter overlying mantle (Fig. 2). Mantle melting occurs when H<sub>2</sub>O-rich fluid reaches a depth that exceeds the peridotite + H<sub>2</sub>O solidus. As shown in Fig. 3, the addition of H<sub>2</sub>O has a dramatic temperature-lowering effect on the mantle solidus. Magma production is controlled by the temperature distribution with depth above the sub-

**FIGURE 1** (A) Schematic pressure–temperature diagram for melting of mantle peridotite. Path X represents a hotter convective upwelling that crosses the solidus at greater depth and higher temperature and undergoes a greater extent of melting. Path Y crosses the solidus at a lower pressure and temperature and undergoes a lesser extent of melting. (B) Cross section of the oceanic crust and mantle corresponding to melting histories shown by paths X and Y. Path X is similar to the melting model shown as squares in Fig. 5, but differs in starting at a greater depth. Path Y is similar to the melting model shown as triangles. [Klein, E. M. and Langmuir, C. H. (1989) Local versus global variations in ocean ridge basalt composition. *J. Geophys. Res.* **94**, 4241–4252.]

ducted slab and by the flux of H<sub>2</sub>O. Magmas produced through this process are hydrous (water bearing). The amount of water that is incorporated into the melt depends on pressure and temperature. The solubility of H<sub>2</sub>O in magma is negligible at surface pressures, but increases dramatically with increasing pressure. At a pressure of 3.0 GPa (1 GPa = 10 kbar) or a depth of 90 km in the mantle about 20 wt% of the magma is H<sub>2</sub>O. Also present in the subduction environment are magmas produced by adiabatic decompression. Deep

**FIGURE 2** Model cross section of a convergent margin showing some of the processes that lead to the generation of subduction zone magmas. Dehydration of minerals in the subducted peridotite and ocean crust provide H<sub>2</sub>O to the overlying mantle wedge over a broad range of depths (indicated by open arrows). Isotherms show the temperature distribution in the wedge overlying the slab, and the inferred partly molten region. Hydrous minerals are indicated by abbreviations: AMPH, amphibole; SERP, serpentinite; TC, talc; CHL, chlorite; Cld, chloritoid; zo = zoisite; law, lawsonite; "A," phase A. Dashed lines show limits of stability in the descending slab. [Reprinted from Schmidt, M. X. and Poli, S. (1998) Experimentally based water budgets for dehydrating slabs and consequences for arc magma generation. *Earth Planetary Sci. Lett.* **163**, 361–379, with permission from Elsevier Science.]

mantle ascends as it approaches the slab-wedge corner and melts during its ascent to produce anhydrous magmas similar to those found in ocean floor environments. Both the hydrous and decompression-produced magmas ascend into the overlying oceanic or continental crust, where they cool and undergo fractional crystallization. The magmas heat, melt, and interact chemically with shallow crust. These processes give rise to a large variation in the chemical composition of convergent margin magmas. The resulting magmas range from basaltic to andesitic to rhyolitic in composition (see Composition of Magmas chapter).

### III. COMPOSITIONAL VARIATIONS IN MAGMAS

#### A. Representing Magma Compositional Variation

The emphasis of this chapter is on the origin of variations in major element composition of magmas. Magmas show a wide range in major element composition, which reflects the conditions under which the magma was gen-

erated in the source and/or modified after melt generation. A common way of illustrating compositional variations is to plot covariations of the oxides of two elements (see Fig. 5 in the Composition of Magmas chapter). Lavas that are spatially and or temporally associated are often chosen. The assumption is made that the variations in composition represent a process (or processes) that affected the chosen lavas and that each was erupted at a different stage of the process. This may or may not be a valid assumption and the examples shown later in this chapter illustrate ways in which spatially associated lavas can be used to infer the operations of magmatic processes.

Magmas produced by melting of a mantle peridotite source will have chemical characteristics that allow their identification. A very useful chemical index is the Mg# of the magma. This value is the molar proportion of MgO relative to FeO in the magma:

$$\text{Mg\#} = (\text{wt\% MgO}/40.311)/[(\text{wt\% MgO}/40.311) + (\text{wt\% FeO}/71.846)].$$

The melt of mantle peridotite will be in equilibrium with the minerals in the source region. Exchange reactions govern the partitioning of FeO and MgO between the crystals in the source and the melt. For olivine (ol), the exchange equilibrium is:

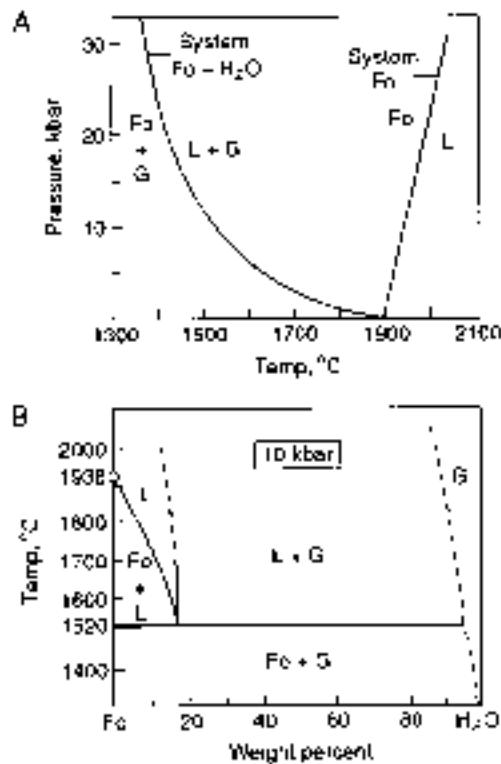

FIGURE 3 (A) Pressure–temperature diagram showing the melting of forsterite ( $\text{Mg}_2\text{SiO}_4$ ) dry and with  $\text{H}_2\text{O}$  present. (B) Temperature composition diagram at 10 kbar showing the melting relations in the system forsterite– $\text{H}_2\text{O}$ . Melting of pure forsterite in the absence of  $\text{H}_2\text{O}$  occurs at  $1938^\circ\text{C}$  at this pressure. G = gas, L = liquid and Fo = forsterite. [Morse, S. A. (1980) Basalts and Phase Diagrams: An introduction to the quantitative use of phase diagrams in igneous petrology. Figs. 19.1 and 19.2, p. 493. Copyright notice of Springer-Verlag.]

The equilibrium constant for this reaction is called  $K_D^{\text{Fe-Mg}}$  and is given by the expression:

$$K_D^{\text{Fe-Mg}} = [(1 - \text{Mg}^{\# \text{ol}}) * (\text{Mg}^{\# \text{melt}})] / [(\text{Mg}^{\# \text{ol}}) * (1 - \text{Mg}^{\# \text{melt}})]$$

and

$$\begin{aligned} \text{Mg}^{\# \text{melt}} &= K_D^{\text{Fe-Mg}} / [K_D^{\text{Fe-Mg}} + [(1 - \text{Mg}^{\# \text{ol}}) / \text{Mg}^{\# \text{ol}}]] \\ \ln K_D &= -\Delta G_{\text{reaction}} / RT. \end{aligned} \quad (2)$$

Over the temperature range for magma generation in the Earth's upper mantle the value of  $\Delta G_{\text{reaction}} / RT$  is nearly constant and as a result the value of  $K_D^{\text{Fe-Mg}}$  for olivine and coexisting melt is 0.30. A representative value for the Mg# of olivine in mantle peridotite is 0.90. Equation (2) predicts that the Mg# of a melt in equilibrium with that of olivine is 0.73. Magmas produced by melting a mantle mineral assemblage are called *primary magmas*, and the Mg# test is one way of identifying such

magmas. A lower value of Mg# indicates that the magma has undergone modification by processes of fractional crystallization, assimilation, or magma mixing. If crystals are present in the magma and gather together and concentrate preferentially in one part, the Mg# can be increased above the correct value for the magma. Magmas with the highest Mg# are sought because they are likely to contain information on melt generation processes.

### B. Methods for Determining the Controls on Magma Composition

Earth scientists have developed several techniques for understanding and interpreting the compositional variation observed in magmas. The most common approach is to reproduce the conditions of pressure and temperature relevant to the melting process and to determine directly the chemical reactions between crystals and liquids. Materials with chemical composition similar to natural magmas and the rocks that melt to produce them have been subjected to laboratory-controlled conditions of melting for time periods sufficient to achieve chemical equilibrium. These experimental efforts began in the 1900s and continue in the present. The exchange between olivine and melt [reaction (1) given earlier] and a similar exchange reaction for plagioclase-liquid NaSi-CaAl exchange are examples of chemical reactions that have been investigated through experiments. Research on the influence of pressure and on the influence of volatiles (like CO<sub>2</sub> and H<sub>2</sub>O) has provided a framework for determining the conditions of magma generation and modification.

Experimental data sets on natural magmas have been used to develop several approaches to determine the melting and crystallization behavior of magmas. The method used by Roeder and Emslie (1970) was to obtain analytical expressions for temperature and melt chemical composition that allowed the description of liquidus volumes for olivine and plagioclase. Ghiorso and Sack (1995) provide a model of chemical mass transfer from liquid to solids by predicting the lowest free-energy state and the compositions of the phases for a given chemical system under a set of temperature and pressure conditions. Longhi (1991) presented a graphical approach that allows one to calculate the melting and crystallization paths followed by magmas. The discussion that follows will draw on a number of these approaches. The interested reader should consult the references cited in this paragraph for discussions of the application of these approaches to prediction of melt composition.

#### IV. MAGMA GENERATION PROCESSES BENEATH MIDOCEAN RIDGES

Melting in the upper mantle occurs as the result of convective upwelling of mantle asthenosphere that accompanies crustal extension at midocean ridge spreading centers. This melting process is known as *adiabatic decompression melting*. When the mantle ascends beneath a spreading center, it cools slightly as its temperature follows the adiabatic gradient ( $0.3^{\circ}/\text{km}$ ). At a depth that depends on the temperature of the upwelling mantle (Fig. 1), the solidus of the mantle material is encountered and melting begins. Melting in the mantle involves four crystalline phases: olivine (~50–60 wt% of mantle peridotite), orthopyroxene (opx, ~20–30 wt% of mantle peridotite), clinopyroxene (cpx, ~10–15 wt% of mantle peridotite), and an aluminous phase (garnet or spinel, ~5% of mantle peridotite). Melting occurs in response to the thermal energy that is obtained from the difference between the temperature that would be achieved in the mantle material if it rose along an adiabat and no melting occurred versus the temperature that is achieved if it stays on the solidus of the mantle material. This thermal energy can be imagined to be released when the mantle cools and remains on the solid–melt phase transition. The heat obtained from cooling the mantle is used to supply the latent heat of fusion, and melting continues until a depth is reached at which the temperature of the parcel of mantle is lower than the solidus temperature for the mantle. The latent heat of fusion for mantle peridotite (~130 cal/g), the heat capacity (0.3 cal/g°C), the ambient mantle temperature, and the pressure and compositional dependence of the mantle solidus control the rate of melt production. Thus, if the mantle could rise  $100^{\circ}\text{C}$  above the solid–melt phase boundary, cooling it to that boundary would supply 33 cal/g of thermal energy that could be used to melt the mantle by 25%.

If the melt stays with its solid residue during ascent and is only extracted at the shallowest depth, the melting process is called *batch melting*. If the melt is constantly extracted from the residue and rises without reacting with the rock that it passes through, the melting is referred to as *fractional melting*. If the melt ascends through the solid mantle and constantly reacts with its surroundings, the melting mechanism is called *equilibrium porous flow*. Whether or not the melt remains with its solid residue as the mantle rises through the melting regime influences the volume and composition of the melts and the residues of the melting process. If the melt stays

with the solid as the solid rises and separates at the top of the melting regime, then the bulk composition of the melting system (residue + melt) is constant, and the pressure signature of the melt produced will be equivalent to the pressure of segregation (the pressure at the top of the melting regime). As we will show in Section VI, this may be the case for melting in subduction zones. In the batch melting case, bulk system composition and pressure of melting are effectively constant for the melting process. The volume and composition of magma produced will be a function of the starting composition of the mantle, the pressure of segregation, and the extent of melting achieved, which is a function of temperature.

If melts segregate from the rising mantle in small fractions, as they are produced, then the bulk composition of the melting system changes continuously as melting proceeds. Moreover, as long as the fractions of melt do not equilibrate with the overlying mantle as they rise, the pressure signature associated with the magma formed by aggregating these small fractions of melt at some depth shallower than the melting regime will reflect the range of pressures over which each of the small melt fractions was produced. This melting process is called *polybaric near-fractional melting*. The volume and composition of the aggregate magma composition that results from this process will depend on temperature, the range of pressures over which the melting occurred, and the changing mantle residue composition. This process is thought to be the mechanism by which melts are produced beneath midocean ridges.

In this view, the magma emplaced into the spreading center is regarded as an aggregate of melts collected from a range of extents and depths of melting and segregation. Thus, this magma consists of a blend of magmas, each produced by relatively small extents of melting (0.1–5%) and segregated from a range of pressures, referred to as an *aggregate primary magma*.

##### A. Crystal–Melt Reactions That Control Mantle Melting

The compositions of both the residual solids and the liquid respond to the effects of variations in pressure and temperature according to their thermodynamic state functions, which dictate the compositions that are stable at a given set of pressure and temperature conditions for a given bulk composition. In the case of natural peridotite melting processes, a relatively complete characterization exists for the changes in melt and solid

compositions over the pressure (depth) range of melting that generates midocean ridge basalts. Most of the melting occurs in the upper part of the upper mantle at depths less than 75 km. The information on solid and melt compositional variations can be combined and shown as the mantle melt reaction. Figure 4 shows the variations in melt reaction coefficients for the major minerals of mantle peridotite. At the pressure of Fig. 4, the stable aluminous phase in peridotite is spinel.

The melt-producing reaction is incongruent, which means that one or more crystalline phases are produced along with melt as melting proceeds. Minerals with positive reaction coefficients in Fig. 4 are consumed by melting, and minerals with negative reaction coefficients are produced along with melt. As pressure increases, the melting reaction changes continuously in response to changes in the bulk composition of the liquid and solids. Above a pressure of about 16 kbar (1.6 GPa), opx appears on the product (melt) side of the reaction. Thus, a near-fractional melting process at pressures greater than 16 kbar will enrich the residue in opx while depleting it in the constituents that are in the phases that are on the reactant side of the equation (cpx, olivine, and spinel).

When examining melt reactions like the one shown in Fig. 4, recall that the bulk compositions of the re-

actants and products are continuously changing in response to variations in pressure and temperature. It is this systematic change that leads to a change in the melting reaction coefficients.

An idealized melting column model of the sort illustrated in Fig. 1 can be used to conceptualize the melting process and explore the effects of melting that begins at different depths and temperatures. Melt is produced in small increments (1%), and then 90% of the melt produced is removed at each step. This variant of near-fractional melting is calculated over a range of pressures to simulate polybaric near-fractional melting. The increment of melting that occurs in mantle peridotite per kilobar of adiabatic rise above the depth of mantle solidus intersection is estimated to be 1%. At some initial pressure, during the adiabatic ascent of mantle peridotite, its temperature reaches that of the mantle solidus, and melting begins. The depleted parcel of mantle, retaining a small amount of melt, rises another kilobar and melts another 1%. Ninety percent of this batch is removed and accumulated with the previous batch, etc. Melts are accumulated and mixed to become an aggregate of primary melts sampled from a range of pressures. Between each step of melt production, the composition and mineral mode of the residual mantle parcel are recalculated using the melt reaction illustrated in Fig. 4. The amount of melt generated at any pressure within the melting column is always the same, and the average pressure of melting is the mean pressure of the melting column.

Compositions of melt increments (solid symbols) are shown for two models on  $\text{Na}_2\text{O}$  versus  $\text{FeO}$  and  $\text{Na}_2\text{O}$  versus  $\text{SiO}_2$  diagrams (Fig. 5). One model corresponds to a hot mantle adiabat where melting begins deeper (25 kbar or 75 km) and at higher temperature and the second represents melting on a cooler adiabat (15 kbar or 45 km). The curvature of each of the arrays of melt increments (Fig. 5) arises from the combined effects of decreasing pressure and increasing depleted character of the mantle source. The  $\text{Na}_2\text{O}$  variation is a function solely of extent of depletion of the source peridotite. As a parcel of peridotite rises in the mantle and melt increments are produced and stripped away, the residual solid becomes increasingly depleted in  $\text{Na}_2\text{O}$ . The  $\text{FeO}$  variation, however, is a function of both the increased extent of depletion and the associated decrease in pressure during the polybaric, near-fractional melting process.

The aggregate primary magma from one melting path or column (open symbols, Fig. 5) is the average composition of the individual increments and represents an equal sampling and complete mixing of all the increments

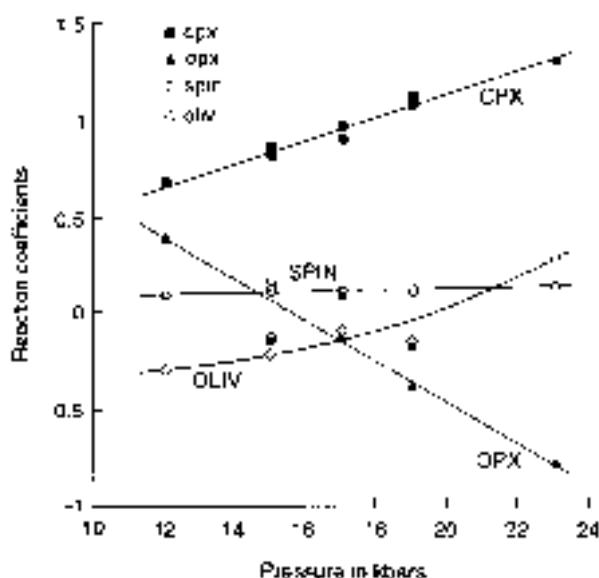

FIGURE 4 Variation in the reaction coefficients for mantle peridotite melting over the pressure range of 12–24 kbar (1.2–2.4 GPa). A reaction coefficient is positive, indicating that the mineral is consumed to produce melt. A negative reaction coefficient indicates that the mineral is produced along with melt. [Kinzler, R. J. and Grove, T. L. (1999) Origin of depleted cratonic harzburgite by deep fractional melt extraction and shallow olivine cumulate infusion. Proc. 7<sup>th</sup> Int'l. Kimberlite Conf. (in press).]

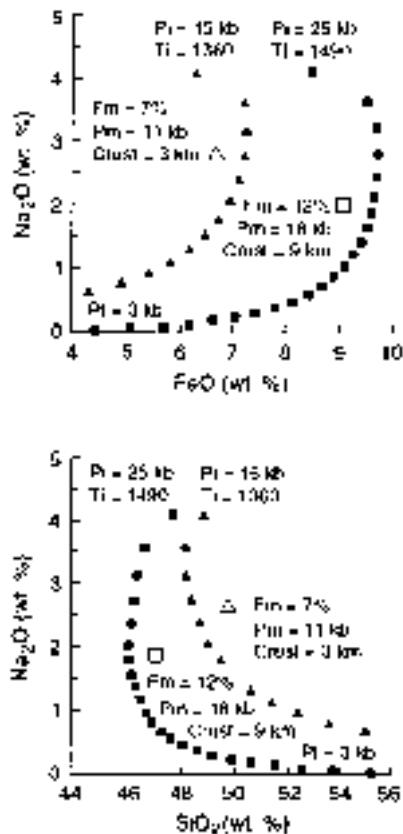

FIGURE 5 Plots of wt% (A) Na<sub>2</sub>O versus FeO and (B) Na<sub>2</sub>O versus SiO<sub>2</sub> for near-fractional melt increments (solid symbols) and aggregate melts (open symbols). Triangles represent a model where the mantle begins to melt at a shallower depth and cooler temperatures. Squares represent a model where the mantle begins to melt at higher pressures and higher temperatures, and melting extends over a larger depth interval.  $P_i$  and  $T_i$  indicate pressure and temperature of initial melting and  $P_f$  = final pressure of melting.  $F_m$  = amount of melting in wt%, and  $P_m$  = mean pressure of melting. Crust = thickness of midocean ridge basalt produced from the melting process. (From Kinzler, 1997.)

from that path. In the case where melting begins at a greater depth and extends over a greater depth interval (open square, Fig. 5) the FeO is higher and the Na<sub>2</sub>O content is lower. In the example where melting begins at shallower depths (open triangle, Fig. 5) FeO is lower and Na<sub>2</sub>O is higher. For both examples in Fig. 5, melting terminates at the same depth due to the intersection of the rising mantle with an assumed lithospheric boundary, above which it is too cool to melt. Because melting is initiated at different depths, however, the total extent of melting achieved from the melting column in each

example varies from ~12% in the 25–3 kbar example to ~7% in the 15–3 kbar example. These differences in melting extent lead to differences in the amount of lava that is generated at a spreading center. In the examples shown in Fig. 5, crust varies between 3 and 9 km thick. The observed average thickness of young oceanic crust is ~6 km and the range is from 3 to 8 km.

When the compositions of all midocean ridge basalts are examined (Fig. 6), a negative correlation of FeO and Na<sub>2</sub>O is observed. The covariation of these elements in the global data set results from the coupling of increased extent of melting (which decreases Na<sub>2</sub>O in primary magmas) and increased pressure of melting (which increases FeO in primary magmas). The low-Na<sub>2</sub>O, high-FeO end of the aggregate primary magma array (Fig. 6) is thus from the deepest, hottest melting column, in which the mantle is melted the most. The high-Na<sub>2</sub>O, low-FeO end of the array is from the shallowest, coolest melting column, in which the mantle is melted the least. The mantle solidus temperature implied by the one-dimensional melting models (Fig. 1) varies from ~1475°C in the 12% aggregate melt to ~1315°C in the 7% aggregate melt and indicates that there are temperature differences of at least 150°C in the mantle that ascends beneath ocean ridges.

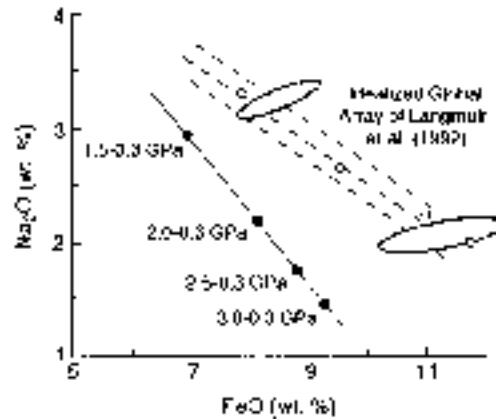

FIGURE 6 Plot of wt% Na<sub>2</sub>O versus FeO for a suite of aggregate magmas produced from variable mantle temperature models (solid circles). Pressure range gives the beginning and end of melting for each model. These primary melts have been fractionated down temperature until the melt contains 8 wt% MgO (open circles) and ellipses. Superimposed is a region encompassed by the global data set of Langmuir *et al.* (1992) of regionally averaged ocean ridge basalt compositions (three dashed lines). This global data set has also been corrected to 8 wt% MgO and shows a well-defined inverse correlation between Na<sub>2</sub>O and FeO. 10 kbar = 1 GPa. (From Kinzler, 1997.)

## V. FRACTIONATION, ASSIMILATION, AND MIXING IN OCEANIC ENVIRONMENTS

Very few sampled ocean ridge basalts have compositions that are similar to those of primary magmas. The Mg# [see Eq. (1)] of a midocean ridge basalt (MORB) that would be in equilibrium with the olivine in mantle peridotite would be >0.73. Most ocean floor lavas have Mg# lower than 0.71 and thus are not primary magmas. Therefore, most MORBs exhibit evolved compositions. To use the chemical compositions of sampled MORBs to infer the melting processes beneath midocean ridge spreading centers, the effects of postsegregation magmatic processes must be removed. Postmelt generation processes include any or all of the following: (1) low-pressure crystallization and mixing processes that occur within the oceanic crust, (2) crystallization of primary magmas in the upper mantle, en route to emplacement into the spreading center, and (3) assimilation of mantle or crust by primary magmas.

Earth scientists traditionally view the process of magma modification as one in which a lava composition (or some subset of lava compositions) may be identified as a parent magma. The parent magma is one that has been least affected by melt modification processes and may be closest to a primary magma. Crystallization induced by cooler surroundings modifies the composition of this parent magma to produce derivative magmas. If the derivative magmas are sampled sequentially during a fractional crystallization process by a series of eruptions from the magma reservoir, the resulting suite of compositions records the modification process. If fractional crystallization is the only modification process that operates on a parent magma, the compositional variation of the derivative suite provides a record of the conditions.

As a midocean ridge primary magma encounters cooler overlying mantle lithosphere and crust, it begins to crystallize. As the magma cools olivine and spinel are the first minerals to crystallize. Continued cooling and crystallization involves olivine, plagioclase, and cpx; the crystallization assemblage depends on the pressure (depth) at which cooling occurs. The paths followed by magmas as they experience fractional crystallization provide a signature of the depth of crystallization, because changes in pressure modify the compositions of the phases that crystallize, the temperature of appearance, and the proportions of the minerals in the crystallizing assemblage. Several techniques are available that provide a quantitative description of the crystalliza-

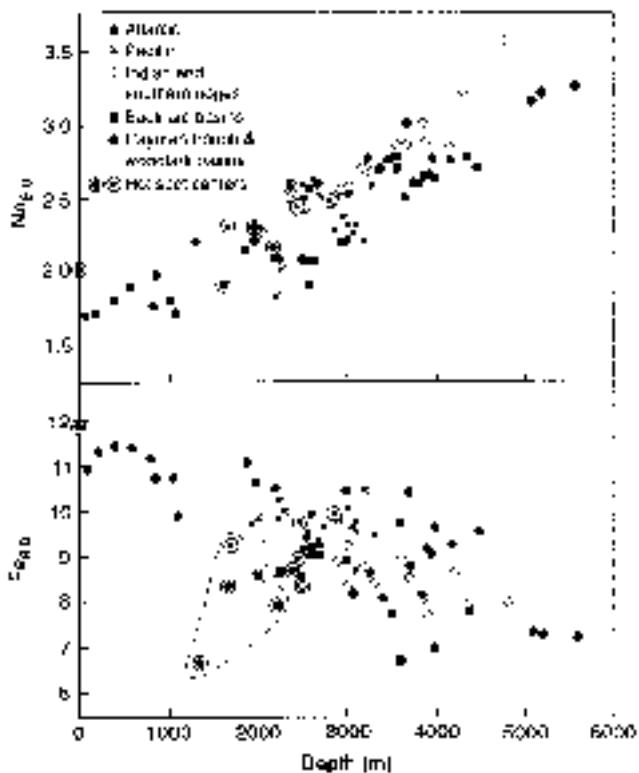

tion paths for ocean floor basaltic compositions, and these were described earlier in Section II. In the case of ocean floor basalts the composition of the magma is adjusted for the effects of crystallization to a reference value. In Fig. 6, for example, the effects of crystallization have been evaluated for FeO and Na<sub>2</sub>O for ocean floor magmas and their compositions have been adjusted to 8 wt% MgO. The two shaded ellipses shown in Fig. 6 are the polybaric, near-fractional aggregate primary magmas from Fig. 5 corrected for fractional crystallization to 8.0 wt% MgO. There is a correspondence between the primary magmas evolved to 8.0 wt% MgO and the global array of ocean floor magmas. The low-FeO, high-Na<sub>2</sub>O end corresponds to shallow melting regimes in which the mantle is depleted to a lesser extent, and the high-FeO, low-Na<sub>2</sub>O end of the trend corresponds to a deeper melting regime in which the mantle is depleted to a greater extent. The high-FeO, low-Na<sub>2</sub>O portion of the global array can be produced by melting at a mean pressure of 15 kbar, to a total extent of ~18 wt%. The low-FeO, high-Na<sub>2</sub>O portion of the global array can be produced by melting at a mean pressure of ~8 kbar to a total extent of melting of ~6 wt%.

In addition, there is also a strong correlation between Na<sub>2</sub>O and FeO and the water depth above an ocean floor spreading center (Fig. 7). The water depth variations are a response to variations in mantle temperature beneath the ocean ridge depth. Hotter mantle that has undergone a higher extent of melting correlates with the shallow water depths and cooler mantle that has begun melting at lower pressures and temperatures is represented by deep water depth above the spreading center.

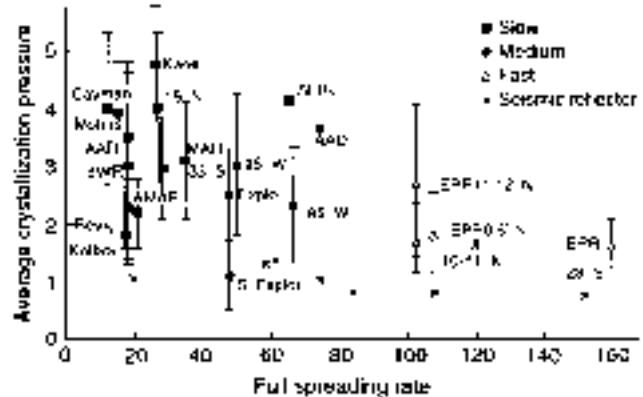

Relationships between MgO, FeO, and Na<sub>2</sub>O also yield information about the fractional crystallization history of MORBs that can be used to infer the depth of crystallization. The influence of pressure on crystallization is best illustrated using a specific example. Consider a primary magma that is emplaced at shallow levels beneath the spreading center. This primary magma first crystallizes olivine + spinel, followed by olivine + plagioclase. After a total of 33% crystallization at 0.001 kbar the differentiated magma contains 2.71 wt% Na<sub>2</sub>O, 8.77 wt% FeO, and 52.4 wt% SiO<sub>2</sub> at 8.0 wt% MgO. Upon emplacement of the same aggregate primary magma at a depth in the upper oceanic mantle equivalent to 4 kbar pressure, it crystallizes olivine + spinel (2%), followed by olivine + plagioclase (16%), followed by olivine + plagioclase + cpx (20%). After a total of 38% crystallization at 4 kbar the differentiated magma contains 2.85 wt% Na<sub>2</sub>O, 9.59 wt% FeO, and 51.8 wt% SiO<sub>2</sub> at 8.0 wt% MgO. The higher Na<sub>2</sub>O and FeO

and lower  $\text{SiO}_2$  abundances in the magma fractionated at the higher pressure result from the appearance of cpx in the higher pressure fractionation path. Both  $\text{Na}_2\text{O}$  and  $\text{FeO}$  are incompatible in the assemblages olivine + plagioclase and olivine + plagioclase + cpx. The crystallization of either assemblage therefore enriches the liquid in  $\text{Na}_2\text{O}$  and  $\text{FeO}$ . However, the crystallization of olivine + plagioclase + cpx takes out less  $\text{MgO}$  as compared to the crystallization of olivine + spinel or olivine + plagioclase (for a given mass of the assemblage crystallized). The elliptical shaded areas in Fig. 6 also illustrate the influence of variable pressure of fractional crystallization. The high- $\text{Na}_2\text{O}$ , high- $\text{FeO}$  end of the ellipse corresponds to fractional crystallization at elevated pressure and the low- $\text{Na}_2\text{O}$ , low- $\text{FeO}$  end of the ellipse corresponds to low-pressure fractional crystallization.

The temperature of the oceanic lithosphere influences the depth of fractional crystallization. In Fig. 8, the

**FIGURE 7** Regional averages of ocean ridge basalts showing the relationship between element compositional parameters and axial depth (depth below sea level to the active spreading ridge). The depth to the spreading center reflects mantle temperature. Hotter adiabat = shallower water depth = higher extent of melting. Cooler adiabat = deeper water depth = lower extent of melting. [Klein, E. M. and Langmuir, C. H. (1987) Global correlations of ocean basalt chemistry with axial depth and crustal thickness. *J. Geophys. Res.* **92**, 8089–8115.]

**FIGURE 8** Average crystallization pressure (in kbars) for MDRBs versus spreading rate (in mm/yr). Bars show one standard deviation about mean pressure. Crosses show seismic reflectors interpreted to represent the tops of magma reservoirs beneath the indicated ridge. Crystallization depth is estimated using magma compositional parameters (see Michael and Cornell, 1998).

average pressure of crystallization has been calculated for suites of ocean floor basalts. There is a correlation between ridge spreading rate and crystallization depth. At fast spreading ridges, magmas ascend into the shallow mantle before encountering cool and rigid lithosphere. In contrast, magmas generated at slow-spreading ridges encounter rigid and cold lithosphere at greater depths, which impedes the ascent of magma to the site of eruption at the ridge. Instead, the magma stalls in deep magma chambers, cools, and crystallizes.

In addition to crystallization at variable pressures, two other postsegregation processes may generate compositional variations. The first involves mixing of a range of evolved magma compositions that achieved their compositions by varying amounts of fractional crystallization from the same primary magma in a crustal level magma chamber. The second involves assimilation of mantle material that may occur and that may modify the melt composition. Assimilation may occur as melts percolate through the mantle, or it may occur within the region where the increments of melts are collected or “aggregated.” Both of these processes are discussed in the following section on subduction zone magmas.

## VI. MAGMA GENERATION PROCESSES IN SUBDUCTION ZONES

Magma generation in subduction zones is generally thought to be a consequence of the presence of  $\text{H}_2\text{O}$  in

the source region of magmas. Subduction zone settings are distinguished by the presence of  $H_2O$  as a component in the magma, but there are also other dynamic processes that lead to melt generation. The influence of  $H_2O$  on mantle melting processes is shown in Fig. 3. Figure 3 shows pressure–temperature ( $P-T$ ) and temperature–composition ( $T-X$ ) relationships for a mantle analog consisting of pure forsterite olivine (Fo,  $Mg_2SiO_4$ ). Shown on Fig. 3A are the melting relations for pure Fo and the melting behavior for the system Fo +  $H_2O$ . The solubility of  $H_2O$  in the melt phase is pressure dependent and increases from ~0.1 wt% at surface pressure to 27 wt% at 30 kbar. The effect of increased  $H_2O$  solubility with pressure is to stabilize the melt phase to much lower temperatures than in the  $H_2O$ -free system. At 30 kbar, Fo melts in the presence of  $H_2O$  at a temperature ~600°C lower than its dry melting point. The  $T-X$  diagram for 10 kbar shows the melting behavior when  $H_2O$  is present. The first melt of the olivine + vapor assemblage contains nearly 20 wt%  $H_2O$ .

In a subduction zone  $H_2O$  is supplied to the mantle by dehydration of  $H_2O$ -bearing minerals as they are carried to depth in the downgoing subducted lithosphere. Figure 2 shows a schematic cross section through a subduction zone. In the subducted lithosphere the maximum stability limits for  $H_2O$ -bearing minerals are shown by dashed curves. The subducted lithosphere consists of layers of sediment, hydrated basaltic crust, and hydrated mantle peridotite. The volumetrically dominant reservoirs for  $H_2O$  are minerals in the lithospheric mantle that are produced during seafloor alteration by circulating fluids when the mantle is altered at the active ridge spreading center. They include the minerals serpentine and chlorite, which contain 8–10 wt%  $H_2O$ . In the ocean crust the dominant minerals are lawsonite, chloritoid, and amphibole. Lawsonite and chloritoid can contain up to 10 wt%  $H_2O$  and amphibole contains about 1.5 wt%  $H_2O$ . As the slab descends the increase in pressure and temperature puts these minerals outside of their stability field and they decompose to anhydrous products and release  $H_2O$ . An  $H_2O$ -rich fluid ascends into the overlying mantle, where it encounters progressively higher temperatures as it ascends. At depths between 110 and 75 km the mantle + fluid melts to an  $H_2O$ -rich melt. This melt is very buoyant, because it contains a large amount of dissolved  $H_2O$ . (The molar volume of  $H_2O$  in silicate melt under these conditions is ~17 cm<sup>3</sup>/mol, about one-third that of anhydrous silicate melt.) The hydrous melt ascends into hotter overlying mantle, where it is heated by the shallow mantle. At these higher temperatures and shallower depths, melt is no longer in equilibrium with its surrounding mantle and it reacts with the solids, forming more melt and

diluting the  $H_2O$  content of the melt. This process continues until the melt ascends into the hottest part of the wedge, where the maximum amount of melting occurs. Upon further ascent into cooler, shallower mantle, the melt will presumably cool and crystallize.

If this melt is sampled as a magma, it should record the conditions under which it equilibrated with the mantle. These magmas are found in subduction zones globally, though they are rare. These primary magmas have been sampled, brought into the laboratory and subjected to elevated pressure–temperature conditions to determine their liquidus phase relations. Figure 9 shows the effect of adding variable amounts of  $H_2O$  to basaltic andesite sample 85-44 from the south Cascades (United States) subduction zone with Mg# = 0.71. At 6 wt%  $H_2O$ , the near-liquidus phases for this melt consist of olivine and orthopyroxene, which are the dominant minerals in the mantle. The temperature of this solid–melt equilibrium is about 150°C cooler than the temperature at which the mantle would melt beneath an ocean spreading center. Thus, the magma records a cool temperature because of the influence of  $H_2O$  on melting. The melt extraction depth inferred from the experiments corresponds to ~30 km, which is near the Mohorovicic discontinuity in the south Cascades. This melt records the depth in the shallow mantle. If it started to melt as a result of the presence of  $H_2O$ , the shallow last pressure of equilibration with the mantle may indicate that the magma is a batch melt that equilibrated with its mantle source up to the final shallow depth at which it was extracted.

Figure 10 shows a basalt (sample 79-35g) from the Cascades with an Mg# = 0.71. The liquidus phase relations also show saturation with shallow mantle peridotite

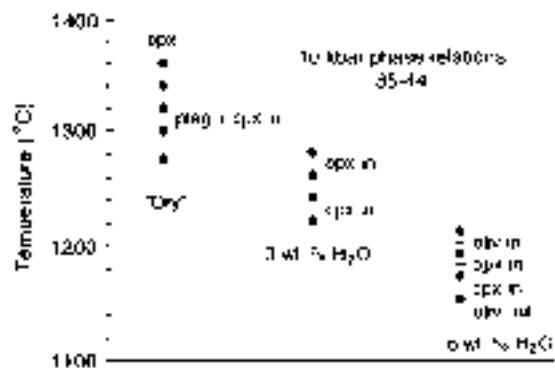

FIGURE 9 Near-liquids melting relations for basaltic andesite 85-44 from the south Cascades, United States, for anhydrous conditions and as a function of increasing water content. Each point shows the conditions of a laboratory experiment. [Baker, M. B., Grove, T. L. and Price, R. (1994) Primitive andesite from the Mt. Shasta region, N. California: Products of varying melt fraction and water content. *Contrib. Mineral Petrol.* **118**, 111–129.]

source under anhydrous conditions. For this magma the melting temperature is near that characteristic of ocean spreading centers. The pressure of multiple-phase saturation is similar for both magmas and corresponds to a depth near the top of the mantle at the crust-mantle boundary. The implications of their phase relations are that the subduction process beneath the Cascades leads to magmatism that involves  $H_2O$  and magmatism that is  $H_2O$  free (anhydrous). In fact, this variation in  $H_2O$  content and temperature of magmas is observed in other subduction zones. Figure 11 is a compilation of pre-eruptive magmatic  $H_2O$  contents and shows variation in the  $H_2O$  in magmas from the Aleutians, Central America, and Japan that are similar in magnitude to those observed in the Cascades.

In subduction zones, it is possible that there is a combination of mechanisms for melt generation. One melting process may be triggered by the rise of  $H_2O$  into the overlying mantle wedge. The second may be the result of mantle convection that occurs near the corner of the wedge. The subduction zone cross section (Fig.

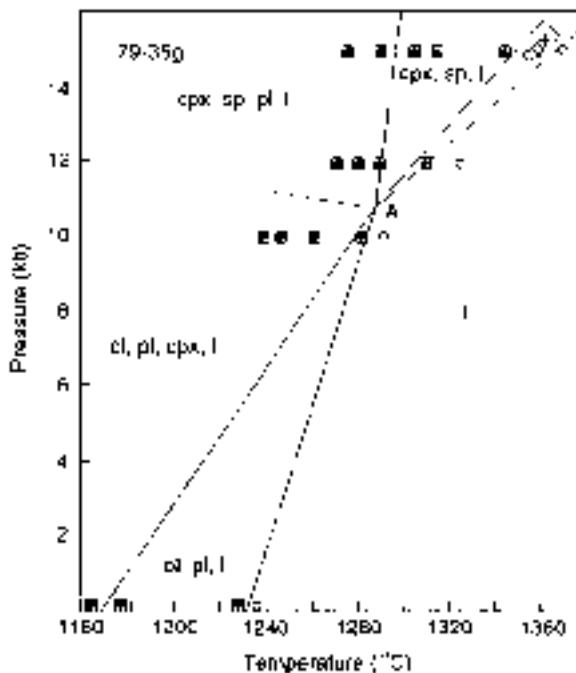

FIGURE 10 Pressure-temperature diagram showing the near-liquids melting behavior of basalt magma from the south Cascades, United States, under dry conditions. At about 11 kbar pressure and 1300°C at point A, the lava is saturated with a mantle peridotite mineral assemblage of olivine + pyroxene. Each square shows the conditions of a laboratory experiment. [Bartels, K. S., Kinzler, R. J. and Grove, T. L. (1991) High pressure phase relations of primitive high-alumina basalts from Medicine Lake volcano, northern California. *Contrib. FIGURE 11 Temperature and pre-eruptive  $H_2O$  contents for representative basalts and andesites from subduction zone environments. See Sisson and Grove (1993) Temperatures and water contents of low-MgO high-alumina basalts. *Contrib. Mineral Petrol.* **113**, 167–184 for method of estimation.

2) shows vectors for mantle flow. Hot mantle ascends from depth and moves toward the slab-wedge corner, before it turns the corner and descends above the slab. Adiabatic decompression melting may occur in the shallow part of the mantle flow regime above the part of the mantle that is being flux melted by  $H_2O$ . This shallow melting leads to the production of anhydrous magmas.

## VII. FRACTIONATION, ASSIMILATION, AND MIXING IN SUBDUCTION ZONE ENVIRONMENTS

### A. Fractional Crystallization in Subduction Zones

The presence of magmatic  $H_2O$  also has a large effect on the composition of magmas that undergo fractional crystallization.  $H_2O$  changes the relative sizes of the olivine, high-Ca pyroxene, and plagioclase primary liquidus volumes with the result that hydrous basalt and basaltic andesite magmas saturated with these minerals have high  $Al_2O_3$  and higher proportions of olivine and high-Ca pyroxene than similarly saturated dry magmas. These differences, which are observed between subduction zone and ocean floor magma series, suggest that the fractional crystallization controls on the two magma suites result from high- and low- $H_2O$  contents, respec-

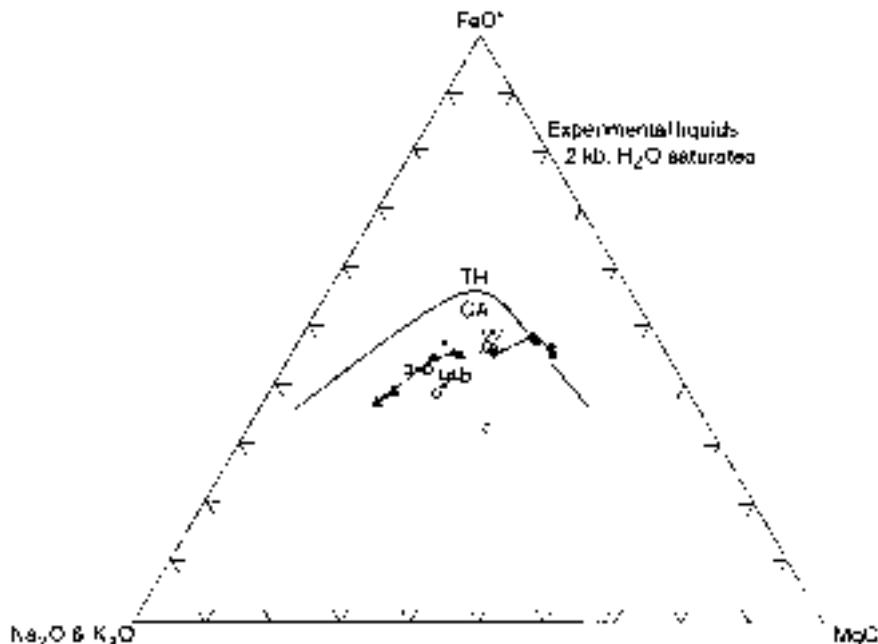

FIGURE 12 The AFM triangular discrimination diagram is used to distinguish fractional crystallization trends that are found in subduction zone environments. Trends that follow paths above the curve labeled TH are characteristic of anhydrous crystallization. Paths that follow trends below the curve in the CA field are characteristic of hydrous fractional crystallization. Symbols show experiments on basalts that were performed at 2 kbar with 6 wt% H<sub>2</sub>O dissolved in the melt. These experimental crystallization paths follow a trend that parallels that of many subduction zone magmas (Sisson and Grove, 1993).

tively. H<sub>2</sub>O also lowers the temperature where silicate minerals crystallize (Fig. 9), but has lesser effect on spinel. Thus, an Fe-rich spinel phase can appear near or at the liquidus of a hydrous basaltic melt. As a consequence, H<sub>2</sub>O-bearing basalts and basaltic andesites can produce derivative liquids by fractional crystallization that are depleted in FeO and enriched in SiO<sub>2</sub> when compared to differentiated ocean floor basalts. The plagioclase that forms from high-H<sub>2</sub>O basaltic melts is CaO- and Al<sub>2</sub>O<sub>3</sub>-rich and alkali- and SiO<sub>2</sub>-poor plagioclase. Crystallization of this phase further promotes the alkali and silica enrichment that is characteristic of the subduction zone magmatic suites and is consistent with the calcic-plagioclase found in many arc magmas. Amphibole stability is sensitive to melt compositional features in addition to H<sub>2</sub>O content. Amphibole will only appear in a subduction zone magma if the melt is Na<sub>2</sub>O rich and at low temperature.

Subduction-related magmas have been long recognized to show distinctive variations in composition. This variation in composition has been called the *calc-alkaline differentiation trend* and it is characterized by early iron depletion and silica enrichment. Iron depletion has been illustrated in two ways. One form of iron depletion is an overall decrease in FeO in the liquid. This is exhibited in Fig. 12 as an enrichment of Na<sub>2</sub>O and K<sub>2</sub>O relative

to FeO. The other form is one of enrichment of SiO<sub>2</sub> with only a modest increase in FeO/MgO (Fig. 13). Also shown in Figs. 12 and 13 are the results of laboratory crystallization experiments of H<sub>2</sub>O-saturated basalts at upper crustal pressures. The crystallization paths de-

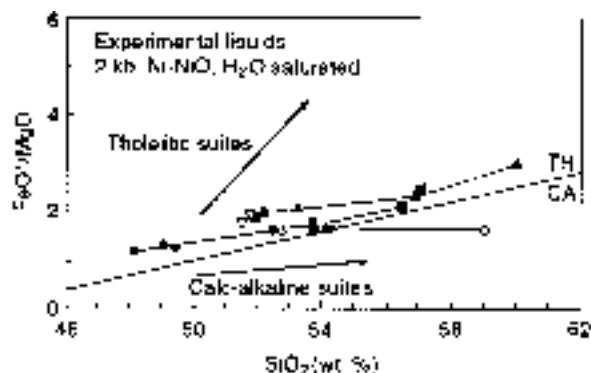

FIGURE 13 FeO\*/MgO versus SiO<sub>2</sub> diagram that is used to discriminate fractional crystallization paths. Gray arrows show the trends followed by anhydrous fractional crystallization (tholeiitic suites) and hydrous fractional crystallization (cal-alkaline suites). Experimentally produced hydrous crystallization paths for basalts are shown as symbols. Symbols are the same as in Fig. 12 (Sisson and Grove, 1993).

fined by these experiments follow the trend of a modest increase in  $\text{FeO}/\text{MgO}$ . The other trend shown in Figs. 12 and 13 has been called the *tholeiitic trend* and it parallels the trend followed by ocean floor magmas during fractional crystallization (discussed earlier in Section IV). The crystal-liquid controls on the tholeiitic trend are crystallization dominantly of plagioclase, reduced proportions of Fe-Mg silicates, and appearance of oxides only at late stages and low temperatures. Plagioclase is enriched in  $\text{Na}_2\text{O}$  and  $\text{SiO}_2$ , and alkali enrichment is suppressed. Fe-Mg silicates crystallize in diminished proportions, and the residual liquid becomes FeO enriched.

### B. Magma Mixing and Assimilation in Subduction Zone Environments

Magmas in subduction zones often contain evidence that processes other than fractional crystallization have operated to modify their compositions. A careful examination of the minerals in a lava often reveals that the crystals are not in equilibrium with their enclosing magma. A test using  $\text{Mg}^{\#}$  (2) often reveals the presence of disequilibrium magma-mineral assemblages, and indicates mixing of several distinct magmatic components. In continental settings the underlying crust is often compositionally distinct from the andesite and basalt that is erupting through it. The basalt can heat the surrounding crust, melt it, and incorporate melted crust into the magma. This process of assimilation can be quite dramatic in its compositional influence.

Volcanic systems are often episodic, and it is the periodic and repeated injection of magma through the same plumbing system that allows significant assimilation to occur. The processes that lead to mixing and assimilation are illustrated in Fig. 14. In this model, an initial input of basaltic magma is emplaced at shallow levels in the crust. This magma cools, crystallizes, and undergoes fractional crystallization to produce a derivative andesite. The crystallization releases a latent heat of solidification that is supplied to heat and melt the surrounding country rock. Another cycle of magmatic activity brings a fresh, undifferentiated batch of basalt into the magma reservoir. This undifferentiated basalt mixes with the differentiated andesite and the melted crust. In panel 1 (Fig. 14A) the geometry is shown for a dike swarm that has intruded into granite crust. The heat from crystallization of the dikes melts the crust at the dike-wallrock boundary (panel 2). A new pulse of undifferentiated basalt intrudes and mixes with the melted granite and

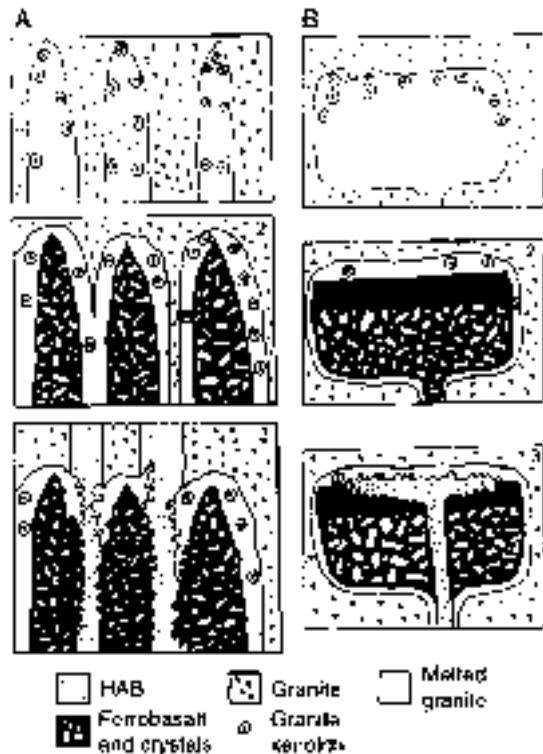

FIGURE 14 Schematic cross sections showing the processes that lead to assimilation of crust by magmas. Panel A shows a dike swarm system that intrudes into granitic crust (panel 1), crystallizes and supplies heat that melts the wallrock (panel 2). The replenishment of the system by fresh undifferentiated magma mixes the fresh input of magma with differentiated liquid and melted crust. Panel B shows the same process for a hypothetical magma chamber. Magma intrudes in panel 1. In panel 2 magma crystallizes and forms a dense cumulate pile and overlying less dense differentiated melt. Heat of crystallization melts wallrock. In panel 3 a fresh batch of undifferentiated magma replenishes the system and rises to a level of neutral buoyancy between the underlying cumulates and derivative liquid and overlying less-dense melted crust. Mixing occurs at the interface from induced convection. HAB = magma produced by mantle melting. Ferrobasalt = magma that has experienced fractional crystallization. [Grove, T. L., Kinzler, R. J., Baker, M. B., Donnelly-Nolan, J. M. and Leshar, C. E. (1989) Assimilation of granite by basaltic magma at Burnt Lava Flow, Medicine Lake volcano northern California: Decoupling of heat and mass transfer. *Contrib. Mineral Petrol.* **99**, 320–343.]

differentiated andesite (panel 3). In (Fig. 14B) the process is depicted for a magma reservoir where the differences in density between the magma can now play a role. The parent basalt magma intrudes (panel 1). The magma crystallizes and the dense crystals accumulate at the base of the magma chamber (panel 2). A fractionated

liquid segregates from the crystals and concentrates at the top of the magma reservoir. Heat from the solidification of the basalt is transferred through the top of the magma chamber and it melts the surrounding wallrock (panel 3). The cap of melted granite crust is significantly less dense than the differentiated basalt (density of the melted silicic cap,  $\sim 2.2 \text{ g/cm}^3$ ; density of differentiated basalt,  $\sim 2.7 \text{ g/cm}^3$ ). A new pulse of undifferentiated magma is supplied to the chamber (density,  $\sim 2.65 \text{ g/cm}^3$ ), and it rises through the accumulated crystals and the dense fractionated andesite into the interface between the differentiated melt and the silicic cap. The hot, low-viscosity undifferentiated magma undergoes turbulent convection when it encounters the cooler melts in the chamber and mixing occurs. Thus, replenishment of a magma reservoir by undifferentiated basalt is one plausible mechanism that leads to mixing of magmas.

## GLOSSARY

**exsolved gas** Gas that has been released from solution in a magma. Gas exsolution occurs when pressure is decreased, such as when magma moves toward Earth's surface.

**fugacity** A gas is considered to be perfect if its behavior can be described by the ideal gas law:  $PV = nRT$ , where  $P$  is pressure,  $V$  is volume,  $n$  is number of moles,  $R$  is the ideal gas constant, and  $T$  is temperature. Most gases are not perfect, especially at high pressures or low temperatures. The fugacity is a kind of equivalent pressure that accounts for the deviation of a real gas from ideal gas behavior.

**glass** If a liquid is cooled very rapidly, it may harden to a glass and not crystallize. Magma contains silicate liquid that, if cooled rapidly enough, forms glass.

**immiscible** Some types of liquids such as molten iron sulfide will not fully mix with or dissolve into a silicate melt to form a homogeneous solution. Such coexisting liquids are described as immiscible.

**magma** Natural silicate melt with or without suspended crystals and bubbles.

**melt (glass) inclusion** During crystallization of magma, many crystals grow imperfectly, trapping small blebs of silicate melt inside the crystals. If the magma is erupted and cooled rapidly, then these trapped inclusions of silicate melt become glass.

**saturation** A melt can be saturated with respect to certain chemical elements in three ways: It may contain bubbles of a pure gas like  $H_2O$ , it may contain crystals rich in the element, such as anhydrite ( $CaSO_4$ , rich in S), or it may contain droplets of immiscible liquid rich in the element, such as drops of sulfide melt (rich in S). In this review we use the word saturation to refer to saturation with respect to a gas (bubbles of an impure gas are present) and to refer to saturation with respect to a crystal or immiscible melt.

**solubility** The maximum amount of a volatile species or component that can be dissolved in a silicate melt under a given set of conditions such as pressure, temperature, and melt composition.

**viscosity** All fluids will flow in response to an applied shear stress, but some fluids flow more slowly than others.

Viscosity can be thought of as the resistance of a fluid to flow. A high-viscosity fluid flows very slowly.

**volatile** An element or compound such as H<sub>2</sub>O or CO<sub>2</sub> that forms a gas at relatively low pressure and magmatic temperature. Volatiles can be dissolved in silicate melts, can occur as bubbles of exsolved gas, and can crystallize in minerals such as biotite and amphibole.

### I. DEFINITION AND SIGNIFICANCE OF MAGMATIC VOLATILES

The observatory worker who has lived a quarter of a century with Hawaiian lavas frothing in action, cannot fail to realize that gas chemistry is the heart of the volcano magma problem.

—T. A. Jaggar, 1940

The quote from T. A. Jaggar, founder of the Hawaiian Volcano Observatory and an influential volcanologist in the first half of the 20th century, attests to the importance of gases in governing volcanic eruptive phenomena. As early as the middle of the 19th century, it was recognized that gas plays a fundamental role in forcing magma to the Earth's surface and generating explosive eruptions. Many different species of gas can dissolve in a molten silicate liquid in the same way that carbon dioxide can dissolve in water. Such gas species are referred to as *volatile components* or *magmatic volatiles* because of their tendency to form gas bubbles at relatively low pressure. The amount of a volatile component that can dissolve in silicate melt increases with pressure. As magma ascends toward the Earth's surface, pressure decreases, thereby decreasing the solubility of volatiles and causing them to come out of solution to form bubbles. In addition, the bubbles expand with further decrease in pressure. At 1 atm pressure and typical magma temperatures, an amount of exsolved H<sub>2</sub>O equivalent to one one-thousandth of total magma mass is sufficient to produce a magmatic foam that has more than 90% bubbles by volume! Truly tremendous expansion occurs near the surface as a result of such volatile exsolution, and this provides the driving force for volcanic eruptions, similar to the fountaining of champagne from an uncorked bottle.

Water and carbon dioxide are the most important volatile components in natural magmas. At higher pressures, deeper within the Earth, most of the water and carbon dioxide are dissolved in the silicate melt portion of the magma, and they have important effects on

magma crystallization, temperature, density, and viscosity. In the upper mantle, where basaltic magmas are generated by partial melting, volatiles affect the composition of melts and their physical segregation from the residual mantle minerals. After H<sub>2</sub>O and CO<sub>2</sub>, the most abundant volatiles are sulfur, chlorine, and flourine; sulfur is particularly important for understanding the composition and fluxes of volcanic gas, and all can be significant in the formation of ore deposits. Many other volatiles, such as He, Ar, and B, can dissolve in natural silicate melts (magmas), but they are generally much less abundant. The noble gases, for example, are usually present at concentration levels of <1 part per million (ppm, 0.0001% by weight) in natural magmas. Despite such low concentrations, the isotopic compositions of noble gases have been studied extensively because of their value in understanding large-scale degassing of the Earth and the formation of the atmosphere.

In this chapter, we focus on the abundant volatiles: H<sub>2</sub>O, CO<sub>2</sub>, and S. We review (1) experimental data on the solubility of volatiles in natural silicate melts, (2) analytical and sampling techniques used for measuring the abundances of volatiles in magmas, (3) volatile abundances in basaltic and silicic magmas typical of various tectonic environments, and (4) Earth degassing and volatile recycling by subduction. We also discuss the evidence for volatile gradients in magmas and pre-eruptive vapor saturation, because both of these are important for understanding explosive eruptive behavior of volcanoes, fluxes of volcanic gases, and the formation of ore deposits. Solubilities and abundances of Cl and F are also mentioned, and we present several references at the end of the chapter that treat Cl and F in more detail.

---

### II. SOLUBILITY OF VOLATILES IN SILICATE MELTS

#### A. Water and Carbon Dioxide

*Solubility* refers to the maximum amount of a volatile species or component that can be dissolved under a given set of conditions, such as pressure, temperature, and melt composition. Laboratory measurements of the solubilities of H<sub>2</sub>O, CO<sub>2</sub>, S, and many other volatile components have been made for a number of different melt compositions. In such laboratory experiments, it is possible to control the parameters that affect solubility. As an example, a silicate melt can be equilibrated with water vapor at high temperature and a variety of

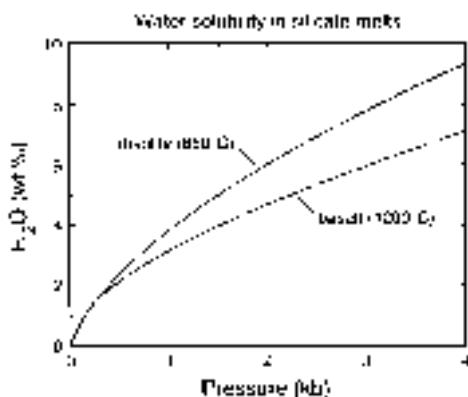

FIGURE 1 Experimental determinations of water solubility in basaltic and rhyolitic melts at typical magmatic temperatures. The solubility of water is greater in rhyolitic melt than in basaltic melt at pressures greater than 0.5 kb. (See Carroll and Holloway, 1994, for reviews of experimental solubility data.)

pressures in order to determine the solubility of water (Fig. 1). Such melt is described as *water saturated* because in the experiment, the melt coexists with water vapor. As seen in the experimental data, the solubility of H<sub>2</sub>O in silicate melts is strongly dependent on pressure. This pattern, in which the solubility increases with increasing pressure, is observed for many volatile components, and occurs because the gaseous form of a volatile component has a larger molar volume than does the same component when it is dissolved in a silicate melt. The solubility of H<sub>2</sub>O in silicate melts is also dependent on temperature and melt composition, such that H<sub>2</sub>O solubility is greater in silica-rich melts (rhyolite) than in silica-poor ones (basalt) at comparable pressures (Fig. 1).

Early studies on the solubility of water in silicate melts recognized that there is a linear relationship between the partial pressure (or fugacity) of H<sub>2</sub>O and the square of the mole fraction of dissolved water in the melt. Such a relationship is consistent with a solution mechanism in which water dissolves by forming OH<sup>-</sup> groups that are structurally bound to the aluminosilicate network of the melt. More recent studies using infrared spectroscopy have shown that dissolved water in silicate melts occurs as two different species: OH<sup>-</sup> groups and H<sub>2</sub>O molecules. The relative proportions of the two species vary systematically with total water concentration. At low total dissolved water concentrations, virtually all of the water is present as OH<sup>-</sup> groups. As total dissolved water concentration increases, the relative proportion of molecular H<sub>2</sub>O increases as well. In rhyolitic melts, the proportions of OH<sup>-</sup> groups and H<sub>2</sub>O molecules are equal at about 3 wt% total dissolved water, whereas in

basaltic melt, the proportions of the two species are equal at about 3.5 wt% total water.

As with H<sub>2</sub>O, the solubility of CO<sub>2</sub> in silicate melts is strongly dependent on pressure (Fig. 2). However, CO<sub>2</sub> solubilities are much lower than for H<sub>2</sub>O. The amount of CO<sub>2</sub> that dissolves into both basaltic and rhyolitic melts is 50–100 times less, by weight, than the solubility of H<sub>2</sub>O at comparable pressure and temperature. Carbon dioxide dissolves in silicate melts in two different species, but in contrast to water, the speciation is controlled by the bulk silicate melt composition. Thus in silica-poor glasses (basalts, basanites, nephelinites), CO<sub>2</sub> is present as structurally bound carbonate (CO<sub>3</sub><sup>2-</sup>), whereas in high-silica (rhyolitic) melts it occurs as CO<sub>2</sub> molecules. Glasses with intermediate silica contents (andesitic) contain both species. Experimental studies have demonstrated that the solubility of CO<sub>2</sub> is strongly dependent on melt composition, and this compositional dependence reflects, in part, the differences in speciation. For example, carbon dioxide is more soluble in rhyolitic melt (as molecular CO<sub>2</sub>) than in basaltic melt (as CO<sub>3</sub><sup>2-</sup>) (Fig. 2). However, in silica-poor melts, the solubility of CO<sub>2</sub> as carbonate increases with decreasing silica content. Thus the solubility of CO<sub>2</sub> in basanitic

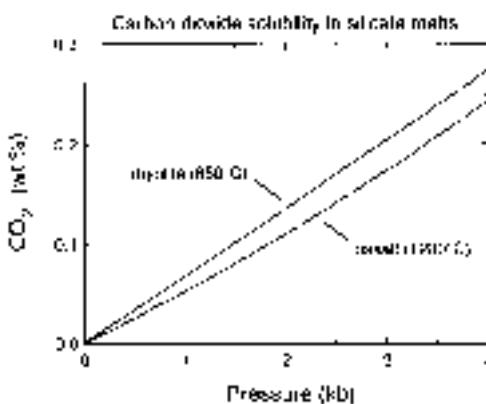

FIGURE 2 Carbon dioxide solubility in basaltic and rhyolitic melts at typical magmatic temperatures as determined by experimental studies and thermodynamic models. As with water, the solubility of carbon dioxide is greater in rhyolitic melt than in basaltic melt. Carbon dioxide dissolves in rhyolitic melts as molecular (CO<sub>2</sub>), whereas in basaltic melt it is present as a dissolved carbonate ion (CO<sub>3</sub><sup>2-</sup>). The slight curvature of the solubility curve for basaltic melt relative to rhyolitic melt results from two factors: (1) small differences in the pressure dependence of solubility for the different melt compositions and (2) greater nonideal behavior for CO<sub>2</sub> gas at the lower temperature of the rhyolitic melt. (See Carroll and Holloway, 1994, for reviews of experimental solubility data.)

melt is similar to that in rhyolitic melt and greater than that in the basaltic melt shown in Fig. 2.

In discussing solubility, it is important to distinguish between saturation and undersaturation with a particular volatile component. *Solubility* refers to the maximum amount of a volatile species or component that can be dissolved in silicate melt at a given set of conditions. In both natural and experimental silicate melts, however, the melt can have a concentration of a dissolved volatile component that is less than the maximum possible. Such a melt is described as *undersaturated* with respect to the volatile component of interest. As an example, laboratory experiments show that a rhyolitic melt can contain about 6% dissolved H<sub>2</sub>O at 2 kbar, but this does not mean that all natural rhyolitic melts that are at 2-kbar pressure in the Earth's crust contain this much water. Instead, they could have any amount from 0 to 6 wt%. A rhyolitic melt containing less than the dissolved H<sub>2</sub>O needed to saturate the melt at a given temperature and pressure is thus *water undersaturated*.

It is possible in laboratory solubility experiments, as described earlier, to equilibrate a melt with a single gas component such as H<sub>2</sub>O. However, in magmas, many volatile components are present together. It is therefore important to distinguish between the dissolved concentrations of individual volatile components and their concentrations in the separate exsolved gas phase. If the sum of the partial pressures of all dissolved volatile components in a magma is equal to the local confining pressure, then the magma is saturated with bubbles of a multicomponent gas containing H<sub>2</sub>O, CO<sub>2</sub>, S, and other minor gases like Cl, F, and noble gases. Because the volatile species have different solubilities, their relative abundances dissolved in the melt will differ from their relative abundances in the gas phase.

For vapor-saturated silicate melts, the solubilities of individual volatile components are dependent in part on the abundances of other volatiles that are present in the system. This is because the amount of a given component that is dissolved in the melt is proportional to the partial pressure of the volatile component in the coexisting equilibrium vapor. As an example, consider a silicate melt that is saturated with vapor consisting only of H<sub>2</sub>O and CO<sub>2</sub>. The sum of the partial pressures (P<sub>H<sub>2</sub>O</sub> and P<sub>CO<sub>2</sub></sub>) of these components in the vapor phase must equal the total pressure in a vapor-saturated melt. Thus at constant total pressure an increase in P<sub>H<sub>2</sub>O</sub>, and hence dissolved H<sub>2</sub>O in the melt, must result in a decrease in P<sub>CO<sub>2</sub></sub> and dissolved CO<sub>2</sub>. On a diagram of dissolved H<sub>2</sub>O versus dissolved CO<sub>2</sub> in silicate melts, vapor saturation isobars, which show the maximum dissolved H<sub>2</sub>O and CO<sub>2</sub> at a given total pressure, have negative slopes (Fig. 3). In many common igneous systems, the

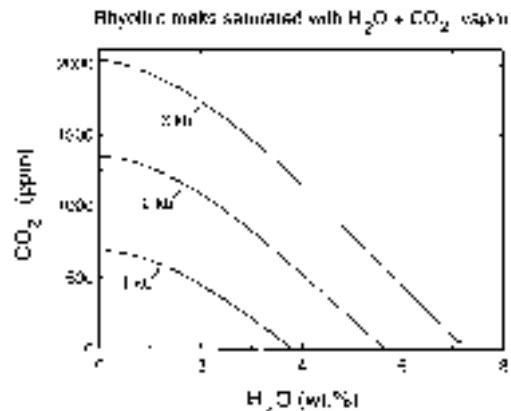

FIGURE 3 H<sub>2</sub>O and CO<sub>2</sub> solubility in vapor-saturated rhyolitic melts at 850°C and 1- to 3-kb pressure based on experimental data and thermodynamic models. The curvature of the saturation curve for a given pressure results from the nonlinear dependence of H<sub>2</sub>O solubility on pressure (see Fig. 1). (See Carroll and Holloway, 1994, for reviews of experimental solubility data and thermodynamic models.)

partial pressures of other volatile components (e.g., Cl, F, S) are probably relatively small compared with those of H<sub>2</sub>O and CO<sub>2</sub>. Knowledge of the pre-eruptive concentrations of H<sub>2</sub>O and CO<sub>2</sub> in a magma can thus potentially constrain the pressure at which the magma was stored before eruption.

## B. Sulfur

The behavior of S in silicate melts is complex because the solubility of S is controlled by the stabilities of sulfide and sulfate-bearing phases and because dissolved S can occur in multiple valence (oxidation) states. The speciation of dissolved S in silicate melts is related to the relative magmatic oxygen fugacity (Fig. 4). At relatively low oxygen fugacities, S is present in solution mainly in the reduced form sulfide (S<sup>2-</sup>), whereas under more oxidizing conditions, sulfate (S<sup>6+</sup>) appears to be the dominant species. For the range of oxygen fugacities from slightly lower than the nickel-nickel oxide (NNO) buffer to almost 2 log<sub>10</sub> units above NNO, both dissolved sulfide and sulfate are present in significant quantities (Fig. 4). The maximum S that can be dissolved in silicate melt is controlled by saturation of the melt with an S-bearing phase. At relatively low oxygen fugacities, this phase is either an immiscible iron-rich sulfide liquid (with as much as 10% oxygen), which occurs in high-temperature basaltic melts, or crystalline pyrrhotite (Fe<sub>1-x</sub>S) in intermediate (andesitic) and silicic (rhyolitic) melts. A Cu-Fe sulfide mineral known as *intermediate solid solution*

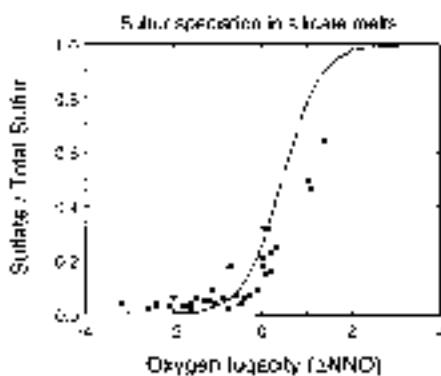

FIGURE 4 Percent of total sulfur that is present as sulfate (sulfate/total sulfur) as a function of oxygen fugacity, relative to the nickel-nickel oxide buffer ( $\Delta\text{NNO}$ ). The curve shows the experimental relationship for hydrous andesitic to dacitic melts. Filled circles are data for natural submarine glasses ranging from basalt to andesite in composition. (See Carroll and Holloway, 1994, for reviews of sulfur speciation data.)

may also crystallize from andesitic to rhyolitic melts. At higher oxygen fugacities, the sulfate mineral anhydrite ( $\text{CaSO}_4$ ) crystallizes from a wide range of melt compositions. Silicate melts at intermediate oxygen fugacities can crystallize both pyrrhotite and anhydrite, an assemblage that was found, for example, in trachyandesite tephra from the 1982 eruption of El Chichón in Mexico. Experimental solubility studies show that S is more soluble at high oxygen fugacities, under which conditions the dissolved S is present as sulfate, and anhydrite is the stable S-bearing mineral (Fig. 5). The solubility of reduced S ( $\text{S}^{2-}$ ) increases with the Fe concentration in the silicate melt (Fig. 6), which indicates that  $\text{S}^{2-}$  dissolves largely by complexing with  $\text{Fe}^{2+}$ . Sulfur solubility under both oxidizing and reducing conditions increases with temperature (Fig. 5).

### C. Halogens (Cl and F)

As with S, the solubility of Cl is complex because silicate melt can be saturated with an immiscible alkali chloride melt (molten salt). If water is present, as it invariably is in natural melts, then the immiscible alkali chloride melt will also contain dissolved water and is referred to as a hydrosaline melt. Chlorine solubility in silicate melts is strongly dependent on silicate melt composition, and the solubility generally increases as the ratio  $(\text{Na} + \text{K})/\text{Al}$  in the silicate melt increases. A silicate melt saturated with molten salt has the maximum dissolved Cl. The saturation concentration of Cl varies with pressure, temperature, dissolved water concentration, and silicate

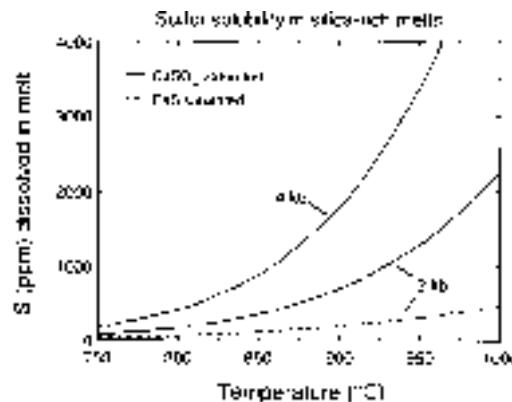

FIGURE 5 Experimental determinations of sulfur solubility versus temperature for hydrous silica-rich melts at different pressures and oxygen fugacities. Curves are shown for both sulfide-saturated melts (oxygen fugacity at the NNO buffer) and sulfate-saturated melts (oxygen fugacity at the  $\text{MnO}-\text{Mn}_3\text{O}_4$  [MNO] buffer). At 2-kbar pressure, S is more soluble under oxidizing conditions (MNO) than under reducing conditions (NNO). The solubility curve for sulfate-saturated melts (MNO buffer) at 4 kbar shows that sulfate solubility increases with increasing pressure. (See Carroll and Holloway, 1994, for reviews of experimental solubility data.)

melt composition. For silicate melts that are saturated with an  $\text{H}_2\text{O}$  and  $\text{CO}_2$ -rich vapor phase, maximum Cl solubilities range from several thousand parts per million to  $\sim 2$  wt%. Thus, Cl solubility in silicate melts is somewhat intermediate between that of  $\text{H}_2\text{O}$  and that

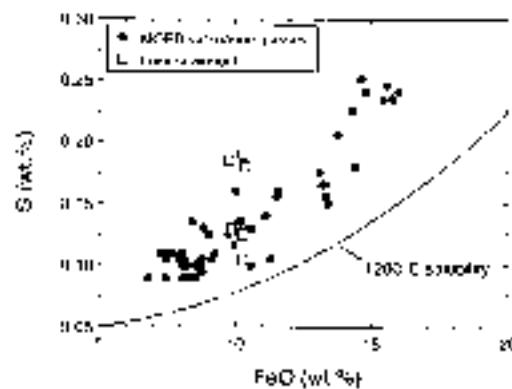

FIGURE 6 Covariation of sulfur and FeO in submarine mid-ocean ridge basalt (MORB) glasses and submarine basaltic glasses from an oceanic island volcano (Loihi seamount). Experimental solubility curve for S in basaltic melts at 1200°C is shown for comparison. Both natural and experimental data are for total S. The natural glasses form an array parallel to the experimental solubility data but offset to higher S contents. This is due to the lower oxygen fugacities of the experimental data compared with natural basaltic magmas. (Data from Wallace and Carmichael, 1992.)

of  $\text{CO}_2$ . In addition, it is possible for a silicate melt to be saturated with both hydrosaline melt and an  $\text{H}_2\text{O}$  and  $\text{CO}_2$ -rich vapor phase.

A natural silicate melt may contain less dissolved Cl than the amount needed to saturate the melt with either molten salt or hydrosaline melt. Many common magma types do not contain Cl-rich mineral phases or evidence of hydrosaline melt. By comparison with experimental Cl solubility studies, most magmas probably have insufficient dissolved Cl to be saturated with hydrosaline melt. In some Cl-rich magmas, however, formation and separation of a hydrosaline melt phase or alkali-chloride-rich vapor may play an important role in the formation of magmatic-hydrothermal ore deposits. For magmas that are saturated with an  $\text{H}_2\text{O}$  and  $\text{CO}_2$ -rich vapor phase, Cl partitions strongly into the vapor. Experimental studies suggest that the concentration, by mass, of Cl in the vapor phase can be 5–20 times or more greater than the mass concentration dissolved in the melt.

The solubility and speciation of dissolved F in silicate melts is complex and still not well understood, but available data clearly show that solubility is strongly dependent on silicate melt composition. In general, F is highly soluble in silicate melts, similar to  $\text{H}_2\text{O}$ . In granitic composition melts, as much as 10 wt% F can be dissolved. Natural melts generally have much lower dissolved F. Rare melts, such as those in tin and topaz-bearing rhyolitic magmas, may contain as much as 5 wt% F, and ultrapotassic mantle-derived magmas can contain as much as 2 wt% F.

### III. MEASURING MAGMATIC VOLATILE CONTENTS

All terrestrial magmas contain dissolved volatiles, the most abundant being  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ , S, Cl, and F. If the dissolved concentrations of volatiles are sufficiently high, a magma may be vapor saturated such that the magma also contains an exsolved vapor (gas) phase. Assessing the total volatile content of magma requires that both dissolved and exsolved volatile abundances be known. Because the solubility of most volatile components is strongly pressure dependent, magmas exsolve gas during ascent to the surface. To understand the crystallization and physical properties of magma, as well as to understand eruptive behavior, it is important to know the total volatile content of magma during its pre-eruptive storage within the Earth's crust. Dissolved volatiles may be estimated in many ways, but exsolved

volatiles are difficult to assess. The following discussion focuses primarily on dissolved volatiles; we discuss exsolved volatiles in a subsequent section.

#### A. Experimental Phase Equilibria

One of the most valuable methods for estimating dissolved volatile concentrations in magmas, particularly  $\text{H}_2\text{O}$  and  $\text{CO}_2$ , is through the use of phase equilibrium experiments. The assemblage of minerals that crystallizes from a melt of a given bulk composition and the sequence and temperature of appearance of those minerals during cooling, varies depending on pressure and dissolved  $\text{H}_2\text{O}$  concentration (Fig. 7). By equilibrating a given rock composition at various temperatures, pressures, and  $\text{H}_2\text{O}$  concentrations, it is frequently possible to find a relatively narrow range of conditions under which the observed phenocryst assemblage in the rock is in stable equilibrium. This technique is particularly suited to constraining the dissolved concentrations of  $\text{H}_2\text{O}$  during pre-eruptive crystallization and storage of magma within the Earth's crust. Experimental studies

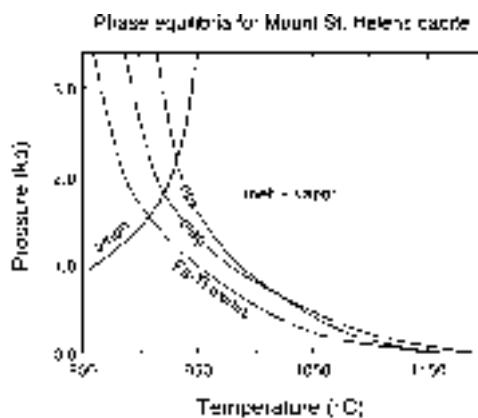

FIGURE 7 Experimental phase equilibria for 1980 Mount St. Helens dacite as a function of temperature and pressure for water-saturated melts. Because dissolved  $\text{H}_2\text{O}$  increases with pressure (Fig. 1), the water contents of the experimental melts increase along the vertical axis of the diagram. With increasing pressure (and dissolved  $\text{H}_2\text{O}$ ), the temperatures at which anhydrous minerals (pyroxene, plagioclase, Fe-Ti oxides) begin to crystallize are significantly diminished. In contrast, increasing pressure and dissolved  $\text{H}_2\text{O}$  increase the stability of amphibole, which therefore crystallizes at higher temperatures as pressure increases. Comparison with the actual observed mineral assemblage in the 1980 Mount St. Helens dacite indicates pre-eruptive temperature and pressure of  $920^\circ\text{C}$  and  $\sim 2.2$  kbar. (Modified from Rutherford *et al.*, 1985.)

have been applied with great success to a number of recent volcanic eruptions, most notably, the eruptions of Parícutin (1943–1951), Mount St. Helens (1980), El Chichón (1982), Mt. Pinatubo (1991), and Montserrat (1996–1998).

In addition to its effect on phase stability, dissolved H<sub>2</sub>O also affects the composition of minerals that crystallize from silicate melts. The most useful effect related to magmatic H<sub>2</sub>O concentrations is the change in plagioclase composition that occurs with variations in dissolved H<sub>2</sub>O. As the dissolved H<sub>2</sub>O concentration in a melt is increased, the equilibrium plagioclase composition becomes more calcic (anorthite-rich). As discussed later, anorthite-rich plagioclase phenocrysts are common in subduction-related basaltic magmas, providing evidence of relatively high concentrations of H<sub>2</sub>O compared to basaltic magmas from other tectonic environments.

### B. Analysis of Quenched Glass (Submarine Glasses, Melt Inclusions, Matrix Glass)

Subaerially cooled volcanic rocks and tephra have lost nearly all of their original magmatic volatiles because of the low pressures of Earth's atmosphere. In contrast, during deep submarine eruptions, the confining pressure exerted by the overlying water may prevent exsolution and loss of many volatile species. Such pressures can be as great as 500–600 bar. Submarine-erupted magmas typically form glassy skins where hot magma is rapidly quenched against cold seawater. Volatiles may be retained dissolved within such glassy basalt, which can be analyzed for volatiles directly. H<sub>2</sub>O is relatively soluble in basaltic melt and as much as 2 wt% may be retained in deep sea basalt glass without eruptive loss. In contrast, for relatively insoluble CO<sub>2</sub>, the pressures on the seafloor are commonly insufficient to prevent exsolution. This results in small vesicles in quenched submarine glasses, usually less than 1% by volume. The small size of these vesicles and their relatively low volumetric abundance result in isolated (noninterconnected) bubbles trapped in the quenched glass. Bulk analyses of these glassy rocks can therefore be used to assess total volatile concentration in the erupted magma, but the magma may have gained or lost bubbles before eruption. Bulk analyses of low-solubility volatiles like CO<sub>2</sub> in samples of glass with trapped bubbles commonly give greater concentrations than do direct microanalyses of the glass.

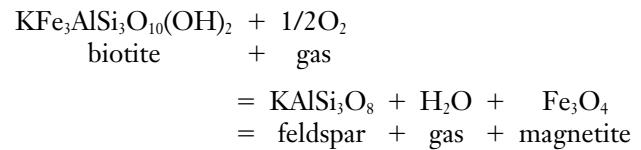

Another important source of information on the dissolved volatile concentrations of magmas is through the

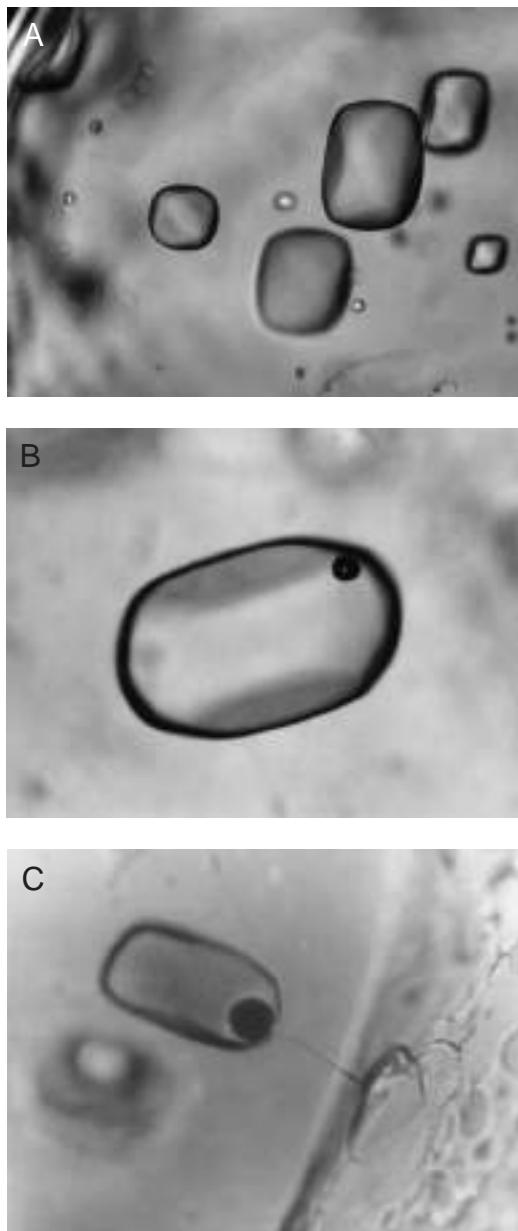

analysis of glass inclusions trapped inside of crystals. When melts crystallize, the crystals grow imperfectly, causing small amounts of melt to be trapped inside of the crystals. If the magma erupts and cools rapidly, then these trapped melt inclusions quench to glass (Fig. 8). Because the crystalline host for the inclusions is relatively rigid, they act as tiny pressure vessels and keep the trapped melt at high pressure, even though the bulk magma decompresses to surface pressure during eruption. For this reason, trapped melt (glass) inclusions commonly retain their original dissolved volatiles. However, melt inclusions may in many instances leak volatiles during explosive eruption due to cracks in the host mineral. This is especially problematic for inclusions in minerals with relatively good cleavages, such as hornblende and plagioclase. Melt inclusions in phenocrysts are trapped during crystal growth and thus sample the liquid from which the crystals grew at the time of entrapment. Inclusions that are trapped at different times during crystallization may preserve a record of changing magma compositions due to processes such as crystal fractionation and magma mixing. Glassy reentrants and hourglass inclusions (Fig. 8C) reveal the composition of melt just before eruption. Pressure-dependent concentrations of volatiles in melt inclusions, hourglass inclusions, and reentrants can reveal crystal settling and decompressive ascent of magma.

Quenched glassy scoria or pumice that formed during subaerial eruptions can also be analyzed for volatiles. Generally such material has extensively degassed during eruption and quenching, so measured volatile contents do not reflect those before eruptive decompression. Analyses of scoria glass or pumice can, nevertheless, be useful for interpreting degassing and eruptive processes.

### C. Thermodynamic Calculation Based on Mineral Compositions

One method that has commonly been used to estimate volatile concentrations in magmas is the application of thermodynamic calculations. For example, reactions involving hydrous minerals and their anhydrous breakdown products can be used along with thermodynamic properties of the phases to estimate water concentrations. One exemplary reaction is:

**FIGURE 8** Glass (melt) inclusions in crystals from volcanic rocks. (A) A fragment of an ~3-mm quartz phenocryst from the rhyolitic Bishop Tuff containing inclusions of glass up to about 100  $\mu\text{m}$  in diameter. (B) Close-up of a melt inclusion containing a small vapor bubble. The inclusion is about 80  $\mu\text{m}$  long and is partly faceted. Bubbles that are small relative to the inclusion size form during cooling after the inclusion is trapped because the melt in the inclusion contracts more on cooling than does the surrounding quartz host crystal. (C) An hourglass inclusion in a late Bishop quartz. The neck of the hourglass is about 3  $\mu\text{m}$  in diameter and it connects the inclusion to a small depression or dimple on the exterior surface of the quartz phenocryst. The main body of the hourglass is partly faceted, partially finely devitrified, and it contains a ~5 vol% bubble near the neck. The

This equation can be used to calculate the water fugacity at the time of crystallization for any volcanic rock containing biotite, feldspar, and magnetite, provided the oxygen fugacity can also be estimated. Then a thermodynamic solubility model calibrated on experimental data can be used to convert the  $\text{H}_2\text{O}$  fugacity to dissolved  $\text{H}_2\text{O}$  concentration. Comparison of this technique with estimates of dissolved  $\text{H}_2\text{O}$  from phase equilibrium and melt inclusion studies shows variable agreement. In general, this approach does not offer the precision or accuracy of modern techniques used to analyze directly volatile concentrations in glasses, but it can be very useful if other types of data are unavailable.

Another way in which thermodynamic equations are commonly used to infer volatile concentrations is through the use of pyrrhotite composition to estimate fugacities of S species. Pyrrhotite ( $\text{Fe}_{1-x}\text{S}$ ) has variable Fe (and other minor element) concentrations. Experimental data on pyrrhotite combined with thermodynamic calculations make it possible to use pyrrhotite composition to estimate  $\text{S}_2$  fugacity. Provided the oxygen and water fugacities are independently known, one can calculate the fugacities of both  $\text{H}_2\text{S}$  and  $\text{SO}_2$ . It is not possible, however, to convert the fugacities of the various S species into concentrations of dissolved S, as is done with  $\text{H}_2\text{O}$ , because experimentally calibrated solution models for pyrrhotite-saturated melts are not available.

#### D. Fluid Inclusions

The presence of primary fluid inclusions in minerals from volcanic or plutonic rocks provides evidence that crystallizing melts were vapor and/or brine saturated. However, it can be difficult to distinguish between primary fluid inclusions, trapped during igneous crystallization, and secondary inclusions formed by lower temperature hydrothermal processes. Many volcanic phenocrysts from basaltic rocks contain dense  $\text{CO}_2$ -rich, primary fluid inclusions, indicating that the basaltic magma was  $\text{CO}_2$  saturated during crystallization. Such inclusions can be used to estimate the pressure of inclusion entrapment. Knowledge of this, coupled with experimentally determined  $\text{CO}_2$  solubilities in basaltic melt, can be used to

---

bubble grew as melt moved outward from the inclusion through the neck to the ascending (decompressing) melt outside of the crystal. Study of hourglass inclusions provides a way to estimate the rate of magma rise and the duration of eruption.

estimate the dissolved CO<sub>2</sub> concentration of the basaltic magma at depth. Phenocrysts in more evolved volcanic rocks (dacites, rhyolites) may contain inclusions containing one or more of the following: fluid, vapor, hydro-saline melt, daughter crystals. The presence of these inclusions also can be taken as evidence for vapor saturation during crystallization, but the multicomponent nature of such inclusions (H<sub>2</sub>O–CO<sub>2</sub>–NaCl) makes it difficult to infer the original dissolved volatile concentrations in the coexisting silicate melt.

### E. Saturation with Volatile-Rich Minerals and Immiscible Liquids

The most common volatile-rich minerals and immiscible liquids that occur in magmas are sulfide and sulfate minerals and immiscible sulfide (Fe-S-O) liquid. The presence of one or more of these phases in a quenched volcanic rock indicates pre-eruptive saturation with a S-rich phase. By comparison with experimental solubility data, this makes it possible to infer a pre-eruptive dissolved S concentration. For basaltic melts at low oxygen fugacities, thermodynamic solution models similar to those for H<sub>2</sub>O and CO<sub>2</sub> are available, allowing precise estimates of dissolved S for sulfide-saturated melts. Under oxidizing conditions and for more silica-rich magmas, no such solution models are available, but there is an excellent experimental database covering a wide range of melt compositions and oxygen fugacities that can be used to make estimates of dissolved S concentration.

For volatile species whose solubility in a melt is controlled by the presence of a volatile-rich mineral or melt, such as a sulfide phase, complex changes in solubility can occur during magma cooling and differentiation. As an example, it has been observed in quenched glassy submarine pillow rinds from midocean ridge basalts (MORB) that only a small amount (<1.5% by mass) of the total S in the magma is present as quenched sulfide globules. This observation may seem somewhat surprising when one considers that the strong temperature dependence of S solubility should cause considerable precipitation of immiscible sulfide liquid during cooling. However, the observed low quenched sulfide globule abundance is consistent with thermodynamic and experimental assessment of the effects of differentiation on S solubility. During the cooling and crystallization of MORB magmas, residual liquids become increasingly Fe enriched due to fractional crystallization of silicate phases. The increase in Fe content increases the S solubility in the melt by an amount that is greater than the

decrease in S solubility brought about by cooling. This results in differentiated Fe-Ti basalts that have higher dissolved S than the parental (unfractionated) magmas. This effect, combined with the increase in residual melt S brought about by crystallization, keeps MORB magmas finely balanced just at the S saturation point, causing the total mass of S in immiscible sulfide liquid to be small throughout the course of differentiation. In contrast, Kilauean tholeiitic magmas do not show an Fe-enrichment trend because crystallizing and fractionating olivine contains approximately the same weight percent FeO as the liquid from which it precipitates. In the absence of Fe enrichment, if the melt is saturated with immiscible sulfide liquid, then the solubility of S will decrease significantly as temperature decreases.

---

### IV. ANALYTICAL TECHNIQUES FOR MEASURING VOLATILE ABUNDANCES IN SILICATE GLASSES

A large number of analytical techniques have been used to measure volatile concentrations in silicate glasses. These techniques fall into two main categories—bulk extraction techniques, in which a bulk rock or glass sample is crushed and analyzed, and microanalytical techniques, in which a tiny portion of glass is analyzed. Bulk extraction techniques can make it difficult to distinguish between the volatiles that are actually dissolved in quenched magmatic liquid (e.g., glassy submarine pillow rinds) and the volatiles that may be present in unopened vesicles. Furthermore, it is critical to select material for analysis that is free of alteration. Microanalytical techniques offer high spatial resolution, making it possible to analyze a tiny portion of alteration-free glass. The variety of analytical techniques available for volatile analysis makes a thorough review beyond the scope of this chapter. References to detailed reviews of analytical techniques are given at the end of the chapter.

---

### V. VOLATILE ABUNDANCES IN BASALTIC MAGMAS

As an introduction to discussing volatiles in basaltic magmas, we first briefly review the abundance and stor-

age of volatiles in Earth's mantle, from which basaltic magmas are generated by partial melting. Volatiles in the Earth's mantle can reside in a number of potential minerals. Recent infrared spectroscopic studies have demonstrated that significant quantities of water can be present as structurally bound OH<sup>-</sup> in the nominally anhydrous minerals olivine, pyroxene, and garnet. Water and other volatiles, such as Cl and F, could also be stored in hydrous minerals such as amphibole, phlogopite, and apatite. Carbon may be stored in magnesian carbonate minerals or as diamond, graphite, or amorphous carbon along grain boundaries of other minerals. Sulfur is bound in sulfide minerals. Estimates of the water content of the depleted upper mantle that is the source region for normal midocean ridge basalts (N-MORB) are on the order of 100–200 ppm H<sub>2</sub>O, based on studies of water in MORB glasses. If the depleted mantle extends to the 670-km discontinuity, then an amount of water equivalent to ~10% of the mass of water in the present-day ocean could be contained in the upper mantle. The mantle source regions for enriched midocean ridge basalts (E-MORB) probably contain 300–500 ppm H<sub>2</sub>O.

During partial melting, water and other volatiles generally behave as incompatible elements—elements that are enriched in the melt phase—because they are not stoichiometric constituents of the major mantle silicates. Even S, which is contained in sulfides, behaves as an incompatible element because of the low modal abundance of sulfide. Thus basaltic magmas act as agents for outgassing the Earth's mantle by carrying volatiles to the surface.

In the following sections, we discuss the volatile concentrations of basaltic magmas from various tectonic settings. We focus particularly on H<sub>2</sub>O because it is the most abundant volatile and exerts the strongest influence on magma physical properties, crystallization and differentiation, and eruptive style. Because of its relatively high solubility, little or no water is degassed from basaltic magmas that are quenched on the seafloor or basaltic melt inclusions trapped inside of growing phenocrysts at crustal pressures. In contrast, less soluble volatiles like CO<sub>2</sub> and the noble gases are strongly concentrated into a coexisting CO<sub>2</sub>-rich vapor phase because of their low solubility. Thus quenched basaltic glasses and melt (glass) inclusions do not generally have dissolved CO<sub>2</sub> concentrations that reflect their deep mantle (original) values. Instead, their CO<sub>2</sub> contents are an indication of the pressure at which the glass was quenched on the seafloor or was trapped inside a phenocryst. Other volatiles such as S, Cl, and F remain largely dissolved in melt like H<sub>2</sub>O. They are useful in basaltic magmas as

indicators of crystallization, degassing, and, in the case of Cl, pre-eruptive contamination of basaltic magma by seawater.

### A. Midocean Ridge Basalts

N-MORB magmas have relatively low H<sub>2</sub>O contents, typically less than 0.4 wt%, but frequently as low as 0.1–0.2 wt% (Fig. 9). E-MORB magmas, which form a volumetrically minor component of the oceanic crust, have systematically higher concentrations, as great as 1.5 wt%. Water concentrations from comagmatic suites of MORB glasses typically show positive covariation with K<sub>2</sub>O. Because K<sub>2</sub>O is a non-volatile, incompatible trace element, these correlations indicate that H<sub>2</sub>O behaves as an incompatible element during partial melting of the mantle and that significant H<sub>2</sub>O is neither lost by degassing nor gained by assimilation in magma reservoirs.

Dissolved CO<sub>2</sub> concentrations in quenched MORB glasses vary from 50 ppm to nearly 400 ppm. Most MORB glasses contain small vapor-filled bubbles as well, indicating vapor saturation of the melt at the time of eruption and quenching. Equilibrium thermodynamic calculations, using measured H<sub>2</sub>O and CO<sub>2</sub> contents and experimental solubility data, suggest that the coexisting vapor phase would be 93–100 mol% CO<sub>2</sub>. Actual measurements of the vapor composition in MORB vesicles are limited, but most have more than 90 mol% CO<sub>2</sub>. Because MORB magmas are saturated with a nearly pure CO<sub>2</sub> vapor, the dissolved CO<sub>2</sub> mea-

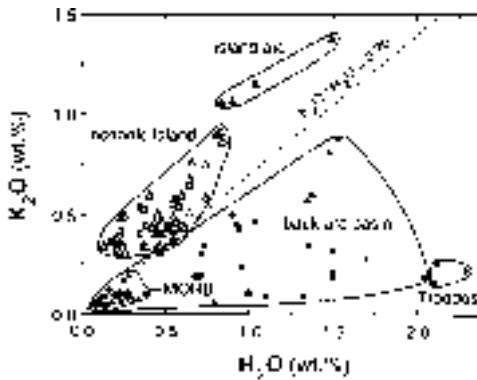

FIGURE 9 Variations in H<sub>2</sub>O and K<sub>2</sub>O in submarine basaltic glasses from different tectonic environments. Data are shown for midocean ridge basalt (MORB), backarc basin basalt (BAB), ocean island basalt (OIB), island arcs, and for unaltered vesicular glasses from the Troodos ophiolite. (Modified from Muenow et al., 1990.)

surements can be used to estimate a pressure of quenching. Such calculations indicate that many MORB melts were supersaturated with CO<sub>2</sub>; that is, they contain more CO<sub>2</sub> than should be dissolved given the pressure equivalent to their depth of eruption on the seafloor. This supersaturation is probably caused by slow diffusion of CO<sub>2</sub> in the basaltic melt during ascent, eruption, and quenching.

Sulfur concentrations in MORB glasses are typically between about 800 and 1400 ppm, but may reach as high as 2500 ppm in Fe-Ti rich basalts. Sulfur contents show strong positive correlation with the FeO content of the melt, consistent with isothermal experimental solubility relations (Fig. 6). Most MORB glasses contain small amounts of quenched immiscible Fe-S-O liquid, indicating that the melts were S saturated at the time of eruption. The most primitive MORB magmas contain 20–50 ppm Cl. In contrast, highly differentiated Fe-Ti-rich basalts contain as much as 1100 ppm Cl, an amount that greatly exceeds what would be expected during closed-system crystallization of basaltic magma. These high concentrations likely reflect assimilation of wall-rocks that have been hydrothermally altered by seawater. Fluorine contents of MORB glasses are very low, generally about 0.01–0.06 wt%. Fluorine contents in suites of comagmatic glasses show F increasing with increasing fractionation, in accordance with enrichment in residual liquids during closed-system fractionation.

## B. Ocean Island Basalts

Dissolved H<sub>2</sub>O in submarine basaltic glasses from ocean island volcanoes ranges from about 0.2 to nearly 1 wt%, significantly higher than N-MORB glass (see Fig. 9). Sulfur concentrations are commonly similar to those in MORB, suggesting that ocean island basaltic magmas, like their midocean ridge counterparts, are saturated with immiscible Fe-S-O liquid before eruption (Fig. 9). Some ocean island basaltic magmas contain as much as 3000 ppm dissolved S but are not highly enriched in FeO, in contrast to S-rich MORB magmas, which are FeO rich. This contrast is consistent with higher oxygen fugacities for these S-rich ocean island basaltic magmas. The higher oxygen fugacities decrease the stability of immiscible Fe-S-O liquid, and a higher dissolved S concentration is required before the basaltic melt is saturated with immiscible Fe-S-O liquid. Thus some ocean island basaltic melts contain more dissolved S than MORB at comparable melt FeO (Fig. 9). Chlorine and F concentrations in ocean island basaltic magmas are

relatively low and are comparable to those found in MORB glasses.

An unusual and voluminous series of deep submarine sheet flows composed of highly silica-undersaturated lavas (alkali basalts, basanites, nephelinites) was recently discovered in the North Arch volcanic field, located north of the Hawaiian island of Oahu. Dissolved H<sub>2</sub>O in glass samples dredged from these sheet flows are variable and in part high, 0.7–1.4 wt%. Dissolved CO<sub>2</sub> varies from 260 to 800 ppm. These magmas have compositional similarities to the posterosional alkalic volcanics that are erupted on many of the Hawaiian islands after the shield-building stage has ended. Thus the North Arch volcanics provide important information on the volatile contents of alkalic magmatism on oceanic islands.

The best understood oceanic island volcano, and probably the most thoroughly studied volcano on Earth, is Kilauea on the island of Hawaii. The dissolved H<sub>2</sub>O concentrations in a variety of basaltic melt inclusions and submarine glasses from Kilauea are shown in Fig. 10. MgO-rich (picritic) glasses from the submarine east rift zone contain mostly 0.37–0.56 wt% dissolved H<sub>2</sub>O. In contrast to this rather narrow range, the H<sub>2</sub>O contents of basaltic glasses ( $6.2 \pm 0.4$  wt% MgO) from the submarine east rift zone vary from 0.10 to 0.85 wt%,

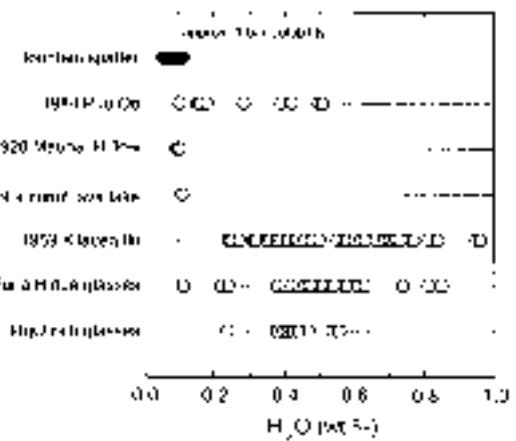

FIGURE 10 Dissolved H<sub>2</sub>O concentrations of submarine basaltic glasses (open circles), melt inclusions in olivine phenocrysts (shaded circles), and glassy tephra from lava fountains (solid circles) from Kilauea volcano. Data are shown for MgO-rich glasses, which occur as sand grains in turbidites (Clague et al., 1995) and basaltic glasses (Dixon et al., 1991) from the Puna Ridge, the submarine extension of Kilauea's east rift zone. Data for melt inclusions from the Kilauea Iki eruption of 1959 are from Anderson and Brown (1993). The approximate solubility of H<sub>2</sub>O in basaltic melt at 1-bar pressure is shown by the vertical dashed line. (Modified from Wallace and Anderson, 1998.)

and basaltic melt inclusions from olivines in the 1959 Kilauea Iki picrite contain 0.24–0.96 wt%. Melt inclusions from episode 16 of the Puu Oo eruption (1984) contain 0.10–0.51 wt% H<sub>2</sub>O. Other melt inclusions from glassy fountain spatter erupted in the summit region and on the southwest rift zone (Mauna Iki) contain about 0.10 wt% dissolved H<sub>2</sub>O, which is approximately the 1-bar solubility of water in basaltic melt. Glass from fountain spatter from Kilauea Iki, the 1919 summit lava lake, and Puu Oo all have  $\leq 0.10$  wt% H<sub>2</sub>O.

Degassing at Kilauea is inferred from gas monitoring studies to occur mainly in two stages that are related to subsurface storage and transport of magma. New batches of mantle-derived magma that enter Kilauea from below are probably saturated with a gas rich in CO<sub>2</sub>. The solubility of CO<sub>2</sub> at the pressures within the summit magma reservoir is low, and the first stage of degassing occurs as most of the CO<sub>2</sub> is lost through noneruptive degassing. The amount of H<sub>2</sub>O that is lost with the CO<sub>2</sub> in the first stage depends on the amount of CO<sub>2</sub> and the pressure, but is generally small, because H<sub>2</sub>O is highly soluble in melt. The second stage of degassing occurs when CO<sub>2</sub>-depleted magma from the summit reservoir moves along one of the two rift systems through dikes several kilometers below the surface, and then erupts, releasing H<sub>2</sub>O-rich gas.

Recognizing primary magmatic volatile contents and understanding eruptive degassing can be complicated by drainback of magma. Drainback was well documented for the 1959 Kilauea Iki eruption: Magma that degassed during eruption collected into a surface lava lake and then drained back into the vent. Drainback magma can mix with unerupted magma stored at depth to yield partially degassed hybrid magmas. Degassed hybrid magmas, with variable and in part low concentrations of H<sub>2</sub>O (0.1–0.85 wt%) and S (0.02–0.15 wt%), have been erupted on the deep submarine flanks of Kilauea. Although the submarine basalts erupted and were collected from depths at which hydrostatic pressure would have prevented significant co-eruptive loss of H<sub>2</sub>O, the low concentrations of H<sub>2</sub>O have been interpreted as reflecting low-pressure degassing prior to repressurized submarine eruption. Such degassing could have occurred by (1) eruption and drainback in the summit region prior to magma being transported down the rift, (2) existence of open fractures connecting magma storage zones to the surface such that pressures were much less than lithostatic, or (3) noneruptive degassing by magma convection in a conduit. The wide range in both submarine glass and melt inclusion H<sub>2</sub>O contents and, in particular, some very low values that occur (Fig. 10), presumably reflect degassing at pressures substantially

less than those in Kilauea's summit magma storage reservoir.

### C. Island Arc and Continental Margin (Subduction-Related) Basalts

It was first suggested in the early 1960s, before the advent of the modern concept of plate tectonics, that subduction of altered oceanic rocks beneath the Aleutian arc was responsible for recycling water into the mantle source region of arc magmas. Early measurements of the H<sub>2</sub>O content of submarine basaltic glasses from the Marianas arc (0.8–1.5 wt% H<sub>2</sub>O) and in melt inclusions from the 1974 eruption of Fuego, Guatemala, led to a view that water played a relatively minor role in the generation of arc basalts. More recent experimental studies on plagioclase-melt equilibria in low-MgO, high-alumina basalts, which are common in arcs worldwide, suggested H<sub>2</sub>O concentrations of 4–6 wt%. Recent measurements of melt inclusions from arc basalts by ion microprobe and IR spectroscopy have yielded H<sub>2</sub>O concentrations as high as 6 wt% (Fig. 11).

High H<sub>2</sub>O concentrations in arc basaltic melts support the view that water is recycled into the mantle by subduction, where it fluxes significant partial melting and formation of hydrous basaltic magma. However, there are other possible sources for some of the water in arc basaltic magmas apart from a recycled oceanic crustal component, especially in arcs built on continental crust, in which significant assimilation of lower crustal material

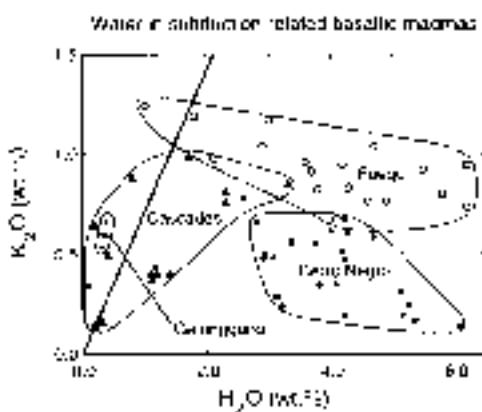

FIGURE 11 Variations in H<sub>2</sub>O and K<sub>2</sub>O in subduction-related basalt and basaltic andesite melt inclusions from Cerro Negro (Nicaragua), Galunggung (Indonesia), Fuego (Guatemala), and the southern Cascades, western United States. Data are from studies by Roggensack *et al* (1997), Sisson and Layne (1993), and Sisson and Bronto (1998). Heavy line shows a K<sub>2</sub>O/H<sub>2</sub>O ratio of 0.7 (c.f. Fig. 9).

may occur. On a global scale, it is now recognized that arc basaltic magmas may vary considerably in H<sub>2</sub>O content, both within and between arcs. Some arc basaltic magmas also contain significant dissolved carbonate, with reported concentrations as high as 1000 ppm in melt inclusions in olivine phenocrysts from Central America and Indonesia. The carbonate may, in part, have ultimately been derived from subduction of carbonate-rich marine sediments. Indeed, the isotopic composition of carbon in CO<sub>2</sub> from gases at some arc volcanoes provides evidence for such recycling of carbon by subduction processes. The complex relationship between recycling of volatiles by subduction to the mantle beneath arcs and the generation of basaltic magmas is still poorly understood.

#### D. Backarc Basin Basalts

Basaltic magmas from backarc basins show wide variations in H<sub>2</sub>O concentration, ranging from values as low as those in the most H<sub>2</sub>O-poor N-MORBs (0.1–0.2 wt%) to values as high as 2 wt% (Fig. 9). Such variations reflect the range of bulk chemical composition of backarc basin basalts, which can vary from MORB-like to showing many similarities to island arc volcanics. Dissolved CO<sub>2</sub> in submarine basaltic glass samples from the Marianas Trough are between 100 and 200 ppm. Negative covariation between H<sub>2</sub>O and CO<sub>2</sub> in these glasses and pressure estimates based on experimental solubility data suggest that the samples were vapor saturated at their depth of eruption and quenching, consistent with the presence of vesicles in the glassy pillow rims. Therefore, the bulk magmatic concentrations of H<sub>2</sub>O and CO<sub>2</sub> may be significantly greater than the dissolved concentrations. Chlorine concentrations vary from 100 to 800 ppm and show positive correlation with H<sub>2</sub>O in some comagmatic suites of glasses.

Some H<sub>2</sub>O-rich basaltic magmas erupted in backarc basins or the submarine portions of island arcs have high enough water concentration that they vesiculate and degas dissolved H<sub>2</sub>O even during eruption in very deep water. These glasses are distinguished by their relatively high vesicularities (as much as 50% vesicles by volume). As expected, they also have anomalously low concentrations of volatile components, such as S, that exsolve from magma together with H<sub>2</sub>O.

Vesicular fresh glasses from pillow margins in the Troodos ophiolite (Cyprus) have volatile contents that are similar to backarc basin basaltic glasses (Fig. 9). These similarities support the interpretation that this ophiolite originated in a backarc basin tectonic setting.

#### E. Flood Basalts and Large Igneous Provinces

Huge outpourings of basaltic lava to form continental flood basalts and oceanic plateaus (or large igneous provinces; e.g., Kerguelen plateau, Ontong Java plateau) have various ages and tectonic settings. Large igneous provinces were common during the Cretaceous and may reflect a mode of heat loss (and consequent outgassing) from the interior of the planet that is fundamentally different than in currently active plate tectonics. Few data are available on pre-eruptive magmatic volatile abundances in these types of magmas. Such data would be of considerable importance because these very large volume units could have released sufficient volatiles to Earth's atmosphere in a short time to significantly perturb global climate. For example, flood basalts of the Deccan traps erupted near the Cretaceous–Tertiary boundary, leading to the idea that their associated ashes and sulfuric acid aerosols cooled the planet enough to cause the mass extinction. This idea does not have wide acceptance now that a large impact structure has been identified as dating from the Cretaceous–Tertiary boundary. However, the rates of formation of provinces of flood basalts and large igneous provinces, and thus their effects on climates and oceans, are poorly constrained.

---

#### VI. VOLATILE ABUNDANCES IN SILICIC MAGMAS

##### A. Andesites

Andesitic magmas typify convergent plate margins and their volatiles play major roles in planetary degassing and differentiation. However, volatile abundances have been less well studied in andesitic magmas than in either basaltic or silicic magmas. Several reasons for this are that (1) deep submarine-erupted andesitic glasses are rare, and typical subaerial andesites have 30 wt% or more of phenocrysts set in a more siliceous matrix or glass; (2) andesitic magmas do not normally contain either olivine or quartz, the minerals that commonly have large melt inclusions and are the best containers for melt inclusions to prevent posteruptive volatile leakage; and (3) experimental studies of H<sub>2</sub>O-rich andesitic compositions have been hampered both by technical problems as well as by problematic application to natural disequilibrium mineral assemblages. Probably the most

important result of phase equilibrium studies on andesitic magmas is that a minimum of ~3 wt% dissolved H<sub>2</sub>O is necessary to stabilize hornblende, a common phenocryst mineral in andesites. However, hornblende stability is also strongly affected by other factors, such as the Na<sub>2</sub>O content of the coexisting silicate melt. Thermodynamic analysis of plagioclase-liquid equilibria in andesitic magmas from the western Mexican volcanic belt suggests about 2.5–4 wt% H<sub>2</sub>O in hornblende-bearing andesites and about 1 wt% in andesites that lack hornblende. Analyzed melt inclusions from andesitic magmas in other subduction-related volcanic arcs vary from about 1–4 wt% H<sub>2</sub>O. We should reemphasize, however, that these analyses are from phenocryst-rich andesitic magmas in which the interstitial melt portion of the magma, as well as trapped melt inclusions, are relatively silica rich (69–74 wt% SiO<sub>2</sub>).

Sulfur concentrations measured in andesitic melt inclusions from subduction zone magmas are normally ≤1000 ppm, with typical values of 200–400 ppm. Sulfur generally shows a positive correlation with the FeO content of the melt. There is a significant difference in the origin of this correlation and the one observed for MORB magmas, though both are related to the effect of melt FeO content on S solubility. During cooling, crystallization, and differentiation of MORB magmas, there is an increase in melt FeO in residual liquids that increases S solubility. In contrast, during crystal fractionation of andesitic magmas, residual liquids have decreasing FeO contents, such that the S solubility in andesitic melts decreases during cooling and crystallization. A further complexity of interpreting S variations in andesitic magmas is related to oxygen fugacity. The range of oxygen fugacity for typical andesitic magmas varies from slightly below the NNO buffer reaction to about 2 log units more oxidized than NNO. Over this range, sulfur speciation changes from dominantly sulfide to dominantly sulfate (see Fig. 4). Thus solubility limits for S in andesitic magmas and their variations during crystallization differentiation are potentially complex. In a few cases, S in andesitic melt inclusions is as great as 3000 ppm; this probably reflects a relatively high magmatic oxygen fugacity because sulfate is much more soluble than sulfide.

Limited data on halogen abundances in andesitic melt inclusions indicate ~1500 ppm Cl and ~500 ppm F.

## B. Dacites and Rhyolites

Water and many other volatiles are relatively abundant in silicic magmas both as dissolved species and in ex-

solved gas. High concentrations of H<sub>2</sub>O, in particular, provide the energy for the powerful explosive eruptions that typify silicic magmas. Glassy dacitic and rhyolitic melt inclusions are common in rapidly quenched phenocrysts from explosive eruptions, and analyses of the inclusions commonly reveal 3–7 wt% H<sub>2</sub>O. Experimental phase equilibrium studies reveal temperatures and depths of equilibration, and dissolved H<sub>2</sub>O concentrations. Analytical (melt inclusion) and experimental results are broadly consistent for dissolved volatiles. Experimental phase equilibria studies cannot be used, however, to determine whether a magma was vapor saturated before eruptive decompression. For cases where independent data suggest pre-eruptive vapor saturation, phase equilibria can constrain the composition of the vapor.

Water-rich rhyolitic melt inclusions are typical of low-temperature (700–800°C) melts containing hydrous phenocrysts of biotite and amphibole. Less H<sub>2</sub>O is found in rhyolitic glasses that cooled from higher temperatures (900–1000°C) and contain pyroxene but no hydrous phenocrysts. Wide variations in dissolved CO<sub>2</sub> are found in rhyolitic melt inclusions, varying from 10 to about 1200 ppm. Based on the pressure-dependent solubilities of H<sub>2</sub>O and CO<sub>2</sub> in rhyolitic melts, the melt inclusion data can be used to compute the pressure at which the melt would be saturated with a vapor phase (the vapor-saturation pressure) and thereby constrain pressures of crystallization (inclusion formation). For vapor-saturated magmas the indicated vapor-saturation pressure equals the pressure of crystallization. For magmas lacking vapor (vapor undersaturated), the actual pressure of crystallization is greater than the vapor-saturation pressure. Vapor-saturation pressures based on melt inclusion H<sub>2</sub>O and CO<sub>2</sub> concentrations vary from about 1 to 4 kbar, implying a range of upper crustal depths through which silicic volcanic magmas differentiate and reside before eruption.

Detailed experimental phase equilibrium studies have been performed on the 1980 Mount St. Helens dacite (Fig. 7) and the 1991 Mt. Pinatubo dacite. The results for both indicate crystallization pressures of ~2.2 kbar and temperatures of 920 and 780°C, respectively, as well as significant dissolved H<sub>2</sub>O. For the Mount St. Helens dacite, the experimentally synthesized mineral assemblage and mineral compositions match the natural assemblage when there is about 4.6 wt% H<sub>2</sub>O dissolved in the melt. If the magma was vapor saturated before eruption, then the experimental data can be used to infer a vapor phase composition of 50–70 mol% H<sub>2</sub>O and 30–50 mol% CO<sub>2</sub>. In contrast, the experimental data for Mt. Pinatubo dacite indicate a higher H<sub>2</sub>O concen-

tration of ~6 wt%, consistent with analyses of melt inclusions trapped in quartz phenocrysts. These pre-eruptive dacitic magmas appear to have contained a vapor phase during crystallization, because the vapor-saturation pressures and pressures based on phase equilibria are equal.

One of the best studied rhyolitic eruptions in terms of magmatic volatile abundances is the 0.76-Ma explosive, caldera-forming eruption that formed the 500-km<sup>3</sup> Bishop Tuff. Melt inclusions in Bishop quartz phenocrysts reveal systematic, pre-eruptive gradients in dissolved H<sub>2</sub>O and CO<sub>2</sub> during crystallization (Fig. 12). Melt inclusions from early erupted pumice fall deposits contain 5.3 ± 0.4 wt% H<sub>2</sub>O and 60 ± 40 ppm CO<sub>2</sub>, whereas those from the middle of the eruption contain higher H<sub>2</sub>O (5.7 ± 0.2 wt%) and CO<sub>2</sub> (120 ± 60 ppm). Thus early erupted magma contained less dissolved H<sub>2</sub>O and CO<sub>2</sub> than magma from the middle of the eruption. Compared with melt inclusions from early and middle Bishop Tuff samples, inclusions from late erupted magma have much lower H<sub>2</sub>O (4.1 ± 0.3 wt%), and higher and variable CO<sub>2</sub> (150–1100 ppm). The estimated pressures of crystallization (vapor-saturation pressures) are lower for inclusions from the earliest

erupted samples than in samples from the middle of the eruption. This pattern is consistent with sequential tapping of a large zoned body of gas-saturated magma, because the first material erupted would likely come from the shallowest (lowest pressure) portion of the magma body.

Dissolved S concentrations in silicic magmas tend to be relatively low ( $\leq 200$  ppm), and are frequently below the minimum detection limit of common analytical techniques. These low concentrations occur despite the fact that most silicic magmas are saturated with a sulfide (pyrrhotite) and/or sulfate phase (anhydrite). The low S solubility is caused by a combination of low melt FeO content and the low temperature of silicic magmas. The former is an important factor at relatively low magmatic oxygen fugacity where dissolved S is dominantly sulfide, whereas decreasing temperature significantly decreases both sulfide and sulfate solubilities (see Fig. 5).

Fluorine and chlorine abundances are relatively low in metaluminous dacites and rhyolites (F, 200–1500 ppm; Cl, 600–2700 ppm). In the Bishop Tuff melt inclusions, F varies from 160 to 460 ppm and Cl varies from 550 to ~800 ppm. Both elements are more abundant in the most highly differentiated, early erupted Bishop Tuff whereas lower concentrations occur in the least differentiated magma that erupted later. Melt inclusions from the 1991 Mt. Pinatubo dacite contain ~1000 ppm Cl. In contrast to halogen abundances in metaluminous magmas, peralkaline rhyolites (pantellerites) contain as much as 1.3 wt% Cl and 1.5 wt% F. These high concentrations reflect the highly differentiated nature of these magmas, which causes Cl and F to increase like other incompatible trace elements, and to the effects of alkalies in increasing Cl and F solubilities in silicate melts. Peraluminous tin and topaz rhyolites of the western United States and central Mexico also contain high halogen concentrations, with Cl reaching 0.5 wt% and F as great as 5 wt%.

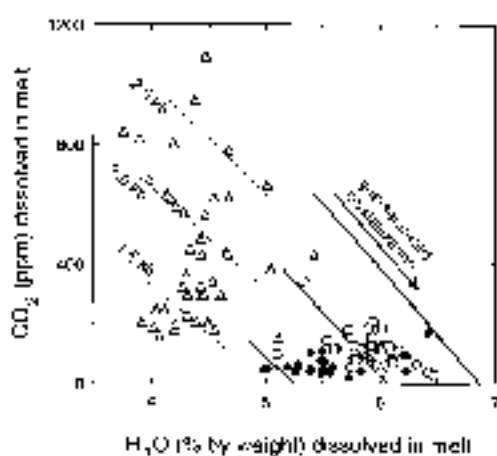

FIGURE 12. Dissolved H<sub>2</sub>O and CO<sub>2</sub> in rhyolitic melt inclusions in quartz phenocrysts from the 0.76-Ma Bishop Tuff. Data are shown for samples from the early (solid circles), middle (open circles), and late (open triangles) parts of the eruption. Diagonal lines show the H<sub>2</sub>O and CO<sub>2</sub> contents of rhyolitic melt saturated with H<sub>2</sub>O-CO<sub>2</sub> gas at pressures from 1.5 to 2.5 kbar and temperatures of 725°C (solid lines) and 790°C (dashed lines), which correspond to the pre-eruptive temperatures for the early and late erupted magmas, respectively. The arrow indicates the trend of H<sub>2</sub>O and CO<sub>2</sub> contents in successive residual liquids formed by isobaric, gas-saturated crystallization. (Modified from Wallace *et al.*, 1995, *Nature*.)

### C. Gradients in Volatile Abundances and Vapor Saturation in Magmas

Gradients in dissolved volatiles, especially H<sub>2</sub>O, within individual silicic magma bodies have been inferred from (1) variations in phenocryst assemblages and compositions; (2) variations in whole-rock abundances of F and Cl; and (3) the observation that many volcanic eruptions evolve with time from high-energy Plinian columns to pyroclastic flows, or culminate with quiescent dome extrusion. Gradients in dissolved H<sub>2</sub>O in silicic magma bodies have more recently been confirmed using ion

probe and infrared spectroscopic techniques on melt inclusions in phenocrysts. However, changes in eruptive style from Plinian column to pyroclastic flow often do not appear to be related to differences in pre-eruptive dissolved water, insofar as this is recorded by melt inclusions in phenocrysts. Even effusive (nonexplosive) eruptions of silicic magma appear to involve magma with initially high dissolved H<sub>2</sub>O concentrations. That such magmas are erupted nonexplosively requires that water be lost prior to extrusion. This probably occurs when magma decompression induces sufficient vesicularity to form a magmatic foam that is highly permeable to gas loss.

It has commonly been thought that magmas of intermediate to silicic composition only become gas-saturated during shallow ascent and emplacement, during eruptive decompression, or during advanced (pegmatic) stages of plutonic crystallization. However, studies of eruptive dynamics, CO<sub>2</sub> and SO<sub>2</sub> emissions, and melt compositional features all suggest that many magmas in subvolcanic reservoirs are saturated with a multicomponent vapor. Volcanoes could be viewed primarily as gas vents. In particular, the small but finite solubility of CO<sub>2</sub> in silicic magmas at crustal pressures could result in saturation with H<sub>2</sub>O-CO<sub>2</sub> vapor during partial melting as well as during ascent, emplacement, and crystallization. High-temperature fluid inclusions in phenocrysts from some silicic volcanic rocks provide direct evidence of pre-eruptive vapor saturation. Gradients in alkali and trace element abundances might result in part from upward flux of exsolved gas in a large magma body.

Correlations between CO<sub>2</sub> and trace elements in melt inclusions from the Bishop Tuff indicate that the magma was gas saturated during pre-eruptive crystallization. Quantitative models of gas exsolution during crystallization of the Bishop magma are consistent with exsolved gas contents varying from about 1 wt% in the deeper regions of the magma body to nearly 6 wt% near the top (Fig. 13). Thus the data and models suggest that there was a gradient in exsolved gas, with mass fractions of gas increasing upward toward the roof of the magma body. Because the exsolved gas phase would be H<sub>2</sub>O rich, such large exsolved gas contents imply that the early erupted Bishop magma had a bulk (dissolved + exsolved) H<sub>2</sub>O content of ~10 wt%. However, these interpretations assume that gas traveled with and remained in the magma during most of its evolution. The presence of significant mass fractions of exsolved gas in Bishop magma is consistent with H<sub>2</sub>O and CO<sub>2</sub> dissolved in minimally degassed rhyolitic obsidians at Mono Craters, California. Similar mass fractions of pre-eruptive

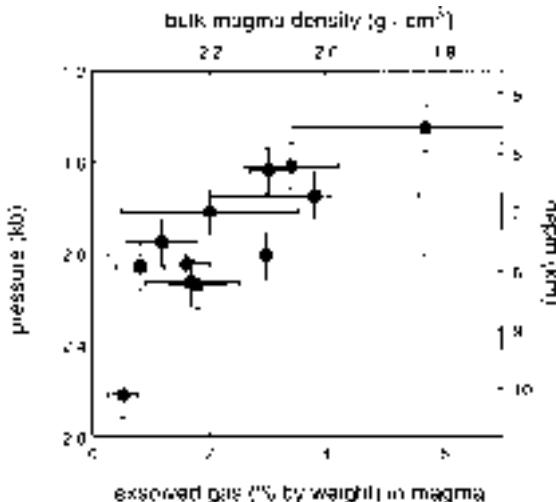

FIGURE 13 Exsolved gas content in the crystallizing Bishop rhyolitic magma as inferred from volatile and trace element analyses of melt inclusions. The bulk magma (melt + crystals + gas) density is given along the top of the diagram. (Modified from Wallace *et al.*, 1995, *Nature*.)

exsolved gas have been inferred for the magma bodies of the 1982 El Chichón and 1991 Mount Pinatubo eruptions by assuming that all SO<sub>2</sub> released (measured by remote sensing techniques) was stored in the erupted volume of magma.

#### D. Volcanic Gases, SO<sub>2</sub> Emissions, and Pre-Eruptive Vapor Saturation in Magmas

One of the most important constraints on bulk (dissolved + exsolved) magmatic volatile contents comes from studies of the fluxes of SO<sub>2</sub> from erupting volcanoes. During the last several decades, scientists have discovered that SO<sub>2</sub> gas injected into the stratosphere by explosive eruptions is converted in a matter of days into aerosols rich in H<sub>2</sub>SO<sub>4</sub> (sulfuric acid) that can affect both climate and atmospheric chemistry. Measurements of the amounts and fluxes of SO<sub>2</sub> emitted from erupting volcanoes can be made with remote sensing techniques, including both ground- and air-based use of the ultraviolet correlation spectrometer (COSPEC) and the satellite-based total ozone mapping spectrometer (TOMS). Comparison of SO<sub>2</sub> emissions with petrologic estimates of dissolved S in volcanic magmas has led to a conundrum, known as the “excess” sulfur problem. Inclusions of melt in erupted phenocrysts indicate dissolved sulfur contents that are far too low (by a factor of 10–100) for

the melt to exsolve the total mass of SO<sub>2</sub> erupted. Excess eruptive S is observed in most eruptions for which remote sensing and melt inclusion data are available. Exceptions to this general pattern are eruptions of basaltic magma from the Hawaiian volcanoes, Kilauea and Mauna Loa. Most SO<sub>2</sub> emission estimates that are based on melt inclusions in volcanic phenocrysts assume that the only source of sulfur released during an eruption is that which was originally dissolved in the silicate liquid (melt) portion of the magma shortly before eruption. However, there is a large body of evidence, based on petrologic, remote sensing, and volcanic gas data, that nearly all of the SO<sub>2</sub> released during many explosive eruptions was actually contained in pre-eruptive exsolved gas. As a result, eruptions of exsolved-gas-rich silicic magmas can release large amounts of SO<sub>2</sub> derived from pre-eruptive exsolved gas, notwithstanding very low concentrations of dissolved S.

---

## VII. IMPORTANCE OF VOLATILES IN VOLCANIC ERUPTIONS

A main goal of volcanology is to understand volcanic eruptions. Decompression of volatile-rich, viscous magmas can result in explosive eruptions because of the thousand-fold volumetric expansion of gas with decompression from 1000 to 1 bar. Gas that occupied 1 vol% of the magma at 1000 bars occupies 91 vol% at 1 bar, and the latter corresponds to a dilute spray of particles in a gas jet. Importantly, gas exsolution generally begins at depth with small amounts of relatively CO<sub>2</sub>-rich gas followed by increasing proportions and amounts of H<sub>2</sub>O-rich gas nearer the surface. Some stiff (high viscosity) magmas may have internal pressures approaching 100 bars only a few meters below the surface, because gas has been slow to escape from the magma. Theoretical modeling reveals that magmatic volatile contents largely govern the explosivity of eruptions. Conversely, plume height and tephra dispersal can be used to infer pre-eruptive volatile contents. Modeled and observed volatile concentrations have been partly at odds, and this has led to critical reassessments and model improvements. In some cases, reconciliation has tended to increase the amount of volatiles needed for specific effects, implicating the presence of significant exsolved pre-eruptive gas.

Modeling of explosive silicic eruptions shows that the velocity of erupting material is strongly dependent on

the amount of exsolved gas. Eruption velocities at the vent, estimated from the maximum size of blocks deposited near the vent, are as much as 400–600 m/s for the most powerful Plinian eruptions. Such velocities are estimated to require 3–6 wt% exsolved H<sub>2</sub>O, an amount that is consistent with dissolved concentrations indicated by experimental work and measured in melt inclusions. In many eruptions, there is an observed or inferred transition from a Plinian eruption column to a collapsing column, resulting in a transition from pumice-fall to ash-flow deposition. Lower magmatic H<sub>2</sub>O concentrations, or increased mass flux of erupting magma with the same H<sub>2</sub>O concentration due to widening of the vent can, theoretically, cause the Plinian column to become unstable and collapse to form pyroclastic flows. Interpretations of the Bishop eruption based on tephra characteristics, however, suggest synchronous eruption of one or more sustained jets that fed both a buoyant (Plinian) column, from which pumice-fall material was deposited, and collapsing clouds, which deposited ash-flows. As the eruption continued, the proportion of ash-flow material increased, the amount of H<sub>2</sub>O in melt inclusions increased slightly (Fig. 12), and the amount of pre-eruptive exsolved gas decreased (Fig. 13). Thus the amount of pre-eruptive exsolved gas may be especially important in regulating eruptive style.

The height of basaltic lava fountains is also controlled largely by the amount of exsolved gas in the erupting magma. The initial (pre-eruption) amounts of H<sub>2</sub>O that are necessary to propel lava fountains to 200- and 800-m heights are about 0.3 and 0.6 wt%, respectively. These estimates have been revised upward in light of the fact that much of the magma in typical Hawaiian-style fountains falls back into a bowl-shaped crater surrounding the vent, forming a pond of relatively dense, degassed magma. Newly vesiculating magma from depth loses some of its kinetic energy as it fountains through this degassed magma pond. After accounting for this effect, the resulting estimates of H<sub>2</sub>O concentration based on observed fountain heights are consistent with both dissolved H<sub>2</sub>O contents determined from analyses of melt inclusions trapped in olivine phenocrysts and with estimates based on the composition and fluxes of volcanic gases. Modeling also suggests that the transition from lava fountaining to intermittent Strombolian explosions is not likely to be related to a decrease in volatile content but rather is caused by a reduction in the ascent velocity of magma, which results in more time for bubble coalescence to occur. In contrast, a decrease in magmatic volatile content is predicted to result in a transition to passive effusion of vesicular basaltic lava.

### VIII. EFFECTS OF VOLATILES ON PHYSICAL PROPERTIES OF SILICATE MELTS

Small amounts of dissolved volatiles have important effects on the density, viscosity, and crystallization of melts and magmas, and these can influence magma ascent, eruption, and differentiation. Experimental data are available concerning the effects of  $H_2O$ ,  $CO_2$ , and  $F$  on melt density and viscosity, but comparable data for  $Cl$  and  $S$  do not exist.

#### A. Density

The partial molar volume of  $H_2O$  dissolved in melt of albite composition ( $NaAlSi_3O_8$ ) has been directly measured by experiment as  $14\text{--}20\text{ cm}^3/mol$  over the temperature range from  $750$  to  $950^\circ C$ . Partial molar volumes of dissolved  $H_2O$  in rhyolitic and basaltic melts estimated indirectly from solubility data are generally similar to the low end of the range for albite melt. In detail, however, determinations from solubility data can be complex because of the concentration-dependent speciation of dissolved  $H_2O$  into both  $OH^-$  groups and molecular  $H_2O$ . Given the molecular weight of  $H_2O$  ( $18\text{ g/mol}$ ) and a partial molar volume of  $\sim 14\text{ cm}^3/mol$ , addition of dissolved  $H_2O$  to a melt represents a component with a density slightly greater than  $1\text{ g/cm}^3$  compared with densities for anhydrous basaltic and rhyolitic melts of  $\sim 2.7$  and  $\sim 2.3\text{ g/cm}^3$ , respectively. Thus addition of dissolved water to a melt decreases the melt density. The effect of adding  $6\text{ wt\%}$  dissolved  $H_2O$  to a rhyolitic melt is to decrease the density by about  $5\%$ , whereas addition of  $2\text{ wt\%}$   $H_2O$  to a typical basaltic melt decreases its density by  $2\text{--}3\%$  relative to anhydrous values.

The best estimates for the partial molar volume of dissolved molecular  $CO_2$  (rhyolitic melt) and carbonate (basaltic melt) derived from solubility data are between  $21$  and  $28\text{ cm}^3/mol$ . The low solubility of  $CO_2$  results in relatively low concentrations in magmas at crustal depths, such that  $CO_2$  is not expected to have a strong effect on the densities of magmas stored in the Earth's crust. At mantle depths, especially in silica poor magmas in which  $CO_2$  solubility (dissolved as carbonate) is relatively high,  $CO_2$  can have significant effects on melt densities. The molecular weight of  $CO_2$  ( $44\text{ g/mol}$ ) and the range of partial molar volumes given earlier indicate that dissolved carbonate represents a component with a density of  $\sim 2\text{ g/cm}^3$ . The effect of adding  $3\text{ wt\%}$   $CO_2$

to an alkali basaltic melt is to decrease the melt density by  $\sim 3\%$ . For comparison, addition of  $3\text{ wt\%}$  dissolved  $H_2O$  to the same melt decreases melt density by  $\sim 5\%$ .

Determining the effects of dissolved  $F$  on silicate liquid density is complex, but available data clearly indicate that addition of  $F$  decreases melt density.

#### B. Viscosity

Experimental studies of viscosity demonstrate three important features of the viscosities of silicate melts. The first is that silicate melts exhibit Newtonian behavior, defined as a liquid in which the rate of shear in the liquid is linearly proportional to the magnitude of the applied shear stress. The second important feature is that silicate melt viscosity increases rapidly with decreasing temperature. Thirdly, silicate liquid viscosities are also strongly dependent on melt composition, the most important component being  $SiO_2$ . With increasing  $SiO_2$  content in a melt, viscosity also increases. The combination of the inverse dependence of viscosity on temperature and the positive covariation with  $SiO_2$  content results in low-temperature rhyolitic melts having a viscosity that is as much as  $8$  orders of magnitude ( $10^8$  times) greater than that of a high-temperature basaltic melt.

Addition of dissolved  $H_2O$  to a melt decreases the viscosity, probably because  $H_2O$  weakens or breaks apart the aluminosilicate framework of the melt, which makes it flow more readily. Experimental studies have shown a nonlinear effect of  $H_2O$  in decreasing viscosity (Fig. 14). Over the range from  $0$  to  $3\text{ wt\%}$   $H_2O$ , water has

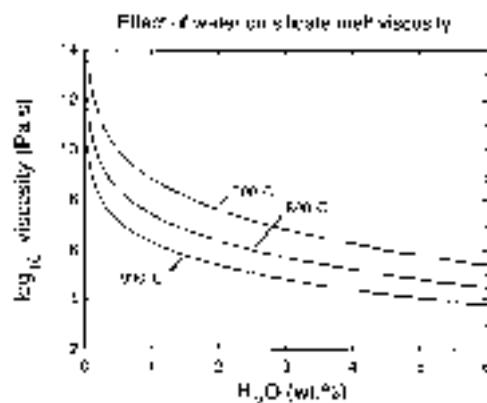

FIGURE 14 Effect of dissolved water on the isothermal viscosity of a granitic (rhyolitic) melt. Note that at low water concentrations, the  $700$  and  $800^\circ C$  curves are for supercooled melt, because the temperatures are below the solidus temperature for melting of dry granite ( $900^\circ C$  for  $H_2O$ -free granite). Calculated from Hess and Dingwell (1996).

a very strong effect in reducing viscosity. In the case of siliceous melts, addition of 3 wt% H<sub>2</sub>O to a dry melt may reduce the viscosity by as much as 5 orders of magnitude. For dissolved H<sub>2</sub>O greater than 3 wt%, addition of more water has a much smaller effect on the viscosity. The reason for the change in the effect of H<sub>2</sub>O is plausibly related to the speciation of dissolved water. From 0 to 3 wt% H<sub>2</sub>O, water is dissolved predominantly as OH<sup>-</sup> groups bound to the aluminosilicate framework—thus in this concentration range, dissolved water has a relatively large effect on viscosity. Above 3 wt% H<sub>2</sub>O, the amount of water that is present as OH<sup>-</sup> reaches a maximum value, and additional dissolved water is mostly present as H<sub>2</sub>O molecules that do not cause weakening or breaking of aluminosilicate bonds. Thus at higher concentrations water has a smaller effect on silicate melt viscosity.

Determining the effects of dissolved CO<sub>2</sub> on melt viscosity is difficult. Available experimental data suggest that dissolved CO<sub>2</sub> reduces the viscosity of silicate melts, but the effect is much smaller than for H<sub>2</sub>O. Experimental studies show that F has a relatively large effect in reducing the viscosity of SiO<sub>2</sub>-rich melts. Although the concentration of F in most natural magmas is low enough to preclude it having a significant effect, F-rich topaz rhyolites have sufficient F to reduce magma viscosity by as much as 3 orders of magnitude. A manifestation of this effect is the eruption of topaz rhyolites to form unusually long lava flows with little associated explosive tephra.

---

#### IX. ORIGIN OF VOLATILES, EARTH DEGASSING, AND VOLATILE RECYCLING VIA SUBDUCTION

Studies of both inert and reactive volatile elements help scientists evaluate the origin and evolution of the Earth. This chapter has as its primary focus the reactive volatiles that mostly become chemically bound into either minerals or molecules in air, water, oil, and ice. In this section, we give an elementary overview of some of the inert volatile elements (usually termed *noble gases*): helium, neon, argon, krypton, xenon, and radon. Studies of inert gases, particularly helium and argon, help constrain ideas about Earth's origin and evolution. The noble gases readily enter the Earth's atmosphere, and they comprise both radiogenic and nonradiogenic isotopes. Thus certain isotopic ratios change in time and may reflect ratios of radioactive parent nuclides and

nonradiogenic inert gas in compositionally distinct and physically separate parts of the Earth. Helium and argon are especially interesting in this regard. Helium has two isotopes: <sup>3</sup>He and <sup>4</sup>He. Radioactive decay of uranium and thorium yield <sup>4</sup>He, whereas radiogenic production of <sup>3</sup>He is negligible in virtually all Earth environments. Furthermore, helium escapes from the atmosphere because in the upper stratosphere, the pressure is low, atoms are far apart, and the average speed of low mass atoms may exceed the threshold value at which Earth's gravitational field can slow outward-moving atoms and return them to the Earth. The more helium there is in the air, the greater the outgoing escaping flux (number of atoms of helium escaping per year, for example). At some point the amount of helium in air is just right for the escaping flux to be balanced by the rate of supply from the interior of the Earth.

Geological processes such as ocean circulation, sea-floor spreading, and continental erosion affect the fluxes of helium from various storage reservoirs within the earth. As a result, the ratio of nonradiogenic <sup>3</sup>He to radiogenic <sup>4</sup>He in different rocks and water bodies characterizes various sources of He: Helium in air is relatively poor in <sup>3</sup>He compared to helium in oceanic ridge basalts and basalts associated with hot spots such as Hawaii. Thus it is likely that most of the helium in air comes from continental rocks, which are rich in uranium and thorium, and have therefore produced significant <sup>4</sup>He from radioactive decay. Such rocks have evolved near the Earth's surface for geologically long periods of time and probably their original <sup>3</sup>He was lost from the Earth's atmosphere long ago. Only deeply buried sources plausibly retain <sup>3</sup>He that was initially present in the Earth when it formed from objects in the solar nebula. Thus comparatively high <sup>3</sup>He/<sup>4</sup>He ratios of basalts from Hawaii suggest that Hawaiian basalts are derived, at least in part, from deep within the mantle, possibly from an undegassed remnant of lower mantle material left over from early in Earth's history.

Similarly, investigations of radiogenic <sup>40</sup>Ar (produced from the radioactive decay of <sup>40</sup>K) compared with nonradiogenic <sup>36</sup>Ar in both terrestrial and meteoritic rocks support the view that the mantle consists of at least two parts. One part has largely lost its argon and presumably most of its other volatiles, including reactive ones such as H<sub>2</sub>O, which readily dissolve in silicate melts and are carried toward the surface in magmas. A second part seems to still have much of its nonradiogenic argon (<sup>36</sup>Ar) and evidently is relatively primordial. An atom of argon is 10 times more massive than one of helium and nearly all argon is retained in the atmosphere by Earth's gravitational field. Nearly all argon in air is <sup>40</sup>Ar, but

there is less  $^{40}\text{Ar}$  than the amount expected based on the  $^{40}\text{K}$  content of the Earth, which is independently reasonably well known. Thus there must be a significant part of the Earth that contains much of the  $^{40}\text{Ar}$  that has been produced by decay of  $^{40}\text{K}$  during the history of the Earth and which has not yet reached the atmosphere. If an incompletely degassed mantle reservoir contains the missing radiogenic  $^{40}\text{Ar}$ , then this reservoir would likely also contain a significant amount of reactive volatiles such as  $\text{H}_2\text{O}$  and  $\text{CO}_2$ .

Studies of inert gases are consistent with the theory that early in its history, the Earth was covered by a deep magma ocean, caused by conversion into heat of some of the gravitational potential energy of accreting material. Inert volatiles would have become predominantly degassed and concentrated in the atmosphere during the Earth's formation. Such an early atmosphere could have been largely lost from the Earth as a result of solar activity or violent impacts. Significant amounts of reactive volatiles such as  $\text{H}_2\text{O}$  could have dissolved in the magma ocean. Subsequent crystallization of the magma ocean and formation of minerals poor in  $\text{H}_2\text{O}$  would promote degassing by concentrating the reactive volatiles in a diminishing residue of liquid, thereby leading to the formation, rise, and escape of bubbles of gas.

It is conceptually important that present degassing rates of primordial, nonradiogenic inert gas from ocean ridge magmatism (based on the  $^3\text{He}$  rate and ratios of other inert gases to  $^3\text{He}$ ), when multiplied by the age of the Earth, yield much less total nonradiogenic neon and argon than is presently in Earth's atmosphere. Thus it is inferred that the rate of degassing from the Earth either was much greater in the past, or that significant inert gas has been separately added to the outermost Earth by meteoritic infall. The present-day isotopic composition of nonradiogenic inert gases being degassed from the Earth is noticeably different from that in air, and intermediate between that of inert gases from the Sun and from meteorites. The discrepancy can therefore be reconciled with either a mixture of sources for the Earth's inert gases or preferential loss from Earth's atmosphere of less massive isotopes.

Subduction provides a mechanism by which sediments and altered oceanic crust are recycled back into the mantle. The sediments and altered crust are relatively rich in the two major reactive volatiles: carbon dioxide stored as carbonates, and water, both as pore water and as water bound in hydrous minerals such as clays. Most of the hydrous minerals break down to anhydrous minerals and release water vapor as the subducting rock heats up. The pore water and the water released from hydrous minerals are buoyant, and in-

creasing pressure from the weight of overlying rocks collapses pores and forces water out of deeply buried rocks. Some deep storage of water is possible, however, in view of experimental studies which show that some dense hydrous magnesian silicates are stable to very high pressures and temperatures. Also, small concentrations of water occur as structurally bound  $\text{OH}^-$  in nominally water-free minerals such as olivine and pyroxene. Subduction-related basaltic magmas are notably more water-rich than midocean ridge and ocean island basaltic magmas, and such magmas may return most or all of the subducted water to the surface. A small fraction of the subducted water may be cycled into the deeper mantle, but this is unconstrained.

The isotopic composition of water is unaffected by radioactive decay (except for bomb tritium) and has probably been negligibly affected by preferential escape from Earth of hydrogen compared to more massive deuterium. Ratios of hydrogen to deuterium in various water reservoirs mainly reflect the geologic processes that partition water into these reservoirs. Water initially released from magmas at igneous temperatures is eventually redistributed by formation of new low-temperature minerals in the reservoirs of altered rocks, seawater, freshwater, and ice. Isotopic fractionation during this redistribution causes the oxygen and hydrogen isotopic composition of seawater to differ from that dissolved in parental basaltic magmas; the balance is made up mainly by the isotopically light water bound in altered rocks. There is no isotopic evidence for a significant source of surface water beyond that which degasses from basaltic magmas. Nor is there evidence for preferential subduction and hidden storage of water that is isotopically distinct from that which is in parental basaltic magmas.

The isotopic composition of carbon in parental basaltic magmas and various terrestrial reservoirs is not certain. There may be a significant isotopic shift upon degassing and this makes it difficult to assess the isotopic composition of carbon in parental basaltic magmas. The predominant recognized reservoir of terrestrial carbon is in sedimentary limestones and dolomites and it differs significantly from that which degasses from basaltic magmas at igneous temperatures. Photosynthesis yields reduced carbon in biological tissues that is relatively poor in  $^{13}\text{C}$  and this affects the isotopic composition of carbon in surficial reservoirs. Existing knowledge permits the amount and isotopic composition of buried organic matter (mainly reduced C in shales and coals) to balance the amount and isotopic composition of carbon in carbonate rocks, yielding a sedimentary average that is consistent with igneous gas. However, significant additions of isotopically distinctive carbon to Earth's

early atmosphere during the final stages of accretion as well as storage of carbon in Earth's core are possible. Furthermore, it is possible that the isotopic composition of carbon now released from magmas reflects a recycling steady state, and it may have differed in the remote past, reflecting a smaller proportion of recycled carbon.

Carbonate rocks, if mixed with quartzose rocks will undergo decarbonation reactions during subduction into the deep crust and shallow upper mantle, and carbon dioxide-bearing gas will form and return to the surface. This may be a source of some carbon dioxide in gas reservoirs and hot springs, but most carbon dioxide in such environments is derived from superficial sources like heated groundwater. Carbonate rocks alone or with silica-poor minerals are refractory and may remain stable to great depths in the mantle. Thus subduction of limestones can potentially introduce carbon dioxide as carbonate rocks into the deep mantle where it may persist. Subduction of carbonate rocks plausibly increased during the past 180 million years owing to biological evolution of pelagic foraminifera and formation of abundant, subductable deep oceanic carbonates, possibly reversing the net flux of carbon dioxide back into the mantle from the crust. The flux of carbon dioxide associated with subduction zone volcanism is poorly known, and this topic could benefit greatly from further study.

The downgoing view of carbon dioxide is illuminated by the fact that at fairly shallow mantle depths the carbonate mineral dolomite becomes stable in a typical assemblage of mantle silicates. Thus a deep residence of mineralogically bound carbon dioxide is feasible. Under the conditions of pressure and temperature where dolomite is stable in the mantle, carbon dioxide is quite soluble in silicate melts and can flux partial melting at comparatively low temperatures. The upgoing view of ascending carbonate-rich magmas is marked by the expected release of carbon dioxide gas at shallow upper mantle pressures. Plausibly this pressure-sensitive effervescence of carbon dioxide gas is partially responsible for the explosive nature of rare magmas, bringing diamonds and fragments of the mantle to the upper crust.

Yearly amounts of reactive volatiles  $H_2O$  and  $Cl$  that are subducted are in the range of rough estimates of what is returned surfaceward by arc magmatism. If there were no surfaceward return of subducted  $H_2O$  and  $Cl$ , then the formation, alteration, and subduction of oceanic crust would comprise a net drain on the water and salt in the oceans. The geologic record and understanding of tectonism reveal that continental crust and ocean water have existed for most of Earth's history; subduction has not caused the oceans to dry up. Thus water

lost to altered oceanic crust is probably largely returned to the oceans via dewatering of subducted crust and subduction-related magmatism.

## X. FUTURE DIRECTIONS

The study of magmatic volatiles lies at the interface of igneous petrology and volcanology. Much of our present state of knowledge has been derived relatively recently due to major advances in techniques of microanalysis. Improvements that are under way will soon make it possible to measure the isotopic composition of volatile and nonvolatile species in silicate melt inclusions, as well as the determination of some volatile trace metals in trapped fluid or vapor + melt inclusions in volcanic phenocrysts. Combined analyses of volatile species, trace elements, and isotope ratios (e.g., H, O, S, C, He, Sr) will contribute to a better understanding of volatile recycling in the Earth, melting processes, magmatic differentiation, and magma degassing.

The pressure-dependent solubilities of the major volatiles  $H_2O$  and  $CO_2$  in silicate melts make it possible to use melt inclusions as geobarometers. Combined with major, trace, and isotopic data, and detailed knowledge of time–volume–compositional variations in eruptive deposits, melt inclusions can be used to place constraints on magma chamber configurations, and magmatic and eruption processes. In this context, petrologic techniques for estimating the bulk (dissolved + exsolved) volatiles in magma bodies need to be further developed and refined in order to better understand volcanic gas fluxes, low-pressure degassing, and the relationship between volatiles and eruption dynamics. Although the interpretation of melt inclusion data is frequently complex due to effects of magma mixing, crystallization, and volatile leakage, the ability to sample melt inclusions from different stratigraphic levels of an eruptive deposit makes it possible to get an unprecedented look at the workings of magma bodies.

It is increasingly being recognized that magmatic volatiles, including volatile trace metals, make important contributions to magmatic-hydrothermal ore deposits. Future analytical developments that make it possible to measure the stable and radiogenic isotope ratios of melt inclusions will significantly add to our knowledge of magmatic inputs to ore-forming systems. Another important area of future research will be the relationship between volatile abundances in volcanic rocks and their plutonic equivalents. The goal of such work will be to

gain a better understanding of the relationship between plutonic and volcanic rocks and, in particular, whether volcanic eruptions tap the volatile-enriched upper portions of larger crustal magma reservoirs, leaving behind less volatile-rich, uneruptable material that eventually solidifies as a pluton.

## GLOSSARY

**basaltic magma** Most typical type of magma erupted on Earth and other terrestrial planets. Basaltic magma is erupted at temperatures of 1000–1300°C, and is made up mainly of SiO<sub>2</sub> (50 wt%), Al<sub>2</sub>O<sub>3</sub> (15%), CaO (12%), and roughly equal amounts of FeO and MgO (10%). The alkalis (Na<sub>2</sub>O+K<sub>2</sub>O) make up most of the difference although trace amounts of every naturally occurring element are invariably present. About 25 km<sup>3</sup> of basaltic magma are generated and erupted or emplaced each year on Earth, primarily along the 75,000 km of diverging plate boundaries. The density, specific heat, viscosity, and thermal conductivity of a typical basaltic magma at 1200°C at low pressure is 2600 kg/m<sup>3</sup>, 1450 J/kg K, 100 Pa s, and 0.6 W/m K, respectively. The heat needed to completely fuse (melt) gabbro, the plutonic (crystalline)

equivalent of basaltic magma, is about 400 kJ/kg. Small amounts (0.2–2 wt%) of volatile compounds (mainly H<sub>2</sub>O and CO<sub>2</sub>) mainly in the dissolved state are commonly found in magmas. These volatile constituents are liberated as gases at low pressure upon eruption and decompression of magma.

**magma** High-temperature multiphase mixture of solids (crystals and lithic fragments), silicate or carbonatitic liquid and H-O-C-S-Cl-rich gas or supercritical fluid formed by partial or total melting of parental source material.

**magma rheology** The science of deformation and flow of magma. The rheological properties of magma depend on temperature, bulk composition, pressure, phase mixture, and shear rate in a complex and intertwined manner. Knowledge regarding the rheology of magma comes from both field observations and laboratory studies.

**magma transport phenomena** The dynamic processes responsible for the generation, ascent, and eruption or emplacement of magma and its subsequent quenching or solidification and interaction in hydrothermal-magmatic systems. These processes involve simultaneous consideration of heat, mass, and momentum transport between various magmatic subsystems. Rates of momentum, heat, and mass transfer are widely varied ranging from creeping (percolative) flow of small degree partial melts

through an otherwise solid parental source rock in response to pressure, buoyancy, and viscous forces to the rapid (several hundred meters per second) eruption of low-density highly expanded magmatic mixtures characteristic of high-silica, volatile-rich rhyolitic magma. The flow of magma in fractures, buoyant rise of magma diapirs, and evolution of magma within crustal magma bodies that undergo simultaneous assimilation of wall rock, recharge of fresh parental magma, and fractional crystallization and convective mixing (or unmixing) are all examples of magma transport phenomena.

**metasomatism** Metasomatism refers to the process whereby a preexisting igneous, sedimentary, or metamorphic rock undergoes compositional and mineralogical transformations associated with chemical reactions triggered by the reaction of fluids (called metasomatic fluids) that invade the protolith. A large-scale example is provided in subduction environments. Dehydration of hydrothermally altered oceanic crust and attached upper mantle generates fluids that migrate upward and metasomatize the ultramafic mantle wedge lying above the subducting slab. Because the peridotite solidus temperature is lowered by the presence of water, metasomatism of the mantle wedge can trigger partial melting there. A smaller scale environment in which metasomatism is important occurs in contact metamorphic aureoles surrounding granitic plutons when emplaced into cooler preexisting crust. The magma body acts as a heat engine and drives hydrothermal circulation in the surrounding country rock. Economically important mineral deposits often form in contact metamorphic environments.

**relative viscosity** Relative viscosity is the ratio of the viscosity of a multiphase mixture (solids + melt + vapor) to the viscosity of the melt. The relative viscosity of crystal–liquid suspensions invariably exceeds unity, whereas for magmatic emulsions (melt + vapor), the relative viscosity depends on shear rate. At very low shear rate, magmatic froths can exhibit a yield strength. At higher rates of shear, spherical bubbles become highly deformed and relative viscosities decrease dramatically.

**rhyolitic magma** Rhyolitic magma is erupted at temperatures of 750–1000°C, and is made up mainly of SiO<sub>2</sub> (75 wt%), Al<sub>2</sub>O<sub>3</sub> (13%), and the alkalis Na<sub>2</sub>O and K<sub>2</sub>O in roughly equal amounts (3–5%). Only a small fraction of a cubic kilometer of rhyolitic magma is erupted each year mainly in continental environments although a significant fraction of rhyolitic and intermediate composition magmas may stagnate at depth within the crust, crystallizing there to form granitic plutons. Granitic batholiths are generally associated with subduction zone magmatism and can extend for hundreds to thousands of kilometers roughly parallel to the strike of oceanic

trenches and along active continental margins. The density, specific heat, viscosity, and thermal conductivity of typical rhyolitic magma bearing 2 wt% dissolved H<sub>2</sub>O at 900°C at low pressure is 2260 kg/m<sup>3</sup>, 1450 J/kg K, 500,000 Pa s, and 1 W/m K, respectively. The heat needed to completely fuse (melt) granite, the plutonic (crystalline) equivalent of rhyolitic magma, is 250 kJ/kg. A water-free rhyolitic melt of otherwise identical composition has a density and viscosity of 2350 kg/m<sup>3</sup> and 1.2 × 10<sup>10</sup> Pa s, respectively. Pristine volatile contents of typical rhyolitic magmas lie in the range of 1–6 wt% and are mainly H<sub>2</sub>O.

**thermodynamic properties** Magma thermodynamic properties may be separated into two families: thermal functions and the equation of state (EOS). Thermal functions relate the temperature of a substance to its internal energy. These properties include the enthalpy, entropy, and heat capacity. The EOS relates the density of a substance to its composition, pressure, and temperature. The reactivity of a material depends on its chemical potential, which involves both thermal functions and EOS data.

**transport properties** In typical dynamic (nonequilibrium) magmatic systems, gradients in pressure, stress or velocity, temperature, and chemical potential give rise to transport of momentum, heat, and material, respectively. Momentum, heat, and mass or species can be transported by advective or diffusive flow. The transport properties that govern diffusive flow of momentum, heat, and matter are the viscosity, thermal conductivity, and species diffusivity, respectively.

## 1. INTRODUCTION

A central goal of studies in igneous petrology and volcanology is to understand the factors that lead to the compositional diversity of magmatic rocks. This understanding is most powerful when framed in terms of petrogenesis—the origin of magma and the rocks formed from cooling and solidification of magma—within the context of the coupling between the thermal evolution and chemical differentiation of the Earth. The growth of oceanic and continental crust throughout the 4560 million years of Earth history, the extent of recycling of crust and lithosphere by subduction, the relationship of mantle plumes to the compositional differentiation of Earth, and the role of subduction in island arc magmatism are problems on which studies of magmas and magmatic processes shed light. In addition, a close

connection exists between magmatic diversity and practical problems, such as volcano forecasting and the mitigation of volcanic hazards. The thermodynamic and transport properties of magma are central to all of these considerations; in this chapter an attempt is made to overview this subject. There has been a sustained and accelerating effort to measure the properties of magma in the last century. It is no exaggeration to claim that without these foundational measurements petrology could not have evolved far beyond its early descriptive stage.

The composition of lava emitted from a volcanic center reflects both the composition of its source as well as myriad dynamic phenomena operative during its generation, segregation, ascent, and eruption. For the purposes of this chapter, magma is defined as a high-temperature (generally  $>900$  K), multiphase mixture of crystals, liquid, and vapor. The vapor can be either a gas or a supercritical fluid. The term *liquid* is used interchangeably with the term *melt* in this chapter. The solid fraction of magma is primarily made up of oxide and silicate crystals, the relative abundance of which depends strongly on composition, temperature, pressure, and additional nonequilibrium or kinetic factors, such as cooling rate, rate of decompression, and rates of mass transfer by molecular diffusion, mechanical dispersion, and advective transport. Bits of local wall rock (lithic inclusions), cognate crystal cumulates, or exotic xenoliths are also commonly found in plutonic and volcanic rocks and provide key clues to understanding magma genesis and dynamics as well as the bulk composition of the source. The liquid or melt portion of magma is generally a multicomponent (O-Si-Al-Ca-Mg-Fe-K-Na) silicate liquid; crustal melts (silicic or rhyolitic to intermediate or andesitic) are rich in O-Si-Al-Na-K-H, whereas melts generated within the Earth's mantle are richer in O-Si-Al-Ca-Mg-Fe (mafic or basaltic). Carbonatitic melts containing  $>50$  wt% carbonate are also generated within the mantle. Although the volumetric rate of eruption of carbonatitic magma is very small compared to the circa  $25 \text{ km}^3/\text{yr}$  of midocean ridge basaltic (MORB) magma produced, rare carbonatitic magmas may be important players in the process of mantle metasomatism. Carbonatites also have an affinity with economically important diamond-bearing kimberlitic magmas, which are rapidly erupted from depths of several hundred kilometers.

Common magmas vary nearly continuously in composition from rhyolitic (75 wt% SiO<sub>2</sub>) through basaltic (50 wt% SiO<sub>2</sub>). These magmas usually contain small amounts (on the order of a few weight percent) of dissolved H<sub>2</sub>O, CO<sub>2</sub>, and other volatile species. H<sub>2</sub>O dissolved in melts occurs in two forms: molecular H<sub>2</sub>O as

well as the hydroxyl group OH<sup>-</sup>. When sufficient total volatiles are present, a melt becomes supersaturated and a discrete vapor or supercritical fluid forms. This fluid has a small viscosity and density compared to common melts and is particularly rich in the components O-H-C-S-N-Cl-F. At crustal pressures and temperatures, supercritical fluids are quite corrosive and can dissolve a few percent or more by mass of various oxide components. At very high pressure and temperature even larger quantities of solid may dissolve in these fluids; silicate melt and hydrous fluids may even become completely miscible under some conditions. The concentration of dissolved volatiles in a melt strongly depends on pressure since the partial molar volume of a volatile species in the dissolved state is much smaller than its molar volume in the gaseous or supercritical fluid state. The huge expansion of a magmatic mixture that accompanies exsolution of volatiles is one of the primary causes of explosive volcanism as pressure-volume expansion work is converted to magma kinetic energy. Other factors, such as magma viscosity and the rate of volatile diffusion, are also important in assessing the dynamics of explosive volcanism.

Volcanic rocks in particular play a unique role in efforts to understand magmatic transport phenomena because, unlike plutonic rocks, they are quenched relatively rapidly and provide more or less direct information regarding the composition of natural melts. To understand the significance of the chemical composition of volcanic rocks, the dynamic and physical aspects of its parental magma evolution must first be unraveled. This is not an easy task. The range of transport phenomena of potential relevance to petrogenesis is quite varied and covers a large span of scales in time and space. Although the dynamics can be complex, it is clear that the thermodynamic and transport properties of magma are absolutely pivotal to the success of any quantitative dynamic theory of magma genesis and transport. If 20th-century research in petrology can be summarized in a few words, it is not too hyperbolic to claim this has been the century of quantification of the physical properties of magma. Although far more needs to be learned, it is reasonable to claim that geologists now have a first-order understanding of the basic properties of the common magma types and are beginning to understand how such properties relate to petrogenesis. In this chapter the most critical properties are briefly reviewed in the context of petrogenesis. Many data are presented in the tables and figures of this chapter. It is generally not possible to tabulate adequate descriptions of all the materials summarized here; particular research applications may require a return to the sources for additional details.

TABLE I Nomenclature

<i>T</i>	Temperature	K
<i>P</i>	Pressure	Pa
<i>ρ</i>	Density	kg/m <sup>3</sup>
<i>C<sub>p</sub></i>	Molar isobaric heat capacity	J/mol K
<i>c<sub>p</sub></i>	Specific isobaric heat capacity	J/kg K
<i>C<sub>p</sub></i>	Partial molar isobaric heat capacity	J/mol K
<i>S</i>	Entropy	J/K mol
<i>H</i>	Enthalpy	J/mol
<i>σ</i>	Interfacial surface energy	N/m
$\beta_T$	Isothermal compressibility, $+(\partial \ln \rho / \partial P)_T$	K <sup>-1</sup>
$\alpha_P$	Isobaric expansivity, $-(\partial \ln \rho / \partial T)_P$	Pa <sup>-1</sup>
<i>X<sub>i</sub></i>	Mole fraction of <i>i</i> th component	
<i>V<sub>i</sub></i>	Partial molar volume of <i>i</i> th component	m <sup>3</sup> /mol
<i>K<sub>T</sub></i>	Isothermal bulk modulus	Pa
<i>K'</i>	Pressure-derivative of bulk modulus	
<i>η</i>	Viscosity	kg/m s
<i>E<sub>a</sub></i>	Activation energy for viscous flow	J/mol
<i>V<sub>a</sub></i>	Activation volume for viscous flow	m <sup>3</sup> /mol
$\eta_r$	Relative viscosity, ratio of mixture viscosity to melt viscosity	
$\phi$	Volume fraction dispersed phase (solid or vapor)	
<i>K<sub>R</sub></i>	Radiative (photon) conductivity	J/m K s
<i>k</i>	Thermal conductivity	J/m K s
<i>κ</i>	Thermal diffusivity, $k/\rho c_p$	m <sup>2</sup> /s
<i>E<sub>A</sub></i>	Activation energy for diffusion	J/mol
<i>V<sub>A</sub></i>	Activation volume for diffusion	m <sup>3</sup> /mol
<i>D</i>	Tracer, self, or chemical diffusivity	m <sup>2</sup> /s
<b>Subscripts:</b>		
fus	Fusion	
form	Formation	
conf	Configuration	
mix	Mixing	
r	Relative	

Table I includes most if not all of the symbols used in the text.

## II. MAGMATIC SYSTEMS: TIMESCALES AND LENGTH SCALES

Lifetimes of magmatic systems and processes vary widely—from the rapid radiative quenching of a pyro-

clast during its high-speed ejection from a vent (several seconds), to the slow cooling of a single lava flow (weeks or months), to the 10<sup>5</sup>- to 10<sup>6</sup>-yr lifetime of a large, slowly cooled pluton. Individual magmatic-hydrothermal systems, such as at Yellowstone National Park in the United States, can be active for a few millions of years. In terms of dynamic process, creeping percolative flow in a partial melt region is of the order of several meters per year and may be contrasted with the explosive eruption of a volatile-rich magma at several hundred meters per second. Although rates of heat, mass, and momentum transfer are wildly different in these systems or subsystems, knowledge regarding the thermodynamic and transport properties of magma is critical in order to meaningfully analyze and ultimately predict the relevant dynamics regardless of the particular scale.

Length scales relevant to magma transport and genesis also vary over many orders of magnitude. At the smallest scale, on the order of millimeters or less, the diffusion of a constituent near the interface of a growing crystal or vapor bubble is relevant to the nucleation and growth of that crystal or bubble from its surrounding melt. At larger scale, individual lava flows and continental dike swarms can extend over many hundreds to thousands of square kilometers and individual plutons emplaced in batholithic terrains can extend for hundreds of square kilometers. In the early part of Earth history it is possible that a globe-encircling magma ocean hundreds of kilometers deep existed. Modeling this sort of system accurately demands knowledge of the properties of magma and phase equilibria for temperatures in the range of 1000–5000 K and pressures from 10<sup>-4</sup> GPa (1 bar or 10<sup>5</sup> Pa) to the core mantle boundary at 135 GPa. Knowledge of the physical, thermodynamic, and transport properties of magmas is therefore essential to virtually all facets of magmatism at a wide variety of scales in both space and time, extending throughout Earth history and includes the very real environmental problems posed by volcanic hazards. Because the terrestrial planets and minor bodies (asteroids) of the solar system have a similar origin, study of magmatism is also a key element in understanding solar system origin and early evolution.

## III. MAGMA THERMODYNAMIC PROPERTIES

Magma properties can be separated into two groups: equilibrium thermodynamic quantities and transport properties. Important equilibrium thermodynamic

quantities include density ( $\rho$ ); heat capacity ( $C_p$ ); third law and configurational entropies ( $S$ ); enthalpies of formation ( $\Delta H_{\text{form}}$ ), fusion ( $\Delta H_{\text{fus}}$ ), and mixing ( $H_{\text{mix}}$ ); and interfacial surface energy ( $\sigma$ ). Application of equilibrium thermodynamic data are most useful in addressing the influence of source bulk composition, pressure, and temperature on the composition and amount of melt generated during partial fusion as well as the composition of solids and residual melts during solidification of magma. Although chemical and thermal equilibrium are not perfectly attained in nature, the concept of local equilibrium is useful because equilibrium is often closely approximated at some scale and because it represents a sort of reference state from which deviations from equilibrium can be assessed. When chemical equilibrium is assumed, all the classical theory of chemical thermodynamics can be applied and many times this greatly simplifies a problem and allows one to test and discriminate between competing hypotheses. For example, at constant temperature and pressure, minimization of the Gibbs free energy for a fixed bulk composition allows one to compute the composition and abundance of each phase in the equilibrium assemblage. To compute the energetics of melting, heat capacities and enthalpies of fusion of appropriate phases are essential. Although not strictly an equilibrium process, calculation of magma heat transport requires heat capacity and fusion enthalpy data. The variation of melt density with temperature, pressure, and composition is needed for analysis of momentum transport since buoyancy is a significant factor driving the segregation, ascent, and eruption of magma. The differentiation of an emplaced magma body by gravity-driven crystal fractionation critically depends on the density difference between melt and newly formed crystals. Like an iceberg in the ocean, there are conditions in temperature and pressure space where crystals grown in a melt float rather than sink. The final solidified state of such a system is obviously quite dependent on the equation of state (EOS)—the relationship between density, temperature, and pressure—for all relevant phases. The compressibility of magma, defined according to  $\beta_T = (\partial \ln \rho / \partial P)_T$ , is a thermodynamic property related to the explosive eruption of magma at or near the Earth's surface. Volatile-rich magma is sometimes erupted at the sonic condition where magma eruption velocity is equal to the speed of sound in the magmatic mixture. The sonic velocity in a mixture is a function of its compressibility. The compressibility informs one regarding the variation of magma density with pressure and is therefore also important in understanding the segregation of melt from its source protolith in the creeping flow regime as well.

These examples show that there is a deep connection between the equilibrium thermodynamic properties of magma and its petrogenetic transport history. Without fundamental property data, it is impossible to breathe life into the equations governing conservation of energy, mass, species, and momentum and thus to solve quantitatively magma transport problems. The equilibrium chemical thermodynamic model provides a logical starting point for the analysis of magma production. Natural silicate melts contain  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{MgO}$ ,  $\text{CaO}$ , iron oxides, the alkalis ( $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$ ),  $\text{P}_2\text{O}_5$ , transition metals and rare earth elements, and minor but important amounts of volatile compounds made up of H-O-C-S-Cl-F-N. A complete thermodynamic description of such a complex multicomponent system over the relevant range in temperature–pressure–composition space is beyond the scope of this chapter, if indeed it is possible at all. Many excellent reviews include quantitative information on the thermodynamic properties of silicate liquids. Only an outline of the salient features drawing on published work in an illustrative rather than exhaustive manner is given here.

### A. Density and Equation of State

The density of a silicate melt may be determined by evaluation of the quotient:

$$\rho = \sum X_i M_i / \sum X_i \bar{V}_i, \quad (1)$$

where  $X_i$  is the mole fraction,  $M_i$  is the molar mass, and  $\bar{V}_i$  is the partial molar volume of the  $i$ th oxide component in the melt. Although  $\bar{V}_i$  depends weakly on composition, to a good approximation, it may be taken independent of composition and only as a function of temperature and pressure for most petrological calculations. Partial molar isothermal compressibilities for the major oxide components have been determined from ultrasonic sound speed laboratory experiments. These parameters can be used to compute melt density as a function of temperature, composition, and pressure up to several gigapascals using a simple empirical EOS:

$$V(T, P, X) = \sum X_i [\bar{V}_{i,T_r} + (\partial \bar{V}_i / \partial T)_P (T - T_r) + (\partial \bar{V}_i / \partial P)_T (P - P_r)], \quad (2)$$

where  $T_r$  and  $P_r$  are constant reference conditions [generally 1400°C and  $10^{-4}$  GPa (1 bar), respectively] and  $\bar{V}_i$  is the partial molar volume of the  $i$ th component. Information for computing melt density as a function of pressure (up to several gigapascals) and temperature is presented in Table II. Densities of some common natural melts at their respective approximate liquidi

<sup>a</sup> Note that  $(\partial V_i / \partial P)_T \equiv -\beta_i V_i$ , where  $\beta_i$  is the isothermal partial molar compressibility of the  $i$ th component and  $(\partial V_i / \partial T)_P \equiv \alpha_P V_i$ , where  $\alpha_P$  is the isobaric expansivity. Modified after Lange and Carmichael (1990), Lange (1997), and Ochs and Lange (1997). Uncertainties are  $1\sigma$ .

temperatures are given in Tables III and IV and are portrayed graphically as a function of temperature, pressure, and volatile content in Figs. 1 and 2. As a rule of thumb, adding  $FeO$ ,  $Fe_2O_3$ ,  $MgO$ ,  $TiO_2$ , and  $CaO$  to a melt increases its density, whereas adding alkalis ( $Li_2O$ ,

$Na_2O$ , and  $K_2O$ ) and volatiles ( $H_2O$ ,  $CO_2$ ) has the opposite effect. The temperature derivative of the partial molar volumes of  $SiO_2$  and  $Al_2O_3$  are both effectively zero. As a consequence, the density of a melt rich in silica and alumina is insensitive to temperature. Densities of melts vary from 2500 to 2900 kg/m<sup>3</sup> at magmatic temperatures ( $\sim 1100^\circ C$ ) for silicic through intermediate to mafic and ultramafic compositions at low pressure. Density increases as pressure rises, although increasing the concentration of the alkaline earth metals, Ca and Mg, serves to decrease the pressure dependence of melt

density. The alkali metals and water are relatively compressible and contribute significantly to the pressure dependence of density. It is important to note that small differences in composition can compensate for relatively large differences in temperature because of the strong dependence of melt density on composition. Whereas a typical value for the isobaric expansivity is  $\alpha_p \approx 5 \times 10^{-5} \text{ K}^{-1}$ , the analogous quantity describing the variation of density with composition is of order 0.1–3 depending on component. The volatile components  $\text{H}_2\text{O}$  and  $\text{CO}_2$  have an especially large effect on melt density. The partial specific densities ( $M_i/\bar{V}_i$ ) for  $\text{CO}_2$  and  $\text{H}_2\text{O}$  in natural melts are  $\sim 1400$  and  $900 \text{ kg/m}^3$ , respectively, for typical crustal magmas. For comparison,  $M_i/V_i$  for  $\text{K}_2\text{O}$ ,  $\text{MgO}$ ,  $\text{FeO}$ , and  $\text{SiO}_2$  are  $\sim 2000$ ,  $3500$ ,  $5300$ , and  $2200 \text{ kg/m}^3$ , respectively. Small amounts of dissolved water dramatically lower melt density and significantly affect other properties such as viscosity and isobaric heat capacity as well.

The change in volume of a crystalline silicate upon fusion is important because it influences the slope of the melting curve in pressure–temperature space and therefore the generation of magma by partial fusion. Additionally, melt density influences the separation rate of melt from its source. In Table V, volume changes accompanying melting of some silicates are given. Typically, the molar volume of a crystalline phase increases by about 10% upon fusion although silica (like ice) may

shrink (i.e., become more dense) when fused at low pressure. Less is known regarding density–temperature–pressure relations or EOS for natural carbonatite melts. Some data pertaining to the density and viscosity of simple carbonate liquids as well as supercritical  $\text{H}_2\text{O}$  are given in Table IV. Relative to common silicate melts, carbonatite liquids are both less dense (by about 30%) and less viscous by several orders of magnitude compared to mafic melts and up to 10 orders of magnitude compared to silicic ones.

At pressures corresponding to depths greater than about 100 km ( $> 3$  GPa), the density of melt is most reliably determined from shock wave and static high-pressure experimental data. A useful relationship is the Birch–Murnaghan EOS, which relates the density of a melt to pressure and temperature according to:

$$P = 3/2 K_T \{(\rho/\rho_{T,0})^{7/3} - (\rho/\rho_{T,0})^{5/3}\} [1 - 3/4(4 - K')((\rho/\rho_{T,0})^{2/3} - 1)], \quad (3)$$

where  $\rho_{T,0}$  is the density of melt at  $10^{-4}$  GPa and temperature  $T$ ,  $K_T$  is the isothermal bulk modulus ( $K_T = 1/\beta_T$ ) at 1 bar ( $10^{-4}$  GPa),  $K'$  is the derivative of  $K_T$  with respect to pressure, and  $\rho$  is the melt density at pressure  $P$  and temperature  $T$ . Some compressibility data from shock wave studies are collected in Table VI. For detailed calculations the original references should be consulted. Density–pressure relations for a model basalt

<sup>a</sup> Depolymerized compositions typically decrease in density 10–20% upon fusion. The volume change is less for tetrahedral fluids like SiO<sub>2</sub>. Modified from Lange and Carmichael (1990). Molar volumes at 1400°C except for H<sub>2</sub>O at 273 K.

melt are shown in Fig. 3 at temperatures corresponding to the upper mantle of the Earth. An interesting application of high-pressure EOS studies is that MgO-rich komatiitic melts, probably the most common magma type erupted in the first billion or so years of Earth history, become denser than olivine crystals at pressure corresponding to depths of roughly 250–400 km. This may have important implications for differentiation of the silicate part of Earth including internal mineralogical layering as well as possible chemical stratification.

## B. Enthalpy, Entropy, and Heat Capacity

In addition to volumetric or EOS data, the calorimetric properties of high-temperature and molten silicates are needed to analyze magma transport problems. These properties inform us regarding the internal energy of melts and crystals and how internal energy and other closely related thermodynamic functions change with temperature. These properties include the enthalpy, entropy, and heat capacity and are inextricably bound to the thermal evolution of magma and relevant to processes such as partial melting, solidification, and the advective transport of heat. In Table VII, melting temperatures, enthalpies of fusion, entropies of fusion, and specific heats of fusion are listed for some common

phases. The specific enthalpy of fusion is the heat per unit mass needed at constant pressure to transform a crystal or crystalline assemblage to the liquid state. There is a wide variation in the specific enthalpy of fusion from 100 to 300 kJ/kg for silica, albite, and sani-

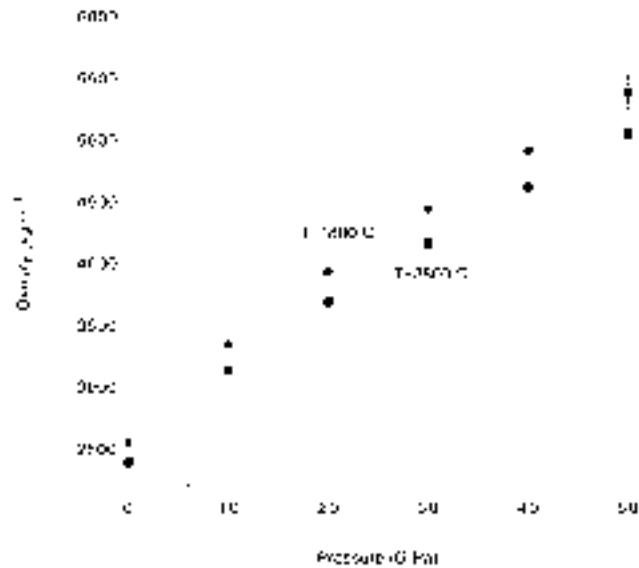

FIGURE 3 Density as a function of pressure in model basalt melt for 1800 and 2800°C. Density is computed using the Birch-Murnaghan EOS and parameters from Table VI. (See Rigden et al., 1984, for details.)

dine, all important components of crustal-derived melts, to  $\sim 1000$  kJ/kg for refractory phases, such as forsterite, enstatite, and rutile relevant to mafic and ultramafic compositions. Estimates of fusion enthalpies for common magmas computed using data in Table VII and typical modal abundances are listed in Table III. There is a factor of 3 difference in the specific heat of fusion for a model granite ( $\sim 200$  kJ/kg) compared to an ultramafic composition ( $\sim 600$  kJ/kg). The more refractory nature of the ultramafic composition is due to the higher fusion enthalpy of olivine and the pyroxenes relative to quartz, alkali feldspar, and plagioclase. Garnet also has a high specific fusion enthalpy. Fusion of an eclogite (pyroxene plus garnet) at high pressure requires more heat (570 kJ/kg) than a corresponding low-pressure plagioclase-pyroxene gabbro ( $\sim 400$  kJ/kg). The relatively low fusion enthalpy for phases making up continental crust implies that anatexis of crust by heat exchange between mafic magma and its crustal host is thermally efficient. It is worth noting that the heat required to completely melt the Earth's mantle,  $\sim 3 \times 10^{30}$  J, is less than 10% of the kinetic energy delivered to the Earth by impact of a Mars-sized body (15% mass of Earth) with an impact velocity equal to the Earth's escape velocity of 11.2 km/s. If in fact the Earth did possess a magma ocean in the Hadean, then its lifetime would have been controlled by the rate at which  $\sim 10^{30}$  J of heat could be dissipated by conduction, radiation, and convection.

In addition to heat effects associated with solid to

liquid phase change, it is important to consider sensible heat effects or the variation of melt enthalpy with temperature. This is measured by the molar isobaric heat capacity,  $C_p$ . For most aluminosilicate glasses and melts of petrologic significance,  $C_p$  can be approximated as an additive function of oxide component partial molar isobaric heat capacities. As temperature increases for glasses, an increased number of vibrational modes become excited and so  $C_p$  increases. In Table VIII, parameters are given for the common oxide components to estimate the isobaric heat capacity of a glass as a function of composition and temperature at low pressure. At the glass transition temperature ( $T_g$ ), there is generally a discontinuous jump in isobaric heat capacity. The magnitude of this jump depends on the atomic structure of the liquid with highly polymerized melts—so-called strong liquids—exhibiting little or no discontinuity in heat capacity at  $T_g$ . For petrologic purposes, it is sufficient to note that the jump in  $C_p$  at the glass transition temperature is small for silica-rich liquids (e.g., rhyolitic melts) and it becomes larger as more and more of the oxygen becomes bonded to a single Si or Al atom rather than two Si or Al atoms as in fully polymerized melts.

For silicate melts (unlike silicate glasses), the temperature dependence of  $C_p$  can generally be neglected unless great accuracy is needed. Parameters for the estimation of  $C_p$  for melts as a function of composition at magmatic temperatures are presented in Table IX. Of the common oxide components,  $H_2O$  appears to have the highest partial molar isobaric heat capacity. Glassy silica containing 1200 ppm OH has a heat capacity 30% greater than silica that is essentially anhydrous. Illustrative values for  $C_p$  of common melts at their liquidus temperatures are provided in Table III. Silicic anhydrous melts have specific isobaric heat capacities around 1300–1400 J/kg K whereas melts with higher MgO concentrations have specific heats around 1600–1700 J/kg K. For comparison, note that the specific isobaric heat capacity of tap water is about 4184 J/kg K. Because the advective transport of heat is directly proportional to  $C_p$ , mafic and ultramafic magmas are good transporters of magmatic heat. Addition of 2 wt%  $H_2O$  to an otherwise anhydrous granitic melt increases  $C_p$  by 15%.

#### IV. MAGMA TRANSPORT PROPERTIES

Transport properties of magma play a crucial role in development of petrogenetic theory. Simple consideration of the various stages of magma transport from source to surface makes this abundantly clear. Some

<sup>a</sup>  $X_i$  is the mole fraction of the  $i$ th oxide component. The gfw is defined according to  $\text{gfw} = \sum X_i M_i$  where  $M_i$  is the molar mass of the  $i$ th component. Modified after Stebbins et al. (1984).

examples include the generation of magma by partial melting, melt segregation by porous or channel flow, and magma ascent by viscous flow in magma-filled propagating cracks. Other examples include differentiation of magma by crystal fractionation and the processes of magma mixing and crustal anatexis. In all of these phenomena significant amounts of momentum, heat, and chemical component transport occur. Transport of momentum, heat, and species by magmas involves the material properties of viscosity, thermal conductivity, and mass diffusivity, respectively. Although data and models for the composition and temperature dependence of melt viscosity are available, relatively little is known regarding the rheological properties of magmatic mixtures. There are relatively few experimental data bearing on the thermal conductivity of melts at high temperatures; this is perhaps the most uncertain of all magma transport properties but one with enormous significance with respect to the thermal history of the Earth. Some chemical and tracer diffusivity data exist and correlations have been developed for estimation of tracer diffusivities as a function of species charge and size for melts of various temperature and composition. The pressure dependence of tracer diffusivity follows roughly the pressure dependence of melt viscosity since the mechanism of oxygen self-diffusion is closely related to that for viscous flow. A brief review of these properties

is presented next. The original references should be consulted for more detail.

### A. Melt Viscosity

The viscosity of magma modulates momentum transport. Critical issues include the effects of composition, pressure, and temperature on the viscosity of melts as well as the rheological properties of magmatic suspensions. Although to a good approximation silicate melts behave as Newtonian fluids (that is, they show a linear relationship between shear rate and shear stress), this is not the case for magmatic multiphase suspensions nor natural glasses although for different reasons.

The temperature dependence of melt viscosity can be described by several models. The simplest one is the Arrhenian model described by the relation:

$$\eta = \eta_0 \exp[(E_a + pV_a)/RT]. \quad (4)$$

In Eq. (4),  $\eta_0$  is the asymptotic viscosity at infinite temperature,  $E_a$  is the activation energy for viscous flow (a

constant for an Arrhenian fluid),  $V_a$  is the activation volume for viscous flow, and  $R$  is the universal gas constant. Activation energies vary systematically with composition from values around 200 kJ/mol for mafic and ultramafic melts to 400 kJ/mol for more silicic compositions. Increasing the concentration of non-framework components such as the alkalis, the alkaline earths, and especially H<sub>2</sub>O results in creation of oxygens bridged to only a single Si or Al. The presence of nonbridging oxygen (NBO) destroys the network structure of the melt created by the formation of tetrahedral rings at intermediate atomic scales of order 0.5 to 1 nm. For the ideal network tetrahedral melt, each oxygen is bound to two Si, two Al, or one Si and one Al simultaneously. The archetypal example is molten silica in which each oxygen has two nearest neighbors of silicon and each silicon is surrounded by four nearest neighbors of oxygen. The increase in the concentration of NBO serves to lower both  $\eta_0$  and  $E_a$  and, in fact, makes the temperature derivative of viscosity a function of temperature itself. Small (several percent by mass) concentrations of water have a dramatic effect in lowering the viscosity of melts because water is 8/9 oxygen by mass, unlike any other common oxide component. This is illustrated in Table IV for the granitic composition where addition of 2 wt% H<sub>2</sub>O to a granitic melt lowers its viscosity by a factor of 10<sup>5</sup>. H<sub>2</sub>O also tends to lower the viscosity of more mafic compositions, although the effect is considerably subdued, because fewer bridging oxygens exist in anhydrous mafic melts.

The activation volume, a measure of the pressure dependence of viscosity, is usually a small fraction of the molar or specific volume of the melt and changes sign, from negative to positive, as the fraction of NBO increases. Fully polymerized network melts, for which essentially all the oxygen is bridging oxygen (BO), typically possess intermediate-range order defined by the formation of  $n$ -membered rings ( $n = 4$  to 10) of tetrahedra. As pressure increases, the ring structure collapses and the “anomalous” effect of viscosity decrease with increasing pressure disappears. Specifically, as pressure increases, the concentration of pentahedral (fivefold) and octahedral (sixfold) Si and Al increases, driving the oxygen into a higher number coordination with both Si and Al as well as with itself. Consequently, the proclivity to form rings decreases significantly. A typical value for  $V_a$  for a network tetrahedral melt such as NaAlSi<sub>3</sub>O<sub>8</sub> is around  $-6 \times 10^{-6}$  m<sup>3</sup>/mol, whereas in a more depolymerized melt  $V_a$  is around  $3 \times 10^{-6}$  m<sup>3</sup>/mol. Melts with a negative value of  $V_a$  show a decrease in viscosity as pressure increases; the opposite is true for melts with positive  $V_a$ . There is a close connection between the  $V_a$

for viscous flow and the activation volume for oxygen self-diffusion. For rough estimates, the former may be equated to the latter.

Unfortunately, not all silicate melts follow the Arrhenian temperature–viscosity relationship. This is especially true for so-called fragile melts or melts that have a significant fraction of NBO. A good example of a fragile natural melt is a water-rich peralkaline rhyolite. An empirical rule for predicting the temperature dependence of viscosity data in fragile non-Arrhenian melts is the so-called Tammann–Vogel–Fulcher (TVF) expression:

$$\eta = \eta_0 \exp[B/(T - T_k)], \quad (5)$$

where  $B$  is a function of composition but not temperature and  $T_k$  is closely related to the so-called Kauzmann catastrophe temperature. At  $T < T_k$ , the entropy of supercooled liquid is smaller than that of its corresponding crystal. At  $T = T_k$  viscosity diverges according to Eq. (5). The relationship between the TVF and the Arrhenian model is noted by examining the temperature derivative of the viscosity. In the Arrhenian model,  $[\partial \ln \eta_A / \partial(1/T)] = E_a/R$  whereas for a TVF fluid  $[\partial \ln \eta_{TVF} / \partial(1/T)] = BT^2/(T - T_k)^2$ . In the limit  $T_k \rightarrow 0$ , the TVF and the Arrhenian models are identical with  $B = E_a/R$ . In general,  $T_k$  is close to but usually somewhat less than  $T_g$ , the glass transition temperature; typically  $T_g \approx 1000$  K for silicate compositions of geochemical importance. The  $T_g$  for pure silica is somewhat higher (1400 K). The TVF model therefore shows that the variation of melt viscosity with temperature decreases as temperature increases and is not a constant ( $E_a$ ) as in the Arrhenian model.

Perhaps the conceptually best model for predicting the viscosity of simple silicate liquids is the Adams–Gibbs–Di Marzio (AGD) configurational entropy theory. In this model, viscosity depends on temperature according to

$$\eta = \eta_0 \exp(B/T S_{\text{conf}}), \quad (6)$$

where  $S_{\text{conf}}$  is the configurational entropy of the melt and includes a contribution computed from liquid and glass isobaric heat capacity data, as well as the residual entropy of glass (frozen liquid) at the glass transition temperature,  $T_g$ . The parameter  $B$  is temperature independent but varies with composition. An important aspect of the AGD theory is that it connects melt thermodynamic and transport properties. It is based on a theory of cooperative behavior relevant to the dynamic rearrangement of atomic configurations characteristic of the liquid state. The AGD theory can be extended to provide a basis for predicting the pressure and, perhaps,

compositional dependence of magma viscosity. Unfortunately, the TVF and AGD theories have not yet been fully developed for application to multicomponent natural melts. There is no comprehensive model to predict  $\eta_0$ ,  $E_a$ ,  $V_a$ , and  $B$  for a given magma composition as a function of temperature and pressure, although there are good prospects that such an extension is possible within the framework of the AGD theory.

For petrologic purposes, it is usually necessary to employ the simpler Arrhenian model. Values for the viscosity of common melts at their  $10^{-4}$  GPa liquidus temperatures are presented in Table III and portrayed graphically in Fig. 4. Melt viscosity can span over 10 orders of magnitude given the variation in composition and temperature in natural systems. Dissolved water has a dramatic effect on lowering melt viscosity; this has important implications for the transport and eruption of silicic and intermediate composition magmas. The effects of dissolved water on the viscosity of common melts at typical eruptive temperatures are shown in Fig. 5.

## B. Magma Viscosity

Far fewer data exist on the rheological properties of magmatic suspensions compared to silicate melts.

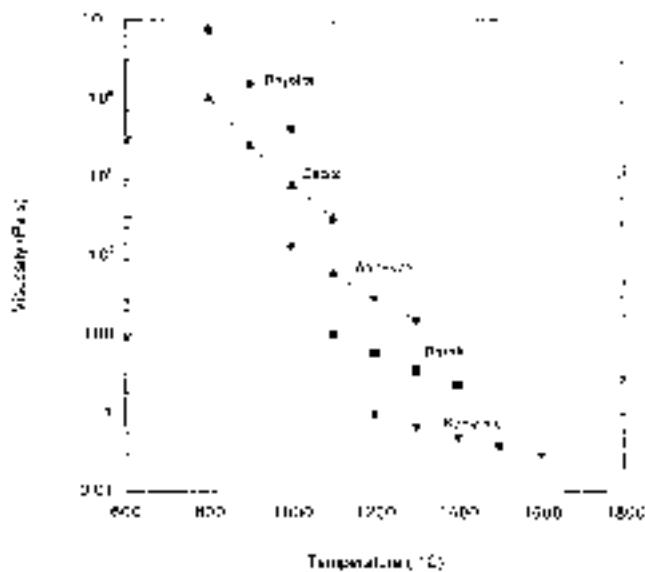

FIGURE 4 Viscosity as a function of temperature at 1 bar ( $10^{-4}$  GPa) for natural melts spanning the compositional range rhyolite to komatiite. All compositions are volatile free. The temperature range is illustrative of typical eruption temperatures for each composition.

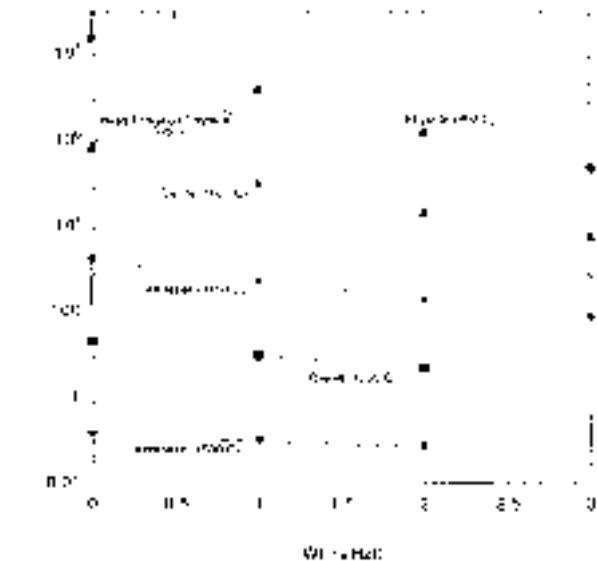

FIGURE 5 Melt viscosity as a function of dissolved water content for natural melts spanning the range rhyolite to komatiite. Temperatures for each composition are characteristic eruption temperatures. Viscosities are calculated for pressure equal to 1 bar ( $10^{-4}$  GPa). For the rhyolite composition, two different models are shown. Note the very dramatic effect of dissolved water on the viscosity of natural melts. Viscosity models are from Shaw (1972) and Hess and Dingwell (1996).

Magma, a mixture of suspended crystals and vapor bubbles in a melt matrix, may be expected to exhibit complex rheological behavior especially when significant amounts of suspended crystals and bubbles are present. There have been few experiments exploring the rheological properties of magma containing significant amounts of crystals and vapor bubbles. Fortunately, there has been some study of two-phase mixtures (both crystal–melt suspensions and melt–vapor emulsions). Silicate foams, defined as concentrated emulsions with porosity greater than about 60 vol% ( $\phi > 0.6$ ) are found in small quantities at virtually all volcanic centers because magma typically contains some volatiles (0.1–10 wt%) and the common volatiles ( $H_2O$  and  $CO_2$ ) are practically insoluble in melts at low pressure.

Many attempts have been made to model the variation of magma viscosity with volume fraction of a unimodal size distribution of spherical solids. To first order, the effect of increasing the volume fraction of crystals,  $\phi$ , in a melt is to increase the relative viscosity,  $\eta_r$ , according to:

$$\eta_r = \eta_{\text{mix}} / \eta_{\text{melt}} = (1 - \phi/\phi_0)^{-5/2} \quad (7)$$

where  $\eta_{\text{mix}}$  is the viscosity of the crystal-laden suspension,  $\eta_{\text{melt}}$  is the viscosity of melt, and the constant  $\phi_0$  is the

maximum packing fraction of the solid. Relation (7) shows that the loading level of crystals is limited by  $\phi_0$ , the geometric limit for contact of solids in the most efficient packing condition. For rhombohedral packing of spherical particles,  $\phi_0 = 0.74$ , whereas in simple cubic packing and body-centered cubic packing  $\phi_0 = 0.52$  and 0.60, respectively. In practice, random packing of spheres generally gives  $\phi_0$  in the range 0.60–0.65. Equation (7) clearly shows that the volume fraction as well as the maximum packing fraction  $\phi_0$  of solids are the two important parameters governing the viscous response of magma. Polydispersity, the presence of a nonunimodal distribution of particles, tends to reduce the viscosity of a magma at a fixed value of  $\phi$  because smaller particles can fit between the larger ones. The viscosity of a unimodal crystal-bearing magma with  $\phi = 0.3$  is about 10 times higher than its value for the melt phase alone based on Eq. (7). In more detail, it is both the size and shape variation of individual crystals, as well as the overall structure of the mixture, that controls the rheological properties of multiphase magmatic mixtures. An extension of the model that takes into account melt entrapped between solid particles and hence not available for shear is given by:

$$\eta_r = \eta_{\text{mix}} / \eta_{\text{melt}} = (1 - \phi / \Psi_M)^{-q}, \quad (8)$$

where  $\Psi_M$  depends on  $\phi$  according to:

$$\Psi_M = 1 - \phi [1 - \phi] / \phi_0, \quad (9)$$

and  $q$  is a positive number in the range 2–3. The parametric variations of  $\Psi_M$  and  $q$  are a direct consequence of the shape, size distribution, and prevailing structure of the solid network within the suspending melt. For magmatic mixtures, it is recommended that Eqs. (8) and (9) be used with  $0.5 < \phi_0 < 0.75$  and  $q \approx 2.5$ . For  $\phi = 0.35$ , Eqs. (8) and (9) give  $\eta_r = 2.9$  for  $\phi_0 = 0.70$  and  $q = -2$  and  $\eta_r = 10.2$  for  $\phi_0 = 0.50$  and  $q = -3$ , respectively. Some typical suspension viscosity values as a function of volume fraction of solids for various  $q$  and  $\phi_0$  are shown in Fig. 6. More experimental work is needed to better constrain the rheometric parameters  $q$  and  $\phi_0$  and especially the shear rate dependence of suspension viscosity. Because the rate at which a suspension is sheared can profoundly alter the distribution of suspended solids, suspension viscosity is likely to depend on shear rate as well as the fraction of solids.

In bubble-melt mixtures,  $\eta$  can be either an increasing or decreasing function of  $\phi$  depending on the rate at which the mixture is sheared. At low rates of shear ( $\dot{\gamma}$ ), bubbles act as nondeformable inclusions and  $\eta$  increases with increasing  $\phi$  as when solids (e.g., crystals) are added to a melt. In distinction, at high shear rate, bubbles

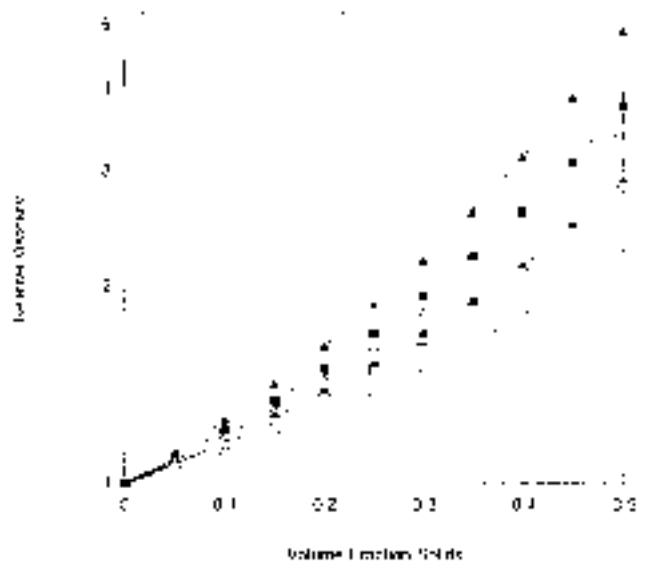

FIGURE 6 Relative viscosity of magmatic suspensions containing solids as a function of volume fraction of solids. The power-law parameter  $q$  equals 2, 2.5, and 3 for circles, squares, and triangles, respectively. Open symbols correspond to  $\phi_m$  equal to 0.52; closed symbols correspond to  $\phi_m$  equal to 0.70.

readily deform and the mixture viscosity decreases with increasing bubble fraction. A dimensionless parameter termed the capillary number (Ca) is useful in determining the appropriate rheodynamic regime. The capillary number is defined as  $Ca = \eta \gamma r_b / \sigma$  where  $\eta$ ,  $\gamma$ ,  $r_b$  and  $\sigma$  represent the melt viscosity, shear or deformation rate, bubble radius, and melt–vapor interfacial tension, respectively. The capillary number can be thought of as the ratio of viscous tractions acting on the boundaries of a bubble that distort it from a spherical shape relative to interfacial surface tension that tends to preserve a spherical shape. Small values of Ca correspond to conditions with dominant surface tension for which bubbles retain their spherical shapes. This is favored in finely dispersed (small bubble size), low-viscosity emulsions subjected to low rates of deformation. One expects a relative viscosity relation of the form  $\eta_r = f(\phi, Ca)$  such that for small capillary number (roughly  $Ca < 1$ ),  $\eta_r$  is an *increasing* function of  $\phi$ . In contrast, for regimes where Ca is large ( $Ca > 1$ ), the relative viscosity *decreases* with increasing bubble content. Natural systems span the range from  $Ca < 1$  to  $Ca \gg 1$  so it is important to consider the dynamic regime when considering the effect of bubbles on the viscosity of magma. Relative viscosity can drop by a factor of 10 as the bubble content increases from 0 to  $\sim 50$  vol% in the high Ca regime.

It is likely that magmatic suspensions of solids and bubbles become significantly nonlinear (non-Newtonian) at high loading and at high rates of shear. That is, the mixture viscosity depends not only on the fraction of the dispersed phase (bubbles or solids) and the capillary number but also on the shear rate. Self-organization of dispersed particles (solids or bubbles) to form structured mixtures giving rise to large spontaneous changes in magma viscosity during flow itself may also be important. These issues have not been adequately studied to date despite the relevance for pyroclastic and lava flows and the mobility of debris avalanches and other particulate flows of petrologic and volcanologic importance. Many volcanic hazards involve the flow of such highly non-Newtonian mixtures. Future experimental work is needed to address these questions and apply them in a meaningful way to various volcanologic and petrologic problems.

### C. Thermal Conductivity

Transport of magmatic heat occurs by several mechanisms including convection (heat transported by bulk flow), phonon conduction (heat transported by atomic vibration), and radiation (an electromagnetic phenomenon involving photon transfer). Radiation travels through a vacuum at the speed of light; most gases are transparent to radiation. Radiative transport of heat may be important in transition metal poor melts due to their relative transparency. Because most gases are transparent, radiative heat transfer may also be important across bubbles in magmatic emulsions and foams. In contrast, radiative heat transport can generally be ignored in mafic melts containing significant amounts of transition metals (e.g., Fe, Ti, Ni) because such melts are relatively opaque to thermal radiation. In these nontransparent magmas, the mean free photon path is short of order several millimeters. The photon (radiative) conductivity ( $K_R$ ) can sometimes be approximated as:

$$K_R = 16/3 \sigma n^2 T^3 \ell_R \quad (10)$$

where  $\sigma$  is the Stefan-Boltzmann constant ( $5.67 \times 10^{-8}$  J/m<sup>2</sup> K<sup>4</sup> s),  $n$  is the index of refraction, and  $\ell_R$  is the mean free path for photons. The thermal transfer by photons depends in a critical way on  $\ell_R$  as well as the emissivities of the surfaces across which heat is being transferred. When  $\ell_R \sim 0$  (as in an opaque melt) or when one is concerned with transport of heat across distances much larger than  $\ell_R$ , radiative transfer is negligible. It is only when  $\ell_R$  is relatively large, as in transpar-

ent high-silica melts or in transparent vapor–melt emulsions, that photon conduction may become appreciable. Because geometric factors are often relevant, the importance of radiative heat transfer in geological processes (as opposed to laboratory small-scale experiments) always needs to be carefully considered.

The thermal conductivity ( $k$ ) provides a quantitative measure of the importance of phonon heat conduction in solids and melts. The thermal diffusivity ( $\kappa$ ) defined as  $\kappa = k/\rho C_p$  is often used in the analysis of magmatic heat transport and involves a combination of thermodynamic properties and the phononic thermal conductivity. Quantized thermal waves called *phonons* carry heat in silicate crystals and melts. Thermal resistivity ( $W$ ), which is inversely proportional to thermal conductivity (i.e.,  $k \propto W^{-1}$ ), arises due to both phonon–phonon interaction and structural disorder. Because disorder is an outstanding characteristic of the glassy and molten state, one might expect the mean free path for the dominant thermal phonons to approximately equal the scale of structural disorder, roughly 5–10 Å in a typical glass or melt. The thermal conductivity of a solid may be estimated according to the relation:

$$k \propto \lambda C_p c^2 / 3\alpha_p^2 T, \quad (11)$$

where  $\lambda$  is an interatomic length scale (~0.5 nm),  $c$  is the sonic velocity (several kilometers per second), and  $\alpha_p \equiv 1/V(\partial V/\partial T)p$  (see Table II). In general,  $k$  decreases as temperature increases. Unfortunately, there are relatively few measurements of the thermal conductivity of molten silicates and even fewer for petrologically important compositions. Because radiative transfer tends to dominate at high temperatures in the laboratory, it can be difficult to accurately separate the effects of phonon conduction from photon radiative energy propagation and hence to determine the intrinsic phonon thermal conductivity. Based on existing measurements of  $k$  for melts (Table X), the dependence of thermal conductivity on temperature and composition in molten silicates may be considerable, although very few reliable measurements have been made. Data on the pressure dependence of  $k$  for melts is even more limited; theory suggests that the pressure derivative of  $k$  scales with  $\beta_T$ , where  $\beta_T$  is the isothermal compressibility. It is estimated that  $(\partial \ln k / \partial P)_T$  lies in the range 0.05–0.5 GPa<sup>-1</sup> for silicate melts. Values of  $k$  for some crystals, glasses, and melts at various temperatures and low pressure are listed in Table X. There is a clear need for more measurements of specific compositions across a large temperature interval (subsolidus to superliquidus) where the effects of radiation are carefully separated from phonon conduction.

#### D. Diffusion

Mass is transported in magmatic systems by bulk flow and by molecular diffusion, the latter of which is defined as the relative motion of different constituents or species in a melt. Diffusive transport of species is characterized by the diffusion coefficient or diffusivity ( $D$ ) of a species and is a function of melt temperature, pressure, and composition including oxidation state. Several types of diffusive transport can be distinguished. Self- or tracer diffusion refers to the mobility of a constituent or species in a homogeneous melt free of any chemical or thermal gradient; there is no net flux of species in tracer or self-diffusion. Self-diffusion refers to the mobility of a constituent that is present in significant concentration. An example is self-diffusion of oxygen in a melt of natural composition. Tracer diffusion is essentially the same as self-diffusion except that the concentration of the

species of interest is low at the parts per million by mass level (ppm). In contrast, chemical diffusion is driven by gradients in chemical potential or activity and results in a net flux of species. Chemical diffusion, unlike tracer or self-diffusion, is complex because coupling exists between the flux of one component and the gradients of all other independent components in the system. That is, for an  $n$ -component system, the flux of the  $i$ th component depends on the chemical potential gradient of any independent set of  $n-1$  components and not simply the  $i$ th component. Because the chemical diffusion rate of the  $i$ th component depends on  $n-1$  chemical potential gradients, whereas isotopic equilibration of the  $i$ th component depends on the tracer or self-diffusivity of that species, decoupling between elemental and isotopic concentrations can and does occur in both natural and laboratory systems.

There is an extensive body of information pertaining to diffusion in melts and glasses as a function of temperature, composition, and, to a lesser extent, pressure. This is due in large measure to myriad industrial and materials processing applications of diffusion as well as the importance of diffusion in petrologic processes such as crystal nucleation and growth, the growth of vapor bubbles, the homogenization of melt inclusions, the resetting of geochronological clocks, and the mixing of magmas. Because of the complexity of dealing with multicomponent systems, chemical diffusion is less studied than self- or tracer diffusion in molten silicates. There is a deep connection between the atomic structure of a melt or glass and the mobility of its constituents. The self-diffusion of oxygen, the most abundant constituent of natural melts and glasses, is intimately related to melt viscosity, a macroscopic property. Hence study of the systematics of diffusion bridges the gap between the microscopic and macroscopic realms relevant to magma transport phenomena. There are many excellent reviews of diffusion for both industrial and geologic materials and these primary references should be consulted for details. In this section, a brief summary along with some typical values of self-, tracer and chemical diffusivities are given to indicate the main trends and illustrate the orders of magnitude.

#### E. Self-, Tracer, and Chemical Diffusion

The dependence of tracer, self-, and chemical diffusivity of a constituent as a function of pressure and temperature is given by:

$$D = D_0 \exp[-(E_A + pV_A)/RT], \quad (12)$$

where  $D_0$  is constant for a fixed composition and  $E_A$  and  $V_A$  represent the activation energy and activation volume for diffusive transport, respectively. Very roughly,  $E_A$  and  $V_A$  for oxygen self-diffusion in a melt are equivalent to  $E_a$  and  $V_a$  for viscous flow because viscous flow in a silicate melt is ultimately related to the mobility of oxygen, the predominant constituent. This relationship, in general, does not hold for other species.  $E_A$  is of order 300–400 kJ/mol for network-forming atoms like Si and Al and is in the range 250–180 kJ/mol for transition metals and the alkaline earth metals. Alkali metals have activation energies in the range 120–220 kJ/mol. Far less is known regarding  $V_A$ . Molecular dynamics simulations suggest values around  $-10 \text{ cm}^3/\text{mol}$  for network-forming atoms, whereas network modifiers have values in the range  $-2$  to  $+5 \text{ cm}^3/\text{mol}$ . These relations apply approximately to melts across the compositional range basalt to rhyolite. In contrast, the pre-exponential term ( $D_0$ ) depends strongly on melt composition and the size and charge of the species. Network-modifying ions of high charge and large size have smaller diffusivities than small cations of low charge, other factors remaining the same. At fixed temperature,  $D_0$  is larger in basaltic melt compared to rhyolitic by a factor of 5–500 depending on the species. In a basaltic melt at 1300°C, oxygen and the network atoms Si and Al have  $D \sim 3 \times 10^{-12} \text{ m}^2/\text{s}$ . This compares with transition metals (e.g., Fe, Ti) and alkaline earths (e.g., Mg, Ca, Sr) for which  $D \sim 1 \times 10^{-11} \text{ m}^2/\text{s}$  and  $\sim 2 \times 10^{-11} \text{ m}^2/\text{s}$ , respectively. The alkalis are more mobile with  $D \sim 3 \times 10^{-10} \text{ m}^2/\text{s}$ ; there is a strong dependence of  $D$  with ionic radius for the alkalis such that  $D_{\text{Li}} \gg D_{\text{Na}} > D_{\text{K}} > D_{\text{Rb}} > D_{\text{Cs}}$ . The diffusivity of the carbonate group ( $\text{CO}_3$ ) is  $D \sim 1.2 \times 10^{-10} \text{ m}^2/\text{s}$ , whereas for  $\text{H}_2\text{O}$ ,  $D \sim 1 \times 10^{-9} \text{ m}^2/\text{s}$  and depends on the concentration of dissolved water. The diffusive length during the  $10^5$ -yr solidification time of a  $10^3\text{-km}^3$  gabbroic pluton (characteristic length  $\sim 10 \text{ km}$ ) is  $\sim 3 \text{ m}$  for O and Si, whereas for Li and  $\text{H}_2\text{O}$  it is  $\sim 60 \text{ m}$ . Diffusive length scales in a granitic magma body are smaller, by factors of 2–20 at 1300°C and factors of 10–1000 at 1100°C compared to a gabbroic body. Self- and tracer diffusivity coefficients, including estimates of activation energy for some species in basaltic and rhyolitic melts, are presented in Tables XI and XII.

Chemical diffusion is more complicated than self- or tracer diffusion because the mass flux of the  $i$ th component depends on the chemical potential gradients of all  $n-1$  independent species, where  $n$  is the number of chemical components in the system. Multicomponent chemical diffusion is described by an  $(n-1)$  by  $(n-1)$  diffusion matrix with elements  $D_{ij}$ . In a multicomponent

Carbonate ( $\text{CO}_3$ group)	1300	$12 \times 10^{-11}$	—

system it is possible to have concentration gradients of more than one component at some location and time. Consequently, simultaneous fluxes of components will occur. Consideration of local charge balance and total mass conservation together with hydrodynamic factors (e.g., a species chooses the path of least viscous resistance) leads to curious phenomena such as uphill diffusion whereby a species moves up its own concentration gradient. In the last few years, there have been several studies of chemical diffusion in three- and four-component systems. There also has been some progress in building models to predict chemical diffusion coefficients, including off-diagonal terms, from appropriate tracer and self-diffusivities and to correlate chemical diffusivities with other transport properties such as viscosity. The systems studied in detail to date are mainly for  $n \leq 4$  (e.g.,  $\text{CaO}-\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ ). Absolute values of chemical  $D_{ij}$  are about the same as tracer and self values and their pressure and temperature dependencies are probably approximately the same. The on-diagonal  $D_{ii}$  are usually larger in absolute value than off-diagonal

	1300	$0.6 \times 10^{-14}$

terms although in natural systems with  $n \approx 8$  this may not always be the case. Off-diagonal terms are commonly negative and this can sometimes lead to the observed effects of uphill diffusion seen in some natural examples. Biotite-rich rinds often surround mafic enclaves, intruded in the molten state into a host of granitic or granodioritic magma. Enrichment in K<sub>2</sub>O along the granite/gabbro interface may be a natural example of uphill diffusion. The main point regarding chemical diffusion is that mixing is not generally describable by linear mixing of two compositions.

## V. CONCLUSIONS

The important thermodynamic and transport properties of magma have been briefly reviewed in this chapter.

The complete description of multicomponent and multiphase magma at temperatures from 800 to 5000 K and pressures from  $10^{-4}$  (surface) to 135 GPa (base of mantle) is an ambitious program that will take many years to accomplish. Although an enormous task, there are reasons to be optimistic. Within the last quarter century knowledge of the thermodynamic properties of high-temperature crystalline, molten, and glassy silicates including melts of natural composition has grown dramatically. Although still far from complete, thermodynamic properties for many crystalline phases relevant to magmatic systems are known at the high-temperature and -pressure conditions equivalent to the base of the lithosphere around 3–4 GPa.

An approximate model for the Gibbs free energy of natural silicate liquids has also been developed in the past 15 years and is undergoing continuous revision and expansion and can only improve efforts to describe and predict equilibrium phase relations involved in the melting and solidification of magma. Similarly, studies of the temperature, pressure, and composition dependence of melt viscosity, the rheology of magmatic (solid-melt-vapor) mixtures, chemical, tracer, and self-diffusion and thermal conductivity have been made for a variety of natural and synthetic melts and glasses. Correlations have been developed for some properties valid in specific regions of temperature-pressure-composition space that enable one to obtain order of magnitude or better estimates of many critical properties.

Development of models based on condensed matter theory has come to supersede earlier purely empirical models and hence are far better suited to rational interpolation. These models, though only approximate, provide a foundation for careful extrapolation as well. In the computational realm, molecular dynamics simulations are increasingly being applied to investigate the structure and properties of molten silicates at very high temperatures and pressures. This method, which involves use of a potential energy expression describing the electrostatic interactions between the various atoms in a fluid or melt, enables one to compute thermodynamic, spectroscopic, and transport properties under a variety of conditions. Although properties so computed are estimates, they do provide a means for understanding, at the atomic level, the effect of temperature, pressure, and composition on physical properties and for identifying critical laboratory experiments.

Study of the properties of molten, glassy, and high-temperature crystalline silicates and oxides of geological relevance has burgeoned in the past quarter century due to the contributions made by an international cast of researchers. The rate of acquisition of new information

is accelerating as new techniques are applied to old problems. There are hundreds of volcanic eruptions each year and many of these present dangers involving the loss of life and property. The first step in taming magma is to understand its nature from a fundamental and broad perspective. At the same time a deeper understanding of the evolution of planet Earth and, by analogy, other terrestrial planets both within our solar system and beyond depends on knowledge regarding the physical properties of magma.

## GLOSSARY

**batholith** A vast collection of solidified magmatic bodies (plutons) commonly forming a mountain range like the Sierra Nevada or Andes.

**capture front** The position in a solidification front denoting a region inward of which crystals are able to move freely relative to one another and outward of which crystals move in concert with their neighbors.

**critical crystallinity** The point in a solidification front where the packing of crystals is close enough to allow formation of a crystalline network.

**dike** A discordant sheetlike body of magma, commonly near vertical, cutting the country rock.

**dilatancy** The tendency of an assemblage of particles to expand or dilate during shear deformation.

**mush zone** The region in a solidification front where crystals and solids tend to move altogether even though the solids are not all physically connected.

**neck** A stalklike magmatic feeder connecting a volcano to a deeper supply of magma.

**plug** The solidified lump or mass of magmatic rock filling a volcanic vent or crater.

**pluton** An isolated solidified parcel of magma found in Earth's crust and thought to represent an extinct magma chamber.

**Rayleigh number** A pure, dimension-free number the magnitude of which indicates the tendency of a layer to undergo sustained thermal convection. The larger this number the more vigorous is convection.

**rigid crust** The region marking the trailing half of a solidification front where all the crystals are interconnected to form a matrix possessing strength.

**sill** A sheetlike concordant magmatic body usually emplaced horizontal in Earth's upper crust.

**solidification front** The marginal zone encompassing all active magmatic and volcanic bodies within which most crystallization takes place.

**stock** Any cylindrical subterranean solidified magmatic body with no clear connection to a volcanic vent.

**suspension zone** The inward leading region of the solidification front in which small, newly formed crystals are able to move with ease relative to one another.

---

## I. INTRODUCTION

Planet Earth owes its gross structure and great diversity of its surface igneous rocks to physical and chemical processes occurring during the crystallization and transport of magma. Although we know broadly what has happened, what exactly goes on in magma to produce these end results is not yet entirely clear. As early as the voyage of the Beagle (1828–1833), Charles Darwin noted in examining Galapagos lavas that magma can evolve chemically simply through the sinking of crystals. Because crystals are always of a different composition than their parent magma, sorting of crystals from melt chemically distills or fractionates magma. The ensuing trail of chemical compositions defines a differentiation sequence. The classical home of the physical and chemical processes of differentiation is the *magma chamber*.

Undoubtedly the largest magma chamber in the solar system is Earth's outer core. Consisting of mainly molten iron, the outer core contains about 30% of Earth's mass. The slow crystallization of the outer core produces crystals that sink to form the inner core, which rotates slightly faster than Earth itself. Even buried at the great depth of about 3000 km, the general spherical shape and size (~2500 km thick) of this magma chamber is well known from seismology. Oddly enough, although the physical nature of this active magma chamber is known in detail, its chemical composition is not nearly as well known. This is quite the reverse of magma chambers associated with volcanism where chemical composition is known in excruciating detail, but the shapes, sizes, and cooling rates of the active reservoirs are not well known.

---

## II. MAGMA BODIES: TYPES AND SIZES

Magma itself, as also defined by Darwin, is any molten mass of Earth material containing any combination of crystals, liquid, and gas. Postmortem studies of old, now solid, magma reservoirs or chambers (generally called *plutons*) exhumed by erosion are commonplace. This is where the most direct information comes from on the nature of near surface chambers. The message from these studies is clear. Magma bodies can be of almost any imaginable shape and size, but some types are much more common than others.

### A. Sills and Dikes

Planar sheets, which parallel local rock strata, are called *sills* and *dikes* when they cut the strata and are by far the most common igneous bodies. In general, dikes transport magma and sills store magma. They each can be of almost any size from a few centimeters to more than a kilometer thick and with aspect ratios from 10 to well over 1000. The Basement sill in the Dry Valleys region of Antarctica, for example, is generally 300–400 m thick and can be traced for 100 km. Single dikes a few meters thick and traceable over tens of kilometers are commonplace in many terranes. Their sheetlike form reflects the fact that these are propagating elastic cracks filled with buoyant magma, and the overall shapes of these bodies are spreading disks and pods with very thin edges. Over a distance of 10 km the Basement sill, for example, thickens from 1 cm at its edge to more than 700 m near the center.

### B. Necks, Plugs, and Stocks

Other once-molten magmas were clearly not sheets, but vertical cylindrical intrusions. Called *necks*, *plugs*, *pipes*, and *stocks*, these were conduits linking deeper reservoirs to volcanoes. Eroded remnants of these feeders, such as Devil's Tower in Wyoming and the Hopi Buttes diatremes—necks that apparently penetrated upward almost as locomotives—in northern Arizona, are particularly distinctive. Although these forms could occur at depth, they are probably only common near the surface where the original crustal rock can be punched out or excavated to the surface by the rising magma. The diamond-bearing pipes of South Africa, for example, connect downward over several kilometers into more dike-like features. The diameter of most necks is in the range of 100 m to 1.5 km.

### C. Plutons

Plutons are bulbous masses that commonly develop beneath strings of volcanoes associated with plate subduction. *Batholiths* may contain vast nests of hundreds of plutons intimately crowded against or penetrating one another. The Sierra Nevada range of California and the Andes literally define the notion of batholiths. Yet the individual plutons within these batholiths are horizon-

tally flattened and, to some degree, sheetlike, although with much smaller aspect ratios (2–20) than sills and dikes. Rather than being injected like sills and dikes, plutons rise diapirically in the fashion of a sluggish thunderhead, eventually losing buoyancy at the leading edge, slowing, and spreading as the lower reaches continue to ascend. The body inflates in place just as do other bodies that begin as necks and locally balloon into a pluton. Although the area of plutons can be enormous (hundreds of square kilometers), many plutons are equivalent to spheres having diameters of 2–10 km.

#### D. Volumes

To put these numbers in perspective, the volumes of composite and stratocone volcanoes are well represented by a cone of a height equal to its radius, which is equivalent to a sphere of diameter 1.25 times that of the volcano's height. With volcano relief commonly in the range of 1–2 km, although the largest are 3–4 km, magma sphere diameters are in the range of 1–9 km. And considering that most stratocones are made principally of pyroclastic materials, which is of high porosity, this range should be reduced to 0.5–5 km. This result should not be construed to mean that volcanoes are simply the outpouring of a pluton of magma, but that volumes of magma of this magnitude (i.e., 0.1–60 km<sup>3</sup>) are not unusual to Earth. The Dufek (Antarctica) and Bushveld (South Africa) intrusions, each on the order of 10<sup>5</sup> km<sup>3</sup>, are the largest known basaltic plutons; both are also strongly sheetlike. Close behind in volume (~30,000 km<sup>3</sup>) is the 1.85-Ga-old Sudbury impact feature, which was originally a multiringed crater perhaps 200 km wide and several kilometers deep filled with extremely high temperature (~1900°C) melt. Single lava flows, either basaltic or silicic ash flows, reach volumes of 2000–3000 km<sup>3</sup>, and these are often part of much larger complexes of either flood basalts or silicic calderas. Some cogenetic igneous complexes, such as oceanic plateaus and rift-related diabase terranes, attain volumes of more than 10<sup>6</sup> km<sup>3</sup>, but these are clearly often the result of volcanism over millions years. For even the largest plutons it is not clear how much of the system was simultaneously molten and dynamically connected. The dynamics of molten systems are determined by the behavior of solidification fronts, which link the smallest scale processes of crystal nucleation and growth to the largest scale dynamics and also determine the nature of the final rock record.

---

### III. MAGMA CRYSTALLIZATION AND SOLIDIFICATION FRONTS

A central key to understanding the dynamic evolution of magma is understanding the crystallization of silicate melts. Magma crystallizes over a wide range of temperature (~200°C) and unlike aqueous solutions and molten metals, silicate melts generally do not form large dendritic crystals (Fig. 1). Moreover, regardless of the size of the magmatic body, crystal sizes commonly range from 1 to 50 mm. This tiny length scale is crucial to the chemical and physical evolution of the magma as a whole. Silicates in magma generally grow in tiny, essentially symbiotic clusters. Individual crystals grow by diffusion of chemical components through the melt at similar rates. The effective rates are similar because coupled multicomponent diffusion depends critically on the slowest diffusing component. Because diffusion is so slow (e.g., ~100 yr/cm), components rejected by one mineral locally build up and the melt saturates in a new mineral; eventually enough minerals appear to use all the local melt.

This is in contrast to dendritic crystallization where large crystals, large buoyant boundary layers of rejected melt, and low residual melt viscosity (<~1 poise) allow continual circulation of melt among the growing crystals. The much larger viscosity of silicate melts, the tiny crystal size, and crystal clustering inhibit melt motion and, instead, favor local equilibration with stagnant melt.

In most common magmas several minerals appear after relatively little cooling (~25°C) and these minerals dominate the chemical evolution of the melt over most of the cooling history. Other minerals appear as needed to use up melt components rejected by the existing minerals. The crystallizing assemblage forms a dynamic, growing feature of all magmas: the *solidification front* (SF).

#### A. Solidification Fronts

The spatial relation between the liquidus (all melt) and solidus (all solid) defines a solidification front about any magmatic body (see Fig. 1). Across this front magma goes from fully liquid at the leading or innermost edge to fully solid at the outer or trailing edge. This bundle of isotherms envelopes the body and propagates inward, meeting in the interior at the point of final solidification. Although thin and sharp just after emplacement, with

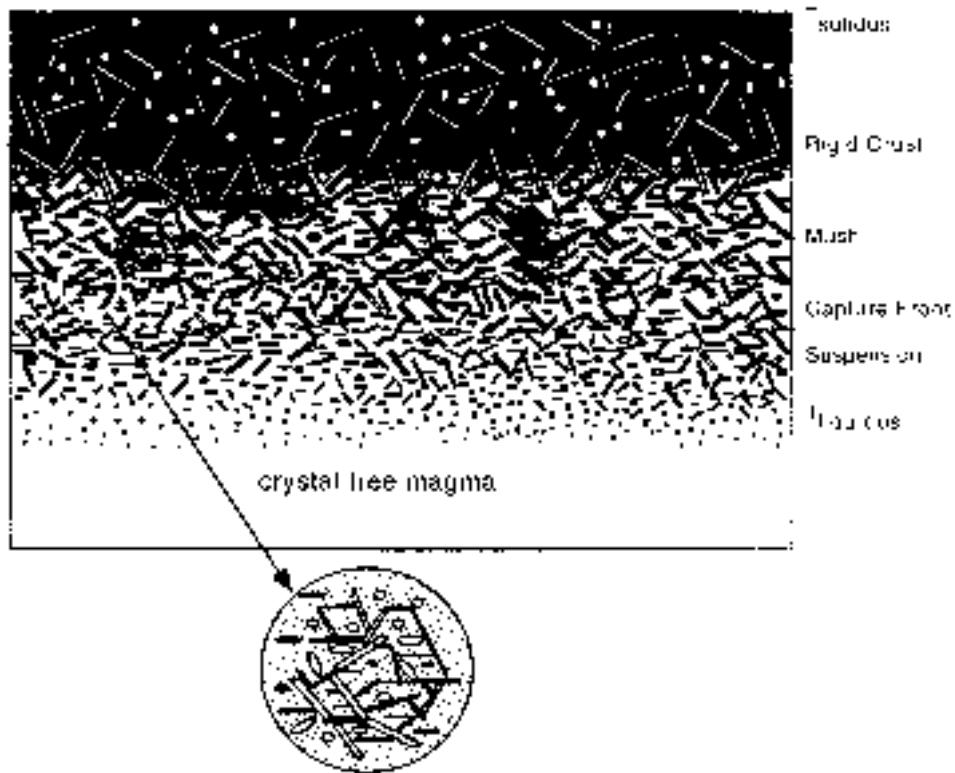

FIGURE 1 Upper solidification front. The base (top here) of the front is defined by the solidus and the leading upper edge is the liquidus. The overall thickness of the front depends on the thermal regime and especially the age of the front and the temperature of the roofrock. The inset depicts the framework-like structure of the crystals at about 30% crystals.

time the SF thickens in proportion to the square root of time, as is well known from the drilling of Hawaiian lava lakes.

Within any SF at least four dynamic and rheological divisions can be identified (see Fig. 1):

1. *Suspension zone*: Beginning at the leading edge or liquidus, the percentage of crystals,  $N$ , equals 0; nucleation commences and crystals grow to an overall concentration of about  $N = 25\%$  at the trailing edge. The small, sparse crystals can move freely relative to one another and perhaps even escape downward from the front itself.
2. *Capture front*: The boundary marking the trailing edge of the suspension zone ( $N = 25\%$ ) where the bulk viscosity has increased by a factor of 10 over that at the liquidus and behind which settling crystals are unlikely ever to escape the advancing solidification front.
3. *Mush zone*: Bounded by the capture front ( $N = 25\%$ ) at the leading edge and the point of critical crystallinity at the maximum packing of the solids

at the trailing edge where  $N = 50\text{--}55\%$ ; individual crystal migration is difficult due to mutual hindrance.

4. *Rigid crust*: Outward of and adjacent to the mush zone and bounded by the solidus ( $N = 100\%$ ) and the point of critical crystallinity ( $N = 50\text{--}55\%$ ). This is the drillable portion of the solidification front commonly referred to as the “crust” in studies of Hawaiian lava lakes.

Two aspects of this subdivided solidification front are important to emphasize. First, these are generalized definitions and are closely tied to the specific phase equilibria of the magma under study; the defining crystallinities will naturally vary somewhat with magma type. In plagioclase-rich basalts, for example, an interlocking network of significant strength may form at crystallinities as low as about 30%. Second, the entire solidification front, which is always present, is a dynamic feature of solidification; it propagates inward at an ever-decreasing rate and thickens with time. All physical and chemical processes occurring as a result of crystallization do so

within the solidification front, and the rates and duration of these processes are limited by the rate of motion of the front itself. Thus the entire evolution of the magma, whether being transported or held in a chamber, is reflected by the dynamic behavior of the solidification front, even when the chamber experiences additional injections.

In an ideal magma emplaced free of crystals, nucleation and growth begin at the inwardly advancing liquidus; the viscosity there is essentially that of the crystal-free magma and only when the crystallinity increases to about 25% does the viscosity increase by a factor of about 10 at the capture front. At the other extreme at the trailing edge of the solidification front, near the solidus, the viscosity is enormous, as the rock is nearly solid. Inward from this point crystallinity decreases, but the crystals form a strong interlocking network and viscosity remains enormous until the crystallinity decreases to about 50–55%. Here the viscosity decreases dramatically as the magma makes the transition from a partially molten solid to a mushy liquid. This is the point of *critical crystallinity*, marking the region of maximum packing of the solids where at all higher crystallinities the crystals form an interlocking network of great strength. Moreover, beyond this point the magma is a dilatant solid, where under shear it expands and chokes any conduit. Thus it is uneruptible. High-alumina basalts in some island arcs erupt carrying 40–50% large crystals, and because they are so near to *dilatancy*, they can erupt explosively. At lower crystallinities the network of crystals is not fully interlocking and the material behaves as a crystal-laden fluid possessing a large effective viscosity. The crystals are, nevertheless, unable to move freely relative to one another and the region behaves as a mush. This mushlike behavior continues inward with decreasing crystallinity (i.e., increasing temperature) until reaching the suspension zone, which connects to the crystal-free deep interior of the body.

#### IV. PHENOCRYSTS AND SOLIDIFICATION FRONTS

Magmas can be put into two convenient categories: (1) those that carry phenocrysts upon emplacement and (2) those that do not. Phenocrysts, being relatively large cognate crystals, are easily recognized in lavas, but much less so in plutons where they can be mistaken for crystals grown after emplacement. Unusually large crystals in the chilled margins of the body are one indication of

initial phenocryst presence. Another is the internal distribution of phenocrysts. Because SFs initially grow exceedingly fast upon emplacement, they capture all phenocrysts in the magma near the contacts. But as the SFs move inward they advance ever more slowly and, at some point, all but the smallest phenocrysts can escape capture and settle to the floor, which is formed by an upward-moving SF. The net result is a loss of phenocrysts in the upper half of the body and an accumulation of phenocrysts in the lower half. The final distribution of phenocrysts from top to bottom is S-shaped (Fig. 2). The efficiency of this process depends on phenocryst size and density and also on magma viscosity; however, many basaltic bodies show this distribution. Shonkin Sag laccolith and Kilauea Iki lava lake are good examples.

A cumulate layer of phenocrysts within a sheetlike body is also an indication of phenocryst emplacement. Many large diabase sills have orthopyroxene or, more rarely, olivine cumulate layers in the central or lower half of the sill, but these phenocrysts are not found elsewhere in the sill. Phenocrysts are most commonly cognate and thus represent an earlier (i.e., prior to em-

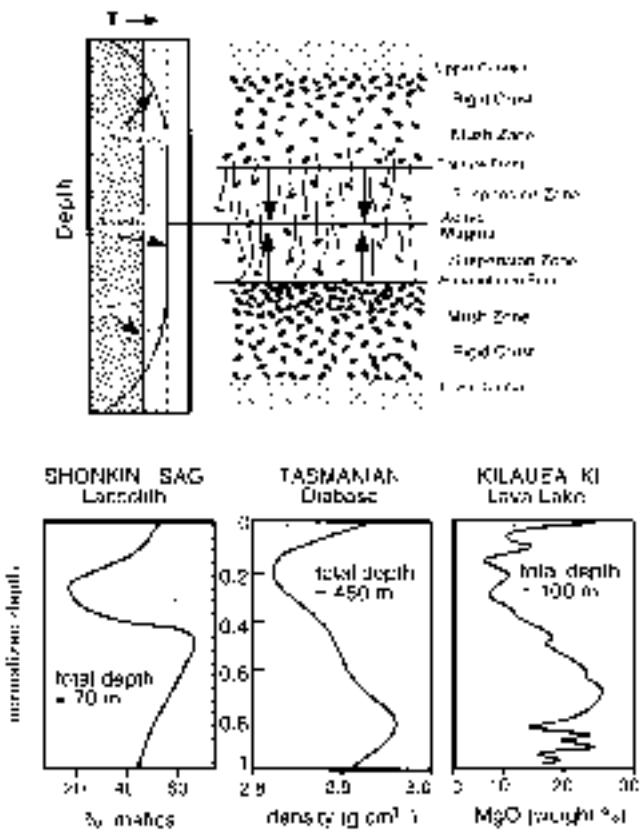

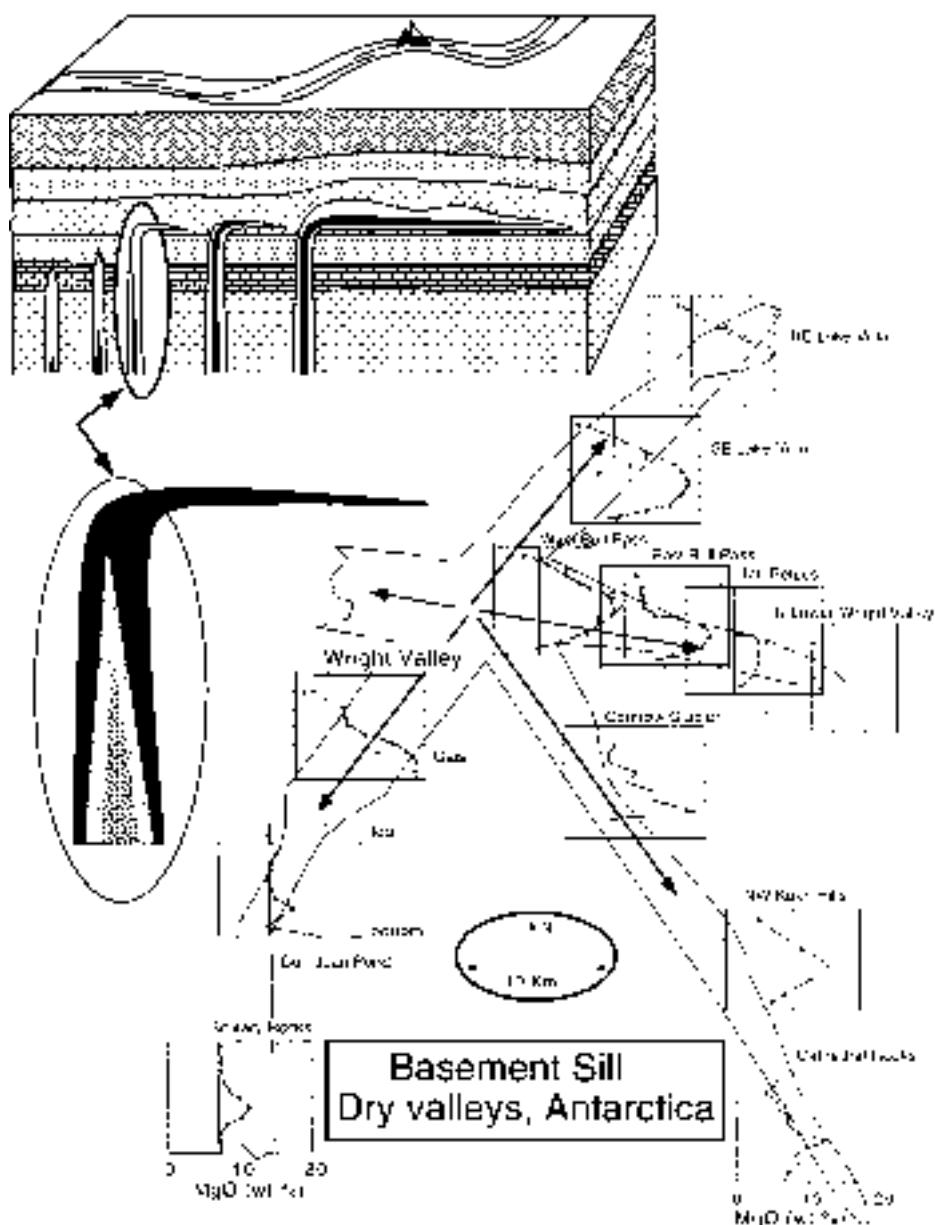

FIGURE 2 The settling and capture of phenocrysts during solidification of a sheet of magma.

placement) crystallization event. This distribution reflects not only the emplacement of the phenocryst-rich magma late in the injection sequence, but also that the magma was *flow differentiated*. That is, the phenocrysts were segregated in the ascending magma into a tonguelike central concentration trailing the leading, phenocryst-free magma (Fig. 3). The leading magma, which forms the margins of the body, therefore, is frac-

tionated, and the central tongue rock is more primitive. Neither rock is a true measure of the original magma composition. Bodies with more evolved compositions at the margins are formed by flow-differentiated magma, and the spectrum of compositions is not something produced *in situ*.

Magma emplaced free of phenocrysts is, of course, also dominated by SFs, but the crystals are formed after

**FIGURE 3** Schematic sorting of phenocrysts during transport and emplacement of a sheet of magma (upper left). Actual distribution of orthopyroxene phenocrysts, as measured by bulk MgO content, from top to bottom in the Basement sill. Each chemical plot is run from 0 to 20 wt% MgO.

emplacement—few magmas are probably ever free of nuclei and very small crystals. As the SFs move inward, crystals are nucleated and the ensemble grows to a solid by the time the solidus isotherm arrives. So crystallization can be viewed as the passage of a packet of isotherms through a particular local volume of melt. The rate of cooling determines the rate of SF advancement and the melt becomes solid regardless of the time given for solidification. The melt does this through a combination of crystal nucleation and growth. Because growth is diffusion controlled, it is slow and insensitive to changes in cooling rate. Nucleation, on the other hand, is sensitive to cooling rate. A balance between growth and nucleation thus sustains solidification. Fine-grained chilled margins and coarse interiors reflect this balance.

Differentiation by crystal fractionation is difficult in phenocryst-free magmas because the crystals are confined to the SFs from which they must escape to fractionate. Once the magma reaches a crystallinity of about 25 vol% it is within the capture front, and escape of individual crystals is unlikely. At lower crystallinities, in the suspension zone at the leading edge of the upper SF, plumes of slightly cooled magma containing small crystals may drop from the SF, traverse the core of the body, and, if the intrusion is not too thick, reach the leading edge of the lower, upward-advancing SF. But since there is no net separation of crystals from the initial melt, chemical differentiation is negligible. Moreover, if the body is sufficiently thick, the plumes will become heated and lose negative buoyancy before reaching the floor, destroying the crystals, and becoming incorporated into the interior melt. This is why phenocryst-free bodies, especially sheetlike intrusions, are frequently uniform in composition from top to bottom.

The 350-m-thick Peneplain sill of the Dry Valleys region of Antarctica is a good example of a phenocryst-free intrusion (Fig. 4). Except for the horizon of silicic segregations near the roof, which will presently be considered, the composition is essentially uniform from top to bottom. Although it might be imagined that this could only occur in relatively small bodies like sills, on a grander scale the Sudbury igneous complex, which is about 3 km thick, shows the same feature. Sudbury is an exceptional example in this respect because it was produced in a matter of minutes by a meteorite impact. Because the initial melt was heated to at least 1900°C, it was initially free of phenocrysts. In more detail, Sudbury consists of an ~2-km layer of granitic rock overlying ~1 km of dioritic. The granitic layer is much too thick to have been produced from differentiation of the diorite and is clearly the result of impact melting of granitic continental crust. The diorite may simply be melted

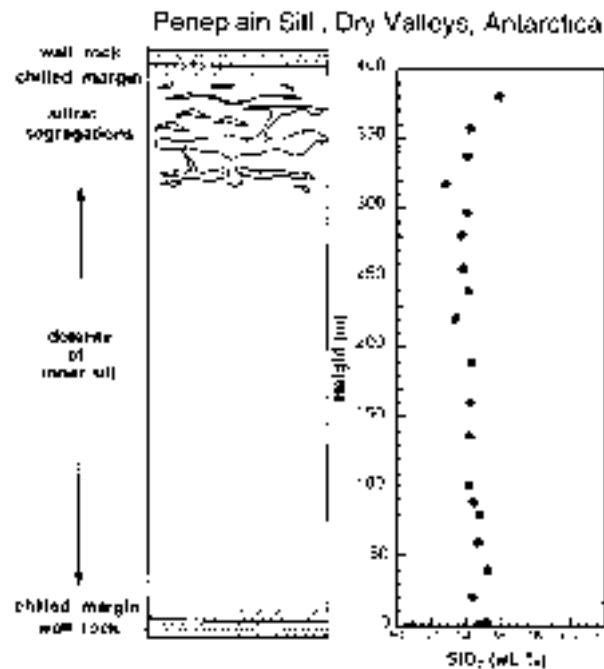

FIGURE 4 The petrologic and chemical variations through the Peneplain sill of Antarctica. This sill was emplaced without phenocrysts and it is nearly homogeneous except for the silicic segregations near the roof.

lower crustal rock; the transient cavity reached depths of 25–30 km. But what is interesting in the present context is that both layers, granitic and basaltic, are essentially uniform in composition. From these and similar bodies, it is becoming clear that differentiation is critically dependent on the presence of crystals in the initial magma. How, then, is the wide range of diversity of igneous rocks produced?

## V. DIFFERENTIATION PROCESSES IN CHAMBERS

There is no doubt whatsoever that chemical differentiation in igneous systems results from the physical separation of crystals and melt. Crystal compositions are always distinct from any natural melt, and progressive crystallization produces residual melts that match the observed compositions of naturally occurring rocks. Thus it would seem simple to produce compositional diversity by removing crystals (by sinking or floating) from the melt. This process of differentiation by crystal fraction-

ation was elucidated in great detail by N. L. Bowen (1887–1955) in the first half of this century.

Numerous mass balance calculations involving reasonable solid phases and derived melts show the great feasibility of crystal fractionation as a means of efficient chemical differentiation. But as reasonable as this process is chemically, the details of the physical process of extensive crystal removal have remained obscure. Many massive basaltic magmatic systems, like Hawaii, produce no silicic magmas whereas other small ( $\sim 1\text{-km}^3$ ) island arc volcanoes erupt lavas of a wide range of compositions. With the recognition of the central role of SFs in crystallization, the controls on the processes of separating crystals and melt have become clear. Refined or fractionated melt is buried deep within the solidification front, and this makes the separation of crystals from melt difficult. Over the first 50% of crystallization, there is relatively little chemical evolution of the melt. It is over the last 50% of crystallization that the melt becomes highly fractionated. Where the melt is hardly fractionated, the melt and crystals are easiest to separate (i.e., at low crystal contents). Where the fractionation is strong, the melt is held in a rigid network and virtually impossible to separate from the crystals. Unless this interstitial melt can be collected into an eruptible mass, the system will show little diversity. The SF must somehow be physically disrupted in order to be purged of the interstitial melt. There are three fundamental ways to do this, as discussed next.

### A. Solidification Front Instability and Silicic Segregations

Because SFs are relatively cool and are partially solid, they are denser than the underlying uncrystallized melt. Once a SF becomes sufficiently thick, it becomes gravitationally unstable. The internal strength is locally overcome by the weight of the leading half of the front and tears begin to develop. As the tears open, local interstitial melt is drawn into them, producing silicic pods and lenses. Interdigitating lenses of silicic rock, 2–3 m thick and 40–50 m long, are common in the upper parts of tholeiitic sills regardless of the initial phenocryst content. Plagiogranite segregations of the oceanic crust are undoubtedly products of solidification front instability (SFI). The silica contents of silicic segregations are in the range of 60–70 wt% and the bulk composition of the sill is near 50%. The more siliceous the sill, the more siliceous are the segregations. Mass balance calculations show that the segregations are produced from local melt and that the tears open when the local crystallinity is

about 65%. This is spatially just behind the point of critical crystallinity when the mush becomes locked into a rigid, but still somewhat weak, network.

If the intrusion is thick enough, the instability may mature to the extent that a large portion of the front detaches and sinks into the core of the chamber. This frees the silicic segregations to collect into eruptible masses of magma; repeated buildup and failure of the SF may thus produce sizable volumes of silicic magma. Overall, however, a characteristic of suites produced by SFI is that they are distinctly bimodal. There are basaltic and silicic compositions, but nothing intermediate. This is a characteristic of many volcanic and plutonic suites, especially in oceanic islands like Rapa Nui (Easter Island), Galapagos, and Iceland, which are considered shortly.

### B. Mush Flow Fractionation

When the center of a magmatic body reaches an advanced stage of crystallization, it is ripe for differentiation by flow fractionation. This occurs when new magma invades the system and forces its way through the established crystalline meshwork, pushing out the fractionated interstitial melt. The original body is thus purged of fractionated melt by replacing it with new magma. Not only is fractionated melt freed to erupt, but also the new magma is contaminated by older crystals of the meshwork, which are thermally and chemically out of equilibrium. The SF meshwork will be partly dissolved, perhaps even disrupted, and the escaping fractionated melt may also carry small telltale pieces of the original SF in the form of clots or clusters of crystals.

The ideal location for this process is in reactivated fissures associated with flank eruptive systems of large active volcanoes. During periods of repose, magma remaining in the dominant fissures can solidify to the point of critical crystallinity (~55%). New activity displaces the residual melt, yielding an eruption of fractionated melt on the flanks of the volcano. This is seen at Hawaii, where the only fractionated lava issues from fissures on the far flanks; and this melt carries small clots of the SF. Deep in these same fissures thick accumulations of phenocrysts form (at Hawaii these are olivine cumulates) and may also be re-entrained and similarly purged by the invading magma, yielding unusually primitive (i.e., olivine-rich) basalt compositions.

The amount of melt available for purging is proportional to the size of the existing SFs. Because magma will always follow the path of least resistance, it will not normally invade an existing SF unless that is the only

course available. Moreover, as the residual melt in the SF becomes enriched in silica its viscosity rises dramatically, making displacement increasingly difficult. It is thus unlikely that highly silicic melt could be freed in this fashion unless enough volatiles build up in the SF to offset the effect of silica on viscosity. In extensive, geometrically diverse, and long-lived magmatic systems, such as mush columns (see later discussion), this form of melt fractionation is most effective.

### C. Reprocessing

The formation of silicic segregations is a normal consequence of solidification. Some alkalic basalts become siliceous only at the latest stages of crystallization when the SF is too strong to be torn, and some bodies are too small to undergo SFI. But in general most basaltic bodies will produce silicic segregations, and once formed they remain as silicic noise in otherwise basaltic systems. Even if the entire body was remelted, these silicic pods are so much more viscous than basalt that they are physically (but not chemically) immiscible in basaltic magmas. Stirring is ineffective in reblending these silicic blobs. Wholesale remelting of basaltic crust frees swarms of segregations to collect into eruptible volumes of rhyo-

litic magmas. This is very likely the means of producing both rhyolite and basalt in Iceland.

About 15% of the surface rocks of Iceland are rhyolitic. There is a preponderance of basalts, but a paucity of lavas of intermediate composition. The suite is strikingly bimodal. Iceland is a prime location for reprocessing of the basaltic crust because it straddles the Mid-Atlantic Ridge. And within Iceland the ridge jumps periodically, refocusing magmatism at a new location in older crust. Prolonged use of new fissure swarms steadily heats the crust, forming outward-propagating, progressive—instead of regressive—solidification (i.e., melting) fronts. These fronts systematically break down and reprocess the crust, freeing silicic segregations to collect as rhyolitic magma (Fig. 5). The ensuing rhyolites, such as those at the large Torfajokull silicic center, are nearly crystal free, but carry ubiquitous, diagnostic crystalline debris from the original SF, including pieces of granophytic rock in various stages of melting. The massive 1875 pumice eruption of Askja volcano in northern Iceland, for example, was laced with chunks of silicic segregations quenched in all degrees of fusion. The oxygen isotopes of the rhyolites show the effects of extensive prior hydrothermal alteration when the silicic segregations were a part of the crust. This is also even true for comagmatic basalts. Thus the Iceland crust undergoes wholesale differentiation through remelting.

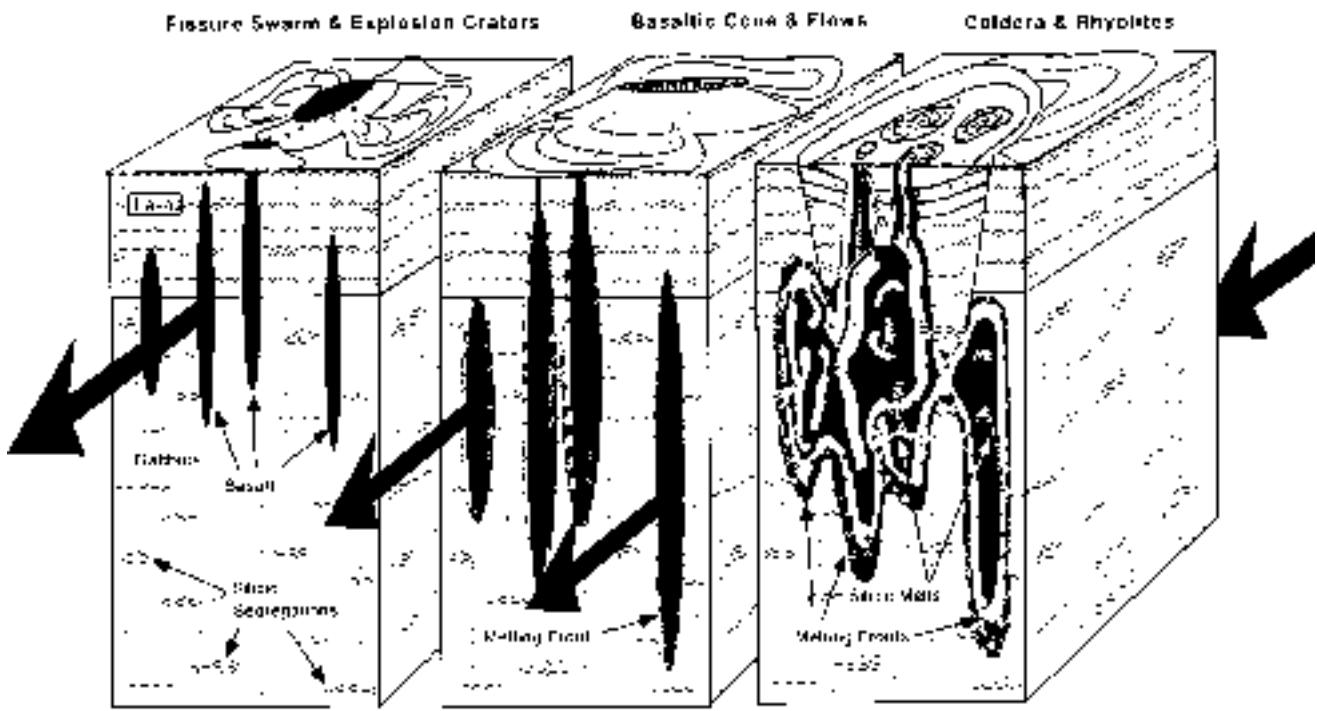

FIGURE 5 Generation of rhyolitic magma in Iceland through reprocessing of older crust.

### D. Compaction

Solidification fronts growing upward on the floors of magma chambers can become so thick or distended that their weight is enough to deform the crystalline matrix and squeeze out the interstitial melt. This is a slow process that can only occur when the growth of the front itself is slow, which occurs either at advanced stages of crystallization in large bodies or deeper in the crust where the wallrock/floor rock is suitably hot, making inward propagation of the solidus sluggish. Depending on the melt density, the evicted melt may accumulate within the upper reaches of the front or continue upward through the core of the body and lodge within the upper solidification front. In thick sheetlike chambers the changeover from solidification control to compaction may be sudden enough to produce a distinct compositional horizon higher in the system, and these segregations may also be collected during reprocessing.

### E. Chemical Fractionation Effects

The chemical aftermath of SF fractionation is virtually indistinguishable from massive crystal fractionation. Both processes involve the separation of an ensemble of slowly grown indigenous solids. There are, strictly speaking, small chemical differences between pulling a melt from an equilibrium assemblage of solids fairly late in the crystallization sequence and separating crystal by crystal from the melt as they appear. But there is no physical process that can systematically cleanse a melt of tiny crystals over a wide crystallization interval. Moreover, it is doubtful whether the resulting rocks contain enough discriminatory evidence to reveal the details of the fractionation process. Nevertheless, certain constraints due to mass balance considerations are generally consistent with solidification front processes. It is the physical evidence, coupled with the chemistry, that reveals process. This is also evident in the deciphering of the dynamics of large magmatic systems.

---

## VI. CHAMBER PROCESSES REVEALED IN THE PLUTON ROCK RECORD

Exotically layered and compositionally varied plutons would seem to hold the key to understanding magmatic processes. The stratigraphic record left on the floors of

Skaergaard, Stillwater, Rum, Bushveld, the Great Dike, and Dufek, among others, have been carefully studied with the hope of discovering the fundamental dynamics, chemical and physical, of magma chambers. All other bodies would then simply be subsets of these more dynamically rich systems. An easy reading of this rock record has proven difficult. It has become clear, however, that the chemistry of the rock record is not enough, in and of itself, to reconstruct the solidification history.

Unlayered plutons have been viewed as containing definitive evidence of processes distinct from those of layered plutons. And lavas and ash flows, lacking any information on pre-eruption stratigraphy, have been examined strictly in terms of chemistry. Thus three separate sets of principles exist that have been garnered from the study of layered, unlayered, and erupted bodies, and they fail to produce a consistent dynamic depiction of magma chambers.

### A. Layered Plutons and Initial Conditions

The historical approach to interpreting layered plutons has been to assume an instantaneous emplacement of a more or less homogeneous magma at or near its liquidus temperature. All subsequent layering and differentiation come from processes occurring in the chamber. Progressive crystallization throughout the magma either rains crystals to the floor, producing more or less homogeneous gabbroic cumulates, which evolve upward into more fractionated compositions, or periodic overturns of crystal-laden melt makes sedimentary layers on the floor. Some crystallization at the roof is unavoidable and an upper border group also develops, but it is much thinner than the floor sequence. A sandwich horizon occurs where the floor and roof sequence meet, and this is where the most evolved rocks should lie.

These irrefutable facts came from the earliest field observations at Shonkin Sag laccolith by L. V. Pirsson (1860–1919) in 1905. Floor sequences, where present, are normally much thicker than roof sequences. This has been interpreted to reflect strong cooling from the roof, promoting strong crystallization and convective circulation throughout the interior and major deposition of crystals on the floor. The inversion of this rock record would seem to be straightforward. But other than the usual sporadic silicic or granophytic segregations, significant volumes of silicic rock are rarely found at the inferred sandwich horizon. They could have been erupted away, but perhaps there were none there in the first place.

Even stranger has been the realization that thick floor

sequences are not seen in phenocryst-free diabase sills, no matter how thick the sill itself may be. A precise determination of the true sandwich horizon is also possible in many sills and lava lakes from the mismatch in roof and floor joints, which are shrinkage or cooling cracks that track the inward propagation of the upper and lower solidification fronts. They always meet approximately in the middle. Cooling would seem to be equal from top and bottom. Thermal modeling, both with and without convection, bears this out. Thus the absence of silicic sandwich horizons points to a fundamental problem with the historical concept of magma solidification in chambers. The field evidence has another interpretation.

Thick accumulations of crystals on the floors of bodies such as Shonkin Sag laccolith are from the deposition of crystals (phenocrysts) carried in by the initial magma. They are essentially snowfalls of crystals; this is sudden and massive cumulate formation. Phenocryst-bearing magmas injected into chambers of any sort—sills, dikes, plutons—form cumulates; it is unavoidable as long as the body is not so small as to cool instantaneously.

Initially crystal-free magma, such as the Sudbury igneous complex, crystallizes to almost featureless rock. The instantaneous emplacement of such magma of any significant size is a rare occurrence. Yet it does happen. Individual eruptions of continental flood basalt reaching volumes of 1000–2000 km<sup>3</sup> often contain very few phenocrysts (2–5%) and are chemically homogeneous. And 100-m-thick ponds of these basalts solidify into featureless rock with some silicic segregations. Were these magmas to cool, instead, in sheetlike chambers at depth, as some must, they would be homogeneous gabbros with signs of SFI.

The central problem in interpreting plutonic rock sequences is that the initial conditions of the system are unknown. Was the body formed of one massive injection? Or did it form by many periodic emplacements, as in long-term volcanic eruptions at Hawaii? What was the phenocryst content of these inputs? Although general impressions are sometimes attainable from nearby dikes and sills, more generally the answers to these and many similar questions have been inaccessible. Some answers may come from layered sequences.

## B. Layering

Phenocryst-charged magma cannot solidify without crystal sorting into layers, however cryptic or well formed; it is unavoidable. The separation of solids from

fluids is a vast subject rich in process and dynamics. Almost any conceivable final sequence of solids of arbitrary shape, size, and density is attainable through reasonable sedimentation scenarios. Moreover, the ensemble of scenarios increases greatly if the shape of the magmatic container is also varied. In a relatively narrow chamber with outward-slanting walls, for example, the well-known Boycott effect controls sedimentation by greatly enhancing the rate of deposition. Crystals near the walls settle quickly and avalanche *en masse*, sorting crystals according to size and density in a delicate fashion (Fig. 6). Moreover, repeated injections of varying intensity supply inputs to the chamber of varying phenocryst concentration and size. The net effect of crystal sorting, chamber form, and input history is to establish a vast dynamic regime that can give rise to intricate layered sequences.

Knowing the dynamic regimes of layering it would seem straightforward to read the history of the injection process, but annealing clouds this inversion, making it nonunique. That is, once any mechanical segregation of crystals takes place, local thermodynamic equilibrium controls further maturation of the texture. Certain minerals may be unstable and dissolve to refine cryptic layering into nearly monomineralic layers. This form of annealing or textural ripening is known from metallurgy and ceramics. Annealing can only be avoided by rapid cooling, which itself is possible only in small bodies.

Large bodies, then, commonly show good layering for two principal reasons. They were formed by many injections; hence the probability is high that phenocryst-laden magma was present. Also, unusually long cooling times provide maximum opportunity for textural ripening.

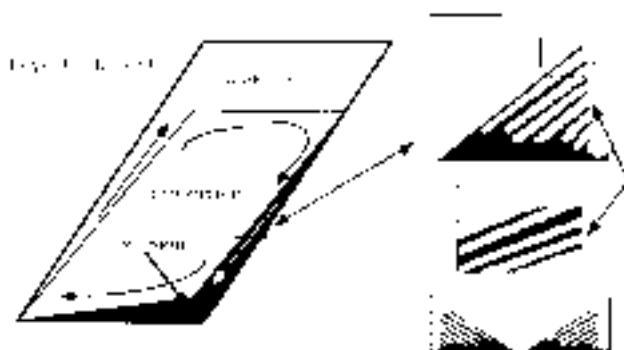

FIGURE 6 The enhanced sedimentation due to an inclined wall. Once on the wall, the sediment avalanches downward along the wall, inducing an upward return flow beneath the hanging wall. Avalanche promotes layering because small and large particles have different angles of repose. The result of two slanting walls is also depicted.

ing. In addition, large bodies may form extensive mush regions, extending at some point through the entire body. This allows interstitial melt to flow and supply nutrients to layer-forming crystals and to destabilize other crystals. This late-stage flow through the porous mush blurs the final chemical spatial state of the system, making inversion to an active magma chamber nonlinear and difficult.

### C. Thermal Convection

If magma did not crystallize and form solidification fronts, the convective regime in chambers could be easily predicted from the shape, thickness, temperature, and viscosity of the magma. From these and a few other physical properties, the magnitude of a pure number (i.e., free of dimensions) called the *Rayleigh number* ( $\text{Ra}$ ) can be determined. Everything dynamic about noncrystallizing fluid can be learned from  $\text{Ra}$ ; the temperature distribution, rate of convection, and rate of cooling are each set by  $\text{Ra}$ . The enormous literature on thermal convection in fluids of almost every kind tells this in great detail, but it tells relatively little about fluids undergoing solidification. Although the general concepts still hold, the details of the dynamic regime cannot be safely predicted from the conventional consideration of  $\text{Ra}$ . It is particularly unclear exactly how to estimate the temperature difference driving convection.

The main reason for this is that the cool, denser magma along the roof, which would normally form descending plumes to be replaced by ascending hotter, lighter magma, is mainly locked in solidification fronts. This minimizes the amount of cool fluid available to drive convection. The SFs also propagate inward with a velocity that tends to override incipient plumes forming at the leading edge of the SF, trapping them forever within the SF. And the onset of nucleation throughout the interior may produce enough heat from latent heat of crystallization to offset the heat potentially transferable by convection. Although the detailed physics is only now emerging, it is clear from a growing set of experiments that solidifying fluids do not convect much, if at all, once they are below their liquidus temperature. If the fluid is superheated (i.e., above the point of initial nucleation), however, vigorous convection occurs in the conventional sense. The absence of erupting superliquidus magma may well reflect the efficiency of convection in dispatching superheat. The absence of superheat indicates a diminished role for thermal convection as a dominant process in chambers, but this does not mean that chambered magma is motionless. Along the walls

in tall chambers, for example, crystal-laden flows may cascade down and sweep across the floor, possibly forming troughs in the basal front and at the same time depositing crystals.

### D. Convection in Sedimentation

Swarms of crystals in freshly injected magma can never be uniformly distributed and so the uneven density along horizontal (i.e., equipotential) surfaces will spawn convection. The motion can take on many forms, but descending plumes is the most common. If the crystals are small ( $<\sim 0.1$  mm), have a low-density contrast, and their concentration is low ( $<\sim 5\%$ ), the crystals form a dusty suspension that may slowly circulate in cells as the dust is deposited on the floor. The flow will be relatively gentle, as it is for highly concentrated ( $>\sim 40\%$ ) mushes, which are too viscous and sluggish to move vigorously.

Between these extremes there is a wide range of dynamic behavior where crystal sedimentation can strongly stir the magma. The more basic the magma, the lower its viscosity and the more pronounced the effects of sedimentation. The aftermath is a sequence of layering clearly due to convection, but not thermal convection. Considering the large size of magmatic systems, the physics of crystallization, and the possible shapes of chambers, some motion, however small, is probably always present.

---

## VII. CHAMBER EVOLUTION AND PLUTON FORMATION

The age-old dilemma in interpreting plutonic rocks is whether to read the sequences as due to purely *in situ* processes or as a result of a series of injection events. This issue, which historically is almost a philosophical matter in petrology, still plagues interpretations; for it is always easy to interpret a complex rock sequence as due to a specific string of injection events, which moves the problem to another venue. Given the geochemical tools and physical insight now available on crystallizing systems, however, this question can be approached with far more objectivity and certainty than ever before. Thick continuous sequences of cumulates on the floor reflect a chamber formed of phenocryst-laden magma (e.g., Shonkin Sag). Thick expanses of uniform texture gabbro or diabase reflect crystallization of mainly phe-

nocryst-free magma (e.g., Sudbury). These are perhaps end members (Fig. 7) and the larger the body the higher the probability that it was formed over a significant period of time (say, hundreds to  $10^5$  years) involving many injections of magma with varying amounts of phenocrysts. The net result can be exotically layered sequences sandwiched within monotonous nonlayered sequences, or even a thick, coarsely layered sequence followed by a finely layered sequence, marking perhaps two distinct injection episodes, much as seen in volcanism itself. The detailed isotopic record through such sequences generally shows the number of injections to increase with the size of the body. Bodies as large as Stillwater, Rum, and Dufek, for example, which are each more than 5 km thick, may have experienced thousands of injections during formation. In spite of this, the thickness of highly fluid magma at any time may have been only a few hundred meters or less, as has been recognized at Rum in piles of pieces of the lower front dislodged by the injections. The lower solidification front, includ-

ing any cumulates, was locally disrupted time and again by these injections. Crystals were reworked and redeposited and crystal growth was interrupted many times. Individual crystals may carry zoning telling of a long and dynamic history.

Further variations on this basic theme come from the geometry of the wallrock container holding the magma. Injection of phenocryst-laden magma along steeply inclined walls, as mentioned already, promotes rapid sedimentation, avalanching, and sorting, leaving a telling sequence reflecting an intricate dynamic record that continues to evolve via diffusion until dropping temperature finally freezes in the record.

The net result is a pluton whose size, container geometry, and overall composition greatly influence the rocks it is composed of. The larger the body, the more injections necessary to build it; the more injections, the higher the probability of injecting a wide variety of phenocryst concentrations and sizes. The wider the variety of phenocryst assemblages, the greater the crystal sorting and layering. Inclined walls enhance this variety, but increasing silica content stifles sorting and variety.

Small, single-injection sills and dikes are most often unremarkable in variety because they are small and of simple geometry. Yet, their story is still important. They tell what systems become when they are not steadily reinjected and cool quickly. At another extreme are lavas. Volcanic sequences are clearly the result of long periods of subareal reinjection or eruption, but the small size of individual injections (i.e., flow thickness) promotes rapid cooling without crystal sorting and annealing. At yet another extreme is large, long-lived, and heavily reinjected chambers.

The lesson learned is that the three dynamic regimes of magma, characterized by large chambers, sills, and lava flows, each show different aspects of the same spectrum of physical and chemical processes common to magma. Magma chambers are thus integrated systems behaving in response to system size, nature of holding regime, and state of crystallinity of the magma itself. An integrated magmatic system is more aptly characterized as a mush column.

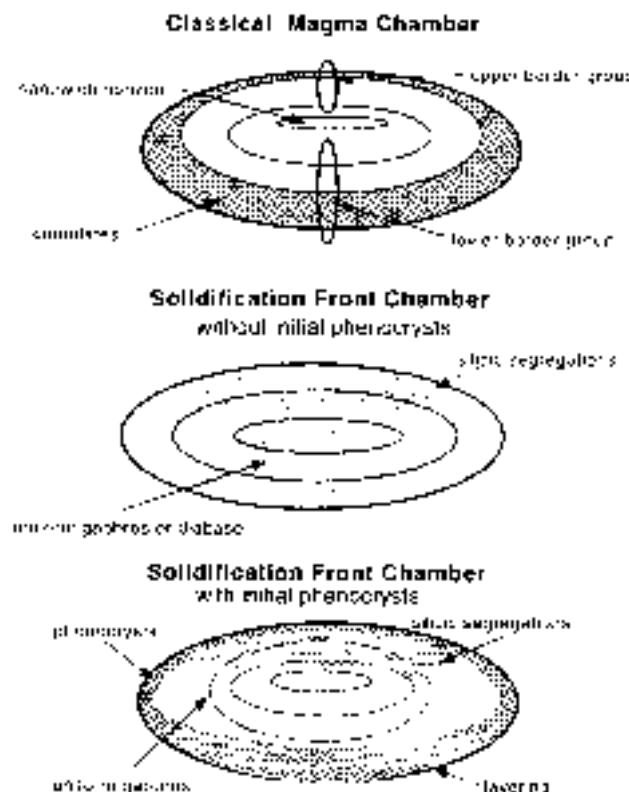

FIGURE 7 Magma chamber final rock sequences with and without initial phenocrysts (lower two sketches) in comparison to the historical interpretation of rock sequences (top). If multiple injections of crystal-laden magmas are added, almost any sequence can be achieved.

### VIII. MAGMATIC SYSTEMS AS MUSH COLUMNS

Mush columns are vertically extensive active magmatic systems in the crust and lithosphere (Fig. 8). At depth they are a blend of sills, stocks, and original wallrock,

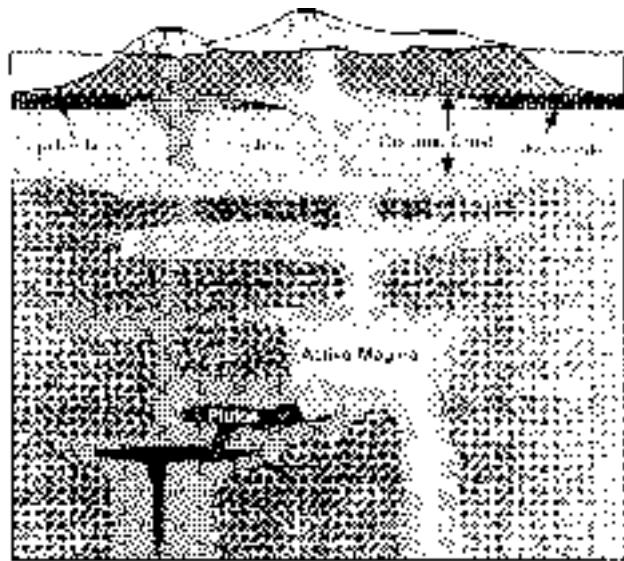

FIGURE 8 A schematic depiction of a mush column magmatic system as might exist beneath Hawaii, Easter Island (Rapa Nui), or other isolated oceanic volcanic centers.

where with time all boundaries, both physical and chemical, become blurred. Thick expansive sills cool slowly and, on average, always contain a core of magma containing few crystals. Narrow interconnecting passages, on the other hand, cool much faster and are choked with crystals in a relatively short time. Yet as long as the magnitude and frequency of magmatism sustain supersolidus temperatures, a distinct, however tortuous, core region is always available to transport magma upward. In the narrow, mushy necks, crystals are entrained and flushed away. The local mush state thus depends on the local magmatic flux or the magnitude and frequency of magma transmission.

#### A. Geophysical Detection

Direct evidence of this kind of system comes from studies of deeply eroded subvolcanic terranes combined with geophysical inferences (e.g., earthquake distributions) on large active systems like Hawaii and the ocean ridges.

Beneath volcanoes, contrary to petrologic expectations, seismic studies find little sign of large magma-filled caverns or chambers. Teleseismic studies generally do find a general slowing of seismic waves (i.e., travel time residuals) around large calderas, like at Yellowstone and Long Valley, but more detailed local surveys do not find anything easily ascribable to a large concentration

of highly fluid magma. Near source studies at Katmai on the Alaska Peninsula showed strong S-wave shadowing presumably due to magma, and the distribution of earthquakes both prior to and after eruption at Mt. Pinatubo (Philippines) as well as at Kilauea (Hawaii) shows a diffuse magmatic region, but nowhere is the picture very clear on *in situ* magmas beneath volcanoes.

Recognizing the dominant role of SFs in magmatic systems, these results are not surprising. Mature solidification fronts, as already mentioned, are made mostly of an interconnected network of crystals that give the SF elastic strength and the ability to transmit seismic waves at velocities not much slower than the solid rock itself. Moreover, large active magmatic systems are generally mature (i.e., size is age) and possess extensive mush regions and relatively small volumes of low crystallinity magma. And individual bodies themselves are small relative to the wavelengths of seismic waves (3–5 km), making detection difficult. Magmatic regions may thus appear seismically solid, and were it not for the manifestations such as surface inflation and eruption itself, the presence of the magma would not be suspected. Detailed seismic reflection studies at ocean ridges find a thin (50- to 150-m) lens or sill of magma residing just below the sheeted dike complex and perched at the top of an extensive mush column (see later discussion). At fast-spreading ridges like the East Pacific Rise the lens is clear and near the surface, but at slow ridges like the Mid-Atlantic Ridge the lens presence is unclear, perhaps ephemeral, and possibly deeper due to the more subdued thermal regime associated with slower plate spreading.

Gravity and magnetic surveys also do not reveal any simple magma chamber system. Near-surface magmas being almost neutrally buoyant have small density contrasts, so resulting gravity anomalies are subtle to detect among background anomalies. The high temperature of magmas makes them nonmagnetic and in magnetic contrast to most country rock. But volcanic areas are often magnetically noisy, again making detection difficult.

The arrival of magma into the near-surface swells the reservoir and inflates the surface, which is directly measured through leveling. This is commonly seen at large shield volcanoes like Kilauea in Hawaii and Krafla in Iceland. Modeling of this inflation gives some idea of the general position and size of the local reservoir, and this inference is also consistent with mush column systems (see Fig. 8). In island arc-style magmatic systems, characterized by small volume central vent eruptions as at Mount St. Helens, inflation is much more localized to the immediate area of the volcano itself.

The associated mush column is similar in basic features, but is weaker, cooler, and much more spatially restricted.

Thus the theory of large swimming pools of magma immediately beneath volcanoes and ocean ridges, a model held for nearly a century, has not proven out. Instead the magmatic system is more like a vertically distended mush column. And it is the individual dynamic and chemical characteristics of mush columns that are responsible for the distinctive petrologic character of these systems.

## B. Igneous Diversity and Bimodality

It may seem odd that neither petrologic diversity nor bimodality (i.e., a preponderance of basaltic and rhyolitic rocks with a paucity of rocks of intermediate composition) is proportional to system size. This is a direct reflection of mush column dynamics.

In relatively small, sluggish, and tectonically immobile magmatic systems, the magnitudes and frequencies of eruption are small, and magma repeatedly traverses similar pathways and encounters earlier intrusions at various stages of crystallization. Tectonic immobility of the magmatic center along with intermittent eruption over a 1- to 5-million-year period, for example, allows most intrusions within the underlying magmatic column, regardless of size, to become highly mushy or even locally to solidify and yet remain in place to be reprocessed through reheating by later magmas. Immobility is central to reprocessing, and reprocessing is central to bimodality. This is the primary difference between Hawaii and Iceland. Hawaii is highly mobile relative to its deep-seated source and escapes reprocessing, whereas Iceland straddles the Mid-Atlantic Ridge, which periodically relocates and extensively reprocesses the crust of Iceland. Bimodality is well developed only at Iceland. The silicic lavas contain pervasive restitic debris, and mingled lavas are not uncommon. Both features reflect reprocessing.

If the mush column is relatively cool and sluggish, only fairly evolved or fractionated basalts reach the surface, which is the rule at small, intermittent magmatic centers like Rapa Nui (Easter Island) and perhaps many island arc centers. The basalts will not form a chemically cohesive group easily related to one another through simple fractionation, instead the compositions of each eruptive batch, in detail, will each be distinct, and the suite as a whole will show a characteristic scatter. Reactivating a cool, weak mush column may also force earlier

stagnated magmas to ascend and sequentially invade one another as new magma climbs toward the surface. Stagnated magma has the highest probability of having compositionally evolved through any number of processes. The erupting magma may thus be a haphazard mix of less and more evolved magma. Reheating by fresh magma also locally remobilizes mushy sills, freeing solidification front-bound silicic segregations to collect and eventually erupt as silicic magma.

If, on the other hand, a resumed flux of magma through the mush column is strong, recently formed cumulate beds can be disrupted and the crystals entrained, partially resorbed, and redeposited higher in the column. They can also be carried in part to the surface. In this fashion a strong vigorous system can erupt primitive, olivine-laden picritic lavas. At Hawaii, for example, both olivine abundance and size are proportional to the eruptive flux of Kilauea. The compositions of these Hawaiian lavas are characterized by strong olivine control, and olivine fractionation produces a basalt with  $<\sim 7$  wt% MgO and multiply saturated, at low pressure, in olivine, clinopyroxene, and plagioclase. The compositions of successive lavas are easily related to one another through simple crystal fractionation, and the suite as a whole will show a certain chemical cohesiveness reflective of this process.

The net chemical result of the mush column, thus, depends on the magmatic strength of the system. Weak, sluggish columns produce a series of disjoint magma compositions due to a series of distinct local differentiation histories, each related to the others through the basic chemistry of the ultimate source of the entire magmatic event itself. Strong systems, especially if immobile, show good chemical cohesiveness due to continual crystal entrainment, transport, and deposition. A general feeling for the evolution of the entire system can be gained by considering the system as a whole, tied together by crystal fractionation in a virtual magma chamber, which at some level must always be true. It is the details of the rock chemistry, petrography, and temporal occurrence that record the details of the local magmatic processes. It is these processes that define magma chambers.

## GLOSSARY

- hypocenter** The point of initiation of an earthquake in the Earth; also called the *earthquake focus*.
- kimberlite** A very low silica igneous rock rich in volatiles that erupts explosively from sources in the upper mantle. Commonly contains mantle xenoliths; occasionally contains diamonds.
- Newtonian fluid** A simple fluid in which the velocity gradient is directly proportional to the applied stress; the constant of proportionality is the viscosity.
- reaction rim** Outer rim on a crystal of different composi-

tion, or different minerals, which has formed by a chemical reaction of the crystal with the surrounding magma.

**subduction zone volcanoes** Volcanoes that occur along the Earth's plate boundaries where one is being subducted or taken down into the Earth's interior. The magmas erupted are typically rich in volatiles and the eruptions often explosive.

**xenolith** A foreign rock fragment in an igneous rock or a magma.

**pumice** A light-colored, cellular, and glassy rock, typically less dense than water because of the large fraction of bubbles (vesicles) in the glass.

---

## I. INTRODUCTION

Volcanoes can erupt explosively, generating high columns of ash and occasional pyroclastic flows, or they can erupt slowly forming lava flows and domes. Mass eruption rates are controlled by the rates of magma ascent through the volcanic conduit and the conduit size. The magma ascent rate itself is a function of the pressure in the magma storage region, the physical properties of the magma, such as its density and viscosity, the conduit diameter, and the resistance to flow in the conduit that connects the magma storage zone to the surface. A number of important characteristics of volcanic eruptions are affected or controlled by the rate at

which magma ascends from depth. For example, the bubble content (i.e., vesicularity) and the degree of crystallization that develop in the melt can be significantly different in rapidly versus slowly ascended material. In fact, the inability of rapidly ascending magma to effectively lose exsolved gas may cause an eruption to change from effusive to explosive, as occurred during the 1997 Soufrière Hills eruption on Montserrat in the West Indies. To better understand the mechanisms of volcanic eruptions, it is therefore important to quantify the rates at which magmas rise to the surface.

The rate of magma ascent strongly influences a number of chemical and mineralogical reactions that occur in volatile-rich magmas, and this relationship provides a number of ways to study ascent rates. One reaction that is a direct result of magma ascent is the exsolution of volatiles from the melt to form gas bubbles. Water is the most abundant bubble-forming gas in many magmas, but CO<sub>2</sub>, SO<sub>2</sub>, and Cl are also important in some magma types. These gases diffuse out of the melt at different rates as pressure exerted on an ascending magma decreases during ascent. It is therefore possible to use the extent of degassing of each of these different species as an indicator of the time involved in magma ascent from depth.

Degassing during ascent also causes the melt portion of the magma to crystallize. The rate and extent of this crystallization have been determined for some magma types and can be used to estimate magma ascent rates. Similarly, some crystals formed in magmas at depth can contain volatile species such as OH, CO<sub>2</sub>, and S in their structure, for example, biotite, hornblende, and Fe-sulfide, and these phenocrysts tend to become unstable and react with the surrounding melt during magma ascent. These reactions occur because the decrease in pressure during ascent causes a decrease in the volatile species dissolved in the melt, which destabilizes the phenocryst. The amount of reaction between phenocryst and melt is controlled by the ascent rate and the kinetics of the mineral breakdown. These degassing-related reactions are particularly important in studying volatile-rich, subduction zone volcanoes such as Mount St. Helens. They are less useful in studies of basaltic volcanic centers because of the generally lower volatile contents in these magmas. Magma ascent rates can also be estimated using the rate of movement of seismic activity toward the surface or theoretical analyses of conduit flow together with measurements of the mass eruption rate for a given event.

Other methods of assessing magma ascent rates involve study of xenolith transport from depth by the magma, the extent of chemical reaction between these

xenoliths and their host liquid in the magma, and evidence of U-Th-Ra isotopic disequilibrium in a magma. The latter approach involves the identification of isotopic disequilibrium of the short-lived isotopes in the U and Th decay series; the disequilibrium indicates a maximum time of magma existence (4–5 half-lives for the decay involved, i.e., ~8000 yr for <sup>230</sup>Th-<sup>226</sup>Ra and 30 yr for <sup>232</sup>Th-<sup>228</sup>Ra) since the disequilibrium was generated. The ability of magma to physically transport xenoliths to the surface depends on the ascent velocity and the rheology of the magma as well as the xenolith size and density. Reactions between xenoliths and magma may occur where a xenolith crystal and magma are in contact but not in equilibrium; the crystal undergoes a time-dependent diffusional exchange of atoms with the melt, allowing an assessment of the time involved in magma ascent. The following sections describe some of the more interesting results on magma ascent rate determinations using these different approaches, but first we consider the problems of the magma source and where ascent begins.

---

## II. MAGMA SOURCE AND MAGMA RESERVOIRS

One of the significant problems that has to be addressed when attempting to determine magma ascent rates is the question of where ascent was initiated. For many volcanoes there is good evidence for a magma storage region in the crust, a magma reservoir from which the final ascent began. Crustal storage zones have been identified seismically for almost all well-studied volcanoes in subduction-zone environments, including Mount St. Helens, Mount Pinatubo in the Philippines, Soufrière Hills on Montserrat, and Unzen in Japan, and the presence of these near-surface (5- to 15-km depths) reservoirs is confirmed by petrological data (Fig. 1a). Density contrasts between magma and surrounding rocks also indicate that there should be both deep and shallow magma reservoirs beneath many calc-alkaline volcanoes, and recent data indicate that two such reservoirs did exist at 3–5 and >8 km under Mount Rainier at the time of its most recent (2200 yr ago) explosive eruption. Using the methods outlined earlier, estimates of magma ascent rates for such volcanoes will generally refer to the transport from the higher, crustal-level storage chamber to the surface. Large-scale eruptions, such as those that occurred at Long Valley and Yellowstone in

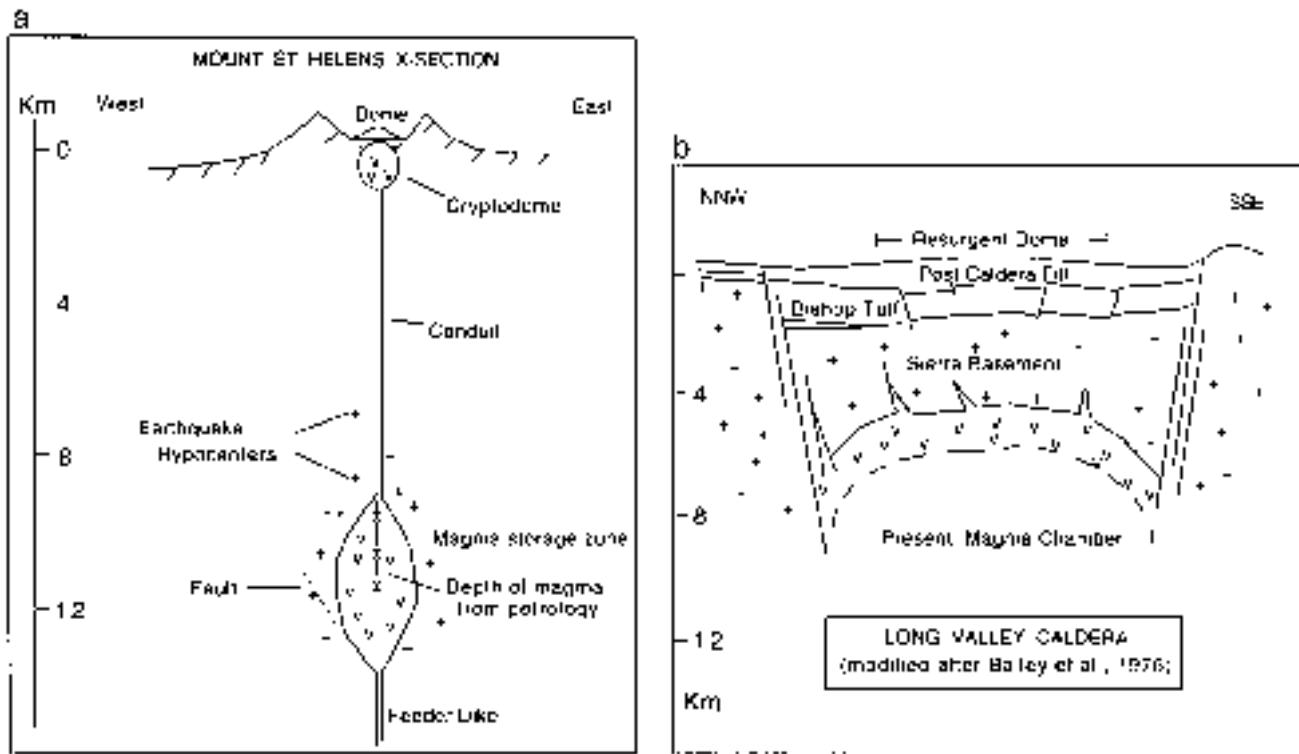

FIGURE 1 (a) A vertical cross section through Mount St. Helens showing the magma storage zone delineated by surrounding seismic activity and determined to be at this depth by the phenocryst-melt phase equilibria. [Modified from Rutherford and Hill, 1993.] (b) Vertical cross section through Long Valley, California, caldera showing the collapse and fill resulting from the eruption of the Bishop Tuff about 700,000 yr ago. The magma chamber depth is indicated by studies that pinpoint the source of resurgent doming, by seismic activity generated around it, and by petrological study of post-Bishop Tuff eruptions. [Modified from Bailey *et al.*, 1976.]

the United States, also originated from well-established crustal reservoirs as indicated by the calderas (Fig. 1b) produced during these eruptions.

Eruption from a crustal reservoir has also generally been the case for basaltic volcanoes such as in Hawaii, Iceland, Etna, and the Canary Islands. For eruptions of basaltic magma at midocean ridges, a magma storage region near the crust-mantle boundary is generally indicated by available seismic evidence. However, it is also proposed that some magmas, specifically kimberlites, and more mafic magmas erupting in midplate oceanic islands and in some island arcs, ascended directly from the mantle without encountering a crustal storage region. In such cases, the magma ascent rate would refer to the time between separation of magma from its source in the Earth's mantle and its arrival at the surface. However, most of the magma ascent rate estimates are for volcanic centers where there is strong evidence of a crustal-level magma storage zone, and the ascent rate is for magma transport from this reservoir to the surface.

### III. BUBBLE FORMATION AND EVOLUTION DURING MAGMA ASCENT

When magma rises from its storage zone, volatiles dissolved in the melt will tend to exsolve and form bubbles because of their lower solubilities in melt at lower pressures. What is the rate of this process, and can measurements of the amount of exsolution be used to estimate the rates of magma ascent? Analyses of volcanic glasses in both explosively erupted and extrusively erupted samples illustrate that most of the water originally in the melt at depth has been lost to the gas phase during ascent. In other words, even for the relatively rapid ascent involved in explosive eruptions of a volatile-rich magma, there appears to have been sufficient time during ascent for most H<sub>2</sub>O to escape from the melt. Other volatile species that have an affinity for the gas phase include CO<sub>2</sub>, SO<sub>2</sub>, and Cl, based on their common occurrence in volcanic gas emissions. The available diffusion data for silicate melts suggest that these species

diffuse at somewhat slower rates than water. Thus, analytical data on the abundance of the different volatile species lost from the melt to the gas phase during an eruption may record the rate of magma ascent, although the rapid diffusion of H<sub>2</sub>O may mean that it is nearly all transferred to the gas phase in most eruptions. Experiments indicate that the loss of water from melt into gas bubbles during decompression (ascent) of a rhyolitic melt is very rapid. At pressure drops of 0.025 MPa/s (1 bar per 4 seconds) water is able to diffuse out of the melt and into the bubbles rapidly enough to maintain equilibrium. At faster decompression rates of 0.25 and 1.0 MPa/s, water diffused too slowly to maintain equilibrium and the melts became supersaturated with water. These experiments indicate that a transition occurs between 0.025 and 0.25 MPa/s decompression rates, beyond which gas bubble-melt equilibria cannot be maintained. Given typical magma densities, these decompression rates equal ascent velocities of 0.7 and 5 m/s, rates much faster than are typically inferred for effusive lava and dome eruptions.

In the high-silica rhyolite (77 wt% SiO<sub>2</sub>) decompression experiments, the 825°C temperature results in a magma that is relatively viscous, so water diffusion is relatively slow. In less viscous basaltic magmas, water diffusion will be faster because of the lower SiO<sub>2</sub> contents and the higher temperatures (typically 1100–1200°C). Numerical modeling of bubble growth in basaltic magmas suggests that for reasonable ascent rates, water diffusion and bubble growth are rapid enough to always maintain equilibrium between bubbles and melt. This includes ascent rates up to 100 m/s.

The earlier discussion focused on degassing of water, which is probably the fastest diffusing volatile species in melts. In contrast, the diffusivity of S and Cl in rhyolitic melts is tens to hundreds of times slower than water at a given temperature. If magma ascends during explosive eruptions at rates controlled by water exsolution (the maximum at which water and melt can maintain equilibrium), then it would be expected that slower diffusing gas species would not maintain equilibrium. Indeed, this appears to be the case, because matrix glasses in volcanic pumices typically contain much if not all of the pre-erupted contents of S and Cl. For example, the pre-eruptive concentrations of H<sub>2</sub>O and Cl in the Pinatubo magma are about 6.4 wt% and 1200 ppm, respectively, whereas their final concentrations dissolved in matrix glasses are about 0.4 wt% and 880 ppm. Degassing of Cl and S is complicated, however, because the partitioning of Cl and S between the melt and a water-rich gas phase varies strongly as a function of water content, pressure, melt composition, and tempera-

ture. This is a research area where additional study may be very productive in understanding magma ascent during volcanic eruptions.

An important implication of the findings is that water is able to diffuse out of silicate melts very rapidly during magma ascent. This is important because several of the processes described later are driven by water degassing during ascent. Hence, the rates at which those reactions occur are not constrained by the exsolution of water from the melt, but by their own reaction kinetics.

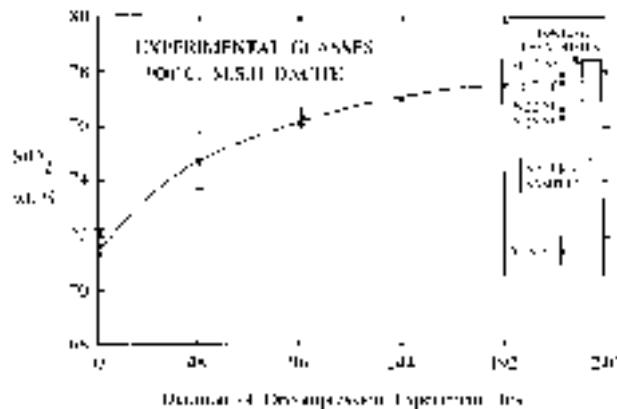

---

#### IV. GROUNDMASS CRYSTALLIZATION DURING MAGMA ASCENT

The degassing of the melt in ascending magma discussed in the previous section causes gas bubbles to form, but also transforms the melt into a variably crystallized groundmass. Groundmass crystals are readily identified by their small grain size relative to large (mm to cm) phenocrysts; they replace the bubble-rich glass that makes up the groundmass in more rapidly erupted magma. Although driven by the loss of volatiles from the melt, the crystallization of the groundmass melt does not necessarily occur at the same rate. For example, while the exsolution of water from a decompressing melt follows equilibrium solubility for decompression rates of <0.25 MPa/s (magma ascent rates less than 5 m/s), a rhyolitic glass crystallizes much more slowly. The rate of crystallization will also differ for different melt compositions, being slower for more silica-rich melts at a given water concentration.

A study of groundmass glass crystallization in the eruption products of the 1980–1986 Mount St. Helens eruption products illustrates what can be done using the extent of groundmass crystallization to estimate magma ascent rates. Earlier work established that all of the erupted magmas came from a storage region at 8- to 11-km depth, and also established that the depth, temperature, and water content of the magma in that storage zone did not change over the time of these eruptions. In addition, the similarity of phenocryst and groundmass mineral compositions (Fe-Ti oxides) in these samples indicates that there was essentially no change in the temperature of any of these magmas during ascent. It can be concluded that differences observed in the groundmass crystallinity of these samples are the result of different ascent rates.

Data on the extent of groundmass crystallization in natural samples can be compared with the results of

**FIGURE 2** Evolution of matrix glass in Mount St. Helens dacite as a function of the duration of the decompression from 220 to 2 MPa compared to natural glasses in different 1980–1986 natural dacites. Crystallization caused by the water loss during decompression produces the melt composition change [From Geschwind and Rutherford, 1995.]

experiments carried out at different decompression rates. The experiments performed on the Mount St. Helens dacitic magma demonstrate that nucleation and growth of microlites in the melt phase is detectable after a 1-day decompression from 220 to 2 MPa, and is essentially complete in a decompression taking 8 days, as measured by the change in melt (glass) composition (Fig. 2). Using the composition of the remaining matrix glass in the experimental and natural samples as an indicator of approach to complete crystallization, average magma ascent rates have been obtained that range from  $>0.2$  m/s for the 1980 explosive plinian event to 0.01–0.02 m/s for the different dome-forming eruptions of 1980–1986 (Fig. 2). Nucleation is unlikely to have been a factor affecting groundmass crystal development in either the natural system or the experiments because the Mount St. Helens magma was crystal rich prior to ascent. A similar study of a crystal-poor magma might show that growth of microlites from the groundmass melt takes much longer when phenocrysts are not present to serve as nucleation sites.

## V. PHENOCRYST-MELT REACTIONS DURING MAGMA ASCENT

Another reaction driven by the loss of volatiles from the melt as magma rises toward the surface is the decomposition of volatile-bearing phenocrysts, such as hornblende

and biotite. Sulfur is also lost from the melt during magma ascent, and thus anhydrite, which occurs in some volcanic rocks, would also tend to similarly break down. Most of these reactions are controlled by the kinetics of the reaction between the phenocrysts and melts involved. These rates have generally not been determined because they are complex functions of many variables, including mineral and glass compositions, melt viscosity, and temperature. However, there are data on the rates of reaction between hornblende phenocrysts and the coexisting rhyolitic melt in the magma recently erupted at Mount St. Helens.

The 1980–1986 eruption of Mount St. Helens began with an edifice collapse that triggered both a lateral blast and a vertical, plinian-style eruption. They produced the blast dacite and dacitic pumice deposits, respectively. Several smaller, vertically directed explosions during the next several months produced less voluminous pumice deposits, but in October 1980 magma began to extrude as a dome-forming lava in the newly formed crater, and this dome continued to grow until 1986. The bulk composition of the magma did not change throughout the entire series of eruptions. Sample studies show no detectable reaction between the hornblende phenocrysts and the groundmass glass (melt) in the May 18, 1980, pumice samples, even though the melt clearly lost all but about 0.3 wt% of the ~4.6 wt% dissolved water it contained before erupting. In all subsequently erupted samples, however, the hornblende phenocrysts have reaction rims at the contact of the crystal with the groundmass melt (Fig. 3). Each post-May 18 sample had a main population of hornblende phenocrysts (30–100 vol% of the crystals present) with uniform thickness (0- to 50- $\mu\text{m}$  range) reaction rims, and a second group with rims ranging to greater thicknesses. These are interpreted to represent, respectively, a main batch of magma that ascended directly from the storage region at 8–11 km beneath the surface, and magma left behind in the conduit from previous eruptions.

Constant-decompression-rate experiments carried out at magmatic temperatures with water contents equal to those in the magma serve to calibrate the time necessary to form the reaction rims observed. Experiments that simulated ascent from 8-km depth to the surface in less than 4 days showed no reaction rims on hornblende crystals, 2- $\mu\text{m}$ -wide rims were produced in 7-day ascents, and 32- $\mu\text{m}$  rims formed in 20 days. Using this calibration (Fig. 4), the magma ascent rates during the lava dome phase of the Mount St. Helens eruption varied from as low as 0.004 m/s up to 0.015 m/s. This is in contrast with the 2–3 m/s at which the magma ascended during the May 18, 1980, plinian phase of the eruption.

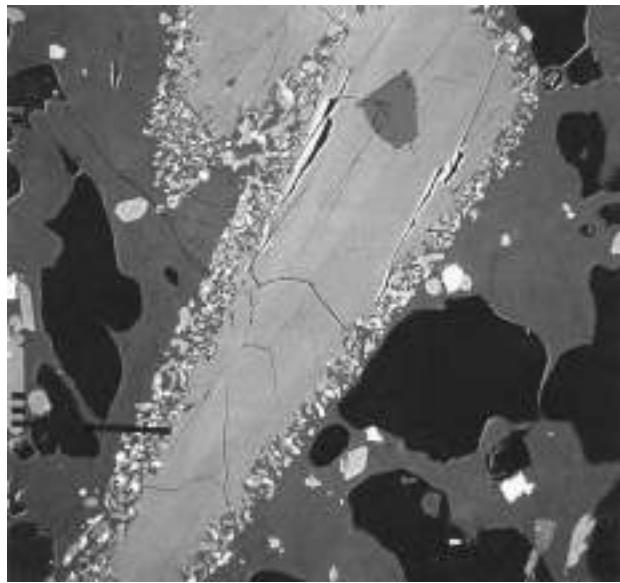

FIGURE 3 Backscatter electron photomicrograph of a hornblende phenocryst in a Mount St. Helens 1981 lava dome sample showing a 20- $\mu\text{m}$ -thick reaction rim at the phenocryst-melt contact. [Courtesy of the American Geophysical Union.]

An application of hornblende reaction rim data can also be made to the hornblende-bearing magmas recently erupted at Soufrière Hills on the island of Montserrat in the Lesser Antilles. Magma first reached the surface in October 1995, following several months of steam eruptions and elevated seismic activity. A lava dome gradually grew at the site, slowly filling an old crater. This dome-forming lava appears to have come from a magma storage region at 5- to 6-km depth (130 MPa). The temperature of the pre-eruption magma was 830°C, although the magma was clearly heated to ~850–900°C prior to erupting. More importantly, however, reaction rims on hornblende crystals adjacent to groundmass melt show significant changes in samples collected during the next 2 years. These changes are not the result of changes in the magma storage region; they formed during magma ascent. The first magma erupted contains hornblendes with 120- $\mu\text{m}$ -thick rims. The magma that erupted 2 months later, in February 1996, has only 18- $\mu\text{m}$ -thick rims, and the rims were only 10  $\mu\text{m}$  wide in an April 1996 eruption. Most hornblendes in magma erupted in July through September 1996 contain no reaction rims.

Using the previously mentioned experimental calibration of rim width versus time, absolute ascent rates and ascent rate changes can be calculated for the Montserrat eruption (Fig. 5). The magma ascent rate increased from

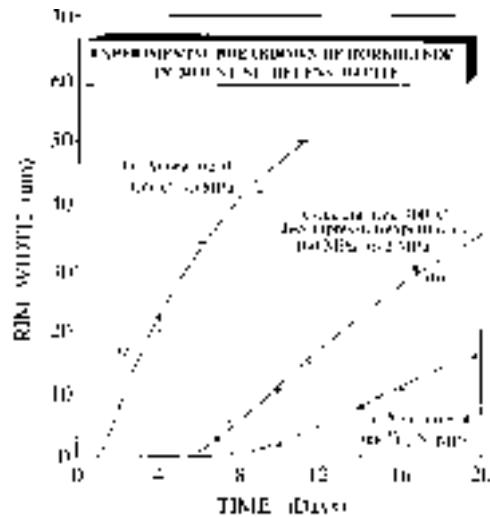

FIGURE 4 (a) Experimental determination of hornblende reaction-rim width as a function of time in a water-rich magma. [After Rutherford and Hill, 1993.] (b) Constant-rate decompression from 160 to 2 MPa. (c) Decompression from 220 to 2 MPa. Curves (a) and (c) are for a constant  $P$  and  $T$  anneal at 900°C and 90 and 20 MPa, respectively.

0.001 to 0.012 m/s during the first 300 days of this eruption. Interestingly, the mass extrusion rate increased over this same time period (Fig. 5). The ascent rate data show that this increase in extrusion rate was not produced simply by an increase in the size of the conduit. The other important observation is the association of numerous explosive eruptions from the summit of the dome with periods of high magma ascent rate.

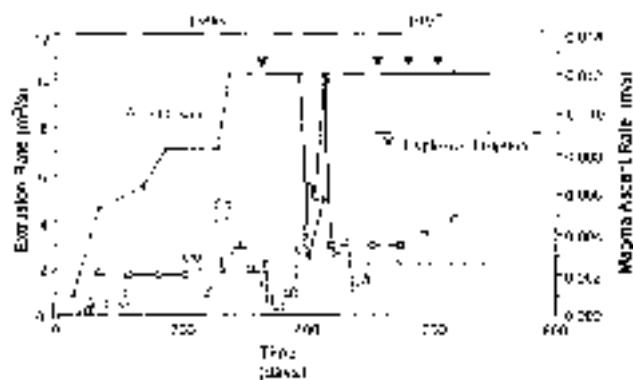

FIGURE 5 Magma ascent rate from hornblende reaction rim thickness and experimental calibration as a function of time for the 1996–1997 eruption at Soufrière Hills on Montserrat. Also shown are the changes in the magma extrusion rate. [From Rutherford et al., 1998.]

These explosions indicate times of less efficient separation of gas and magma, a logical consequence of higher magma ascent rates.

---

## VI. MAGMA ASCENT RATES CALCULATED FROM MASS ERUPTION RATES

Measurements of the mass eruption rate of magma can be used to calculate conduit diameter and ascent velocity if certain assumptions are made about an eruption. This technique is illustrated by an application to the May 18, 1980, plinian eruption of Mount St. Helens. Magma flowing through a conduit below the depth where it is saturated with a gas phase can be described as a one-phase, laminar flow of an essentially Newtonian fluid. In this case, magma ascent in the conduit can be modeled by the Hagen-Poiseuille law

$$M = (\Delta P / \Delta L) * (\pi \rho_F r^4) / 8 \eta,$$

where  $M$  is mass flux (in kg/s),  $\Delta P / \Delta L$  is the pressure gradient driving the flow,  $\rho_F$  is the fluid (magma) density,  $\eta$  is fluid viscosity, and  $r$  is conduit radius. Exsolution of a vapor phase changes the bulk density and viscosity of the magma and thus affects flow conditions, but exsolution is slow at first and does not significantly affect the flow until the magma is within a kilometer of the surface. We make a calculation for depths greater than 1 km, assuming that the driving force for flow is due to the density difference between the surrounding rocks and the magma. For quantitative applications of the Hagen-Poiseuille law, numerical values for the magma mass flux, density, and viscosity of Mount St. Helens magmas are needed. Using recently revised data for these parameters, and assuming the conduit radius remains constant at depth, the conduit radius during the explosive 1980 eruption of Mount St. Helens is calculated to be 33 m. For the late 1980 and subsequent eruptions, the calculated radius decreases to 7 m and remains essentially constant.

Ascent velocities for the Mount St. Helens eruptions can be calculated from the relationship expressing conservation of mass,  $M = \Pi r^2 \rho_F u$ , where  $u$  is the velocity. Given the conduit radii calculated earlier, conservation of mass requires ascent velocity to have decreased from 2 to 3 m/s on May 18, 1980, to 0.08 m/s (290 m/hour) in October 1980. The latter velocity leads to an ascent time of 30 hours from a depth of 8.5 km, which is less than the approximately 4 days indicated by the petrolog-

ical methods above for the dome-forming eruptions. Exsolution of a vapor phase and crystallization of micro-lites lead to increases in magma viscosity as the eruption progresses, however, which decreases the magma velocity in the upper parts of the conduit. This may explain the differences between the calculated velocity and the velocity derived from hornblende breakdown. A near-surface decrease in ascent velocity is consistent with modeling of surface deformation, which indicates a velocity of only 0.014–0.028 m/s for magma ascent near the surface during the dome eruptions of 1981 and 1982.

---

## VII. SEISMIC EVIDENCE FOR MAGMA MOVEMENTS

Earthquakes are commonly associated with volcanic eruptions and volcano unrest and have been effectively used for monitoring and forecasting eruptions. Volcanic earthquakes generally occur in four main types: high- and low-frequency earthquakes, explosion earthquakes, and tremor. The direct association of earthquakes with magma migration can be ambiguous, however, because earthquake generation requires stressed and brittle rock, and so aseismic regions may be unstressed and unfractured or hot and ductile. On the other hand, pressurized magma may generate earthquakes in brittle rock adjacent to magma conduits. Hence, magma zones may be either seismic or aseismic.

One case of an unambiguous association of earthquakes and magma movement occurred during the September 1977 deflation of Krafla Volcano in Iceland. Earthquakes began under the central volcano, at the same time that the volcano began to deflate, and then migrated along the adjacent rift zone. When the hypocenters of this migrating tremor passed a geothermal bore hole, fresh basaltic pumice erupted from the hole. The tremor hypocenters migrated along the rift system at a rate of about 0.5 m/s.

Migration of tremor hypocenters like that at Krafla Volcano has also been observed in the East and Southwest Rift Zones of Kilauea Volcano, Hawaii. These swarms also define the motions of magma in the rift systems, as many of them are related to the eruption of basaltic magma. The rates of down-rift swarm movement span a range of about 0.005–8.5 m/s, and are similar regardless of whether magma simply intruded into the rift or eventually erupted. In a few cases, upward movement of earthquake swarms in the rift is also identi-

fied, with rates on the order of 0.03–1.7 m/s. Interestingly, this upward migration tends to slow as the magma approaches the surface.

Although it is expected that earthquake hypocenters should migrate as magma migrates beneath volcanoes, as in the earlier-described cases of Krafla and Hawaii, there are surprisingly few documented cases of such trends. A magma ascent velocity of 0.6–0.7 m/s is estimated for the explosive May 18, 1980, eruption of Mount St. Helens based on the arrival time of new magma at the surface as detected initially by a change in the seismic signals adjacent to the 8- to 11-km-deep storage zone. For a time later in the Mount St. Helens eruption, seismic signals at depth and the following onset of an eruption at the surface indicate an ascent velocity of 0.007–0.01 m/s, essentially identical to estimates from hornblende reaction rims. Preceding the 1991 eruption of Unzen Volcano, Japan, earthquakes migrated from a depth of 10 km to about 3 km beneath the volcano, possibly indicating magma movement toward the surface. Magma ascent during the final kilometer is estimated to have been at 0.007–0.3 m/s.

### VIII. XENOLITH TRANSPORT AND MAGMA ASCENT RATES

Some basaltic magmas are extruded on the Earth's surface carrying pieces of the mantle, called *mantle xenoliths*. These xenoliths make it possible to estimate how rapidly these magmas ascended from depth to the surface, because the upward flow of magma must exceed the settling velocity of the xenoliths. Two magma types, alkali basalt and kimberlite, commonly carry such mantle xenoliths. Both originate by small degrees of partial melting in the upper mantle near the base of the lithosphere. Interestingly, tholeiitic basalt magma, which originates by higher degrees of partial melting in the upper mantle, almost never carries mantle xenoliths. One possible explanation is that tholeiitic basalt eruptions are commonly staged from magma reservoirs within or at the base of the crust, and any mantle xenoliths may settle out in these reservoirs. Such magma reservoirs have been documented for tholeiitic eruptions on Iceland, Hawaii, and at most midocean ridge sites studied in detail.

The common occurrence of dense mantle xenoliths in tephra and lava flow eruptions of alkali basalt indicates that this magma carried them from depth. An average

settling rate for xenoliths of different sizes can be calculated by balancing the different forces on the xenoliths during ascent, and by making certain assumptions about the rheologic properties of the magma. Figure 6 shows the results of settling calculations for spherical xenoliths, a density difference of 500 kg/m<sup>3</sup> between the xenoliths and the melt (melt density = 2800 kg/m<sup>3</sup>), and an assumption of Bingham plastic rheology for the xenolith-laden magma.

As a Bingham fluid, the magma has a yield strength that correlates well with the apparent viscosity. A yield strength of 100 N/m<sup>2</sup> corresponds to a phenocryst content of ~25 vol% in a basalt. The calculation (Fig. 6) indicates that a 20-cm-wide xenolith will settle at a rate of 0.1 m/s. Obviously, the magma ascent rate would have to be greater in order to carry the xenolith to the surface; the xenolith settling velocity gives a minimum estimate of magma ascent rate. Published minimum estimates for alkali basalt ascent rates range from 2 to 10 m/s.

Two factors that have not been considered in this calculation are the effect of nearby xenoliths and the effect of bubbles in the magma. If significant, both of these would decrease the settling rate of xenoliths, and therefore reduce the minimum ascent rate required to carry a xenolith of a given size to the surface. Based on the relative abundance of vesicles and xenoliths in alkali basalt, however, it is possible that neither has a significant effect on calculated ascent rates.

Kimberlites, the other mantle xenolith-bearing magma, are known to be very gas-rich and also com-

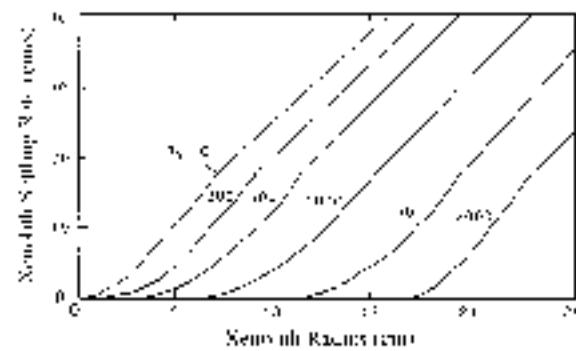

FIGURE 6 Calculated xenolith settling velocity as a function of xenolith radius for different magma yield strengths. A density difference of 500 kg/m<sup>3</sup> is assumed between the xenolith and the melt; the melt density is 2800 kg/m<sup>3</sup>, and a Bingham rheology (viscosity 350 poise) is assumed. Units of yield strength are N/m<sup>2</sup>, and yield strength of 1000 N/m<sup>2</sup> is approximately equal to a crystallinity of 25%. [From Spera, 1984.]

monly have high phenocryst and/or xenolith contents. Thus, the magma ascent rates estimated for kimberlitic volcanism from xenolith settling velocities (10–100 m/s at 1-km depth) may be somewhat high; estimates from phenocryst-melt reactions range from 10 to 30 m/s for kimberlites.

#### IX. MAGMA ASCENT RATES BASED ON XENOLITH-MAGMA REACTIONS

Some magmas erupt at the surface carrying inclusions of rock or a second, variably crystallized, magma with clear textural and compositional evidence to indicate that the inclusion is not in equilibrium with the host magma. The extent of reaction that takes place at the magma-inclusion contact can be used, along with available kinetic data, to estimate the rate of magma ascent. To make this estimate, the depth at which the inclusion was incorporated into the magma must be determined, and the ascent must have been essentially isothermal. This section describes an eruption where these determinations can be made.

Alkali basalt laden with inclusions of peridotite has erupted both historically (six eruptions in the past 500 yr) and prehistorically on La Palma in the Canary Islands. The inclusions are spinel-bearing peridotites, ranging up to 15 cm in diameter, and they are almost always encased by a crystalline selvage zone (<1 mm thick) of titanium-rich augite, hornblende, and magnetite. The selvage minerals are fine grained at the inclusion contact, and coarsen toward the host magma. Fluid inclusions in recrystallized grains and in the selvage minerals are essentially pure CO<sub>2</sub>, and their densities indicate that the selvage minerals and recrystallized grains in the peridotite grew at pressures of 200–400 MPa, which is equivalent to a depth of 7–15 km.

Olivine crystals in the peridotite adjacent to the selvage zone have developed diffusion zones that are 0.9–2.6 mm wide as a result of reaction with the magma (Fig. 7). This diffusion zone is interpreted to have developed in olivine at the xenolith margins while the magma was stored in a deep (7–15 km) crustal reservoir. Using recent diffusion data for Fe and Mg in olivine for a magma temperature of 1200°C, the measured diffusion zone thicknesses yield development times of 8–110 yr. These times are interpreted as indicating the length of time the inclusions spent in the crustal magma storage zone.

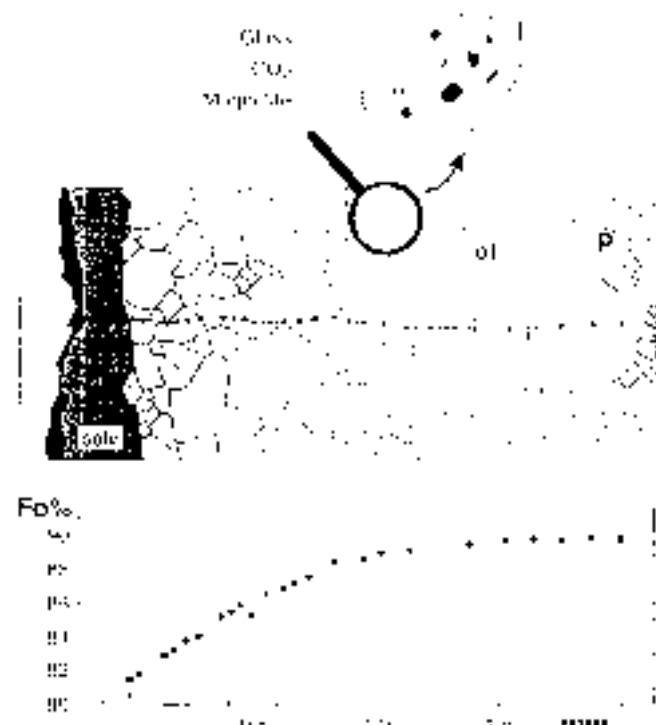

FIGURE 7 Drawing of a contact between an olivine-rich xenolith and basalt with a thin selvage zone at the boundary typical of such occurrences in the La Palma lavas (Canary Islands). Lower panel shows the zoning profile (Fo% is equal to the mole % Mg) in the Fe-Mg olivine. Time to create this type of zonation is calculated to be 8–100 yr for profiles ranging from 0.9 to 2.2 mm long. [After Klugel, 1998.]

Interestingly, some of the fractures and surfaces in the xenoliths in the Canary Island samples have no selvage zones. The diffusion zones in olivine adjacent to the melt along these surfaces are 0–0.02 mm wide. The fractures with no selvage zone are interpreted to have formed by a fracturing event at the time of the final eruption. The times calculated for development of the thin diffusion zones range from 0 to 4 days. If it is correct to assume the surfaces formed when the magma began to ascend, then average ascent rates of greater than 0.06 m/s are calculated for the movement of this alkali basalt from 11 km to the surface. This is in the same general range as the >0.2 m/s magma ascent rates calculated to carry the xenoliths to the surface in this magma. The lack of diffusion rims of intermediate thickness on olivine in the xenoliths is interpreted to mean that the xenolith-bearing magma was stored in the lower crust and was not affected by a fracture-producing event in the 8- to 110-yr period before the eruption began.

---

### X. U-TH DISEQUILIBRIUM DATING CONSTRAINTS ON MAGMA ASCENT RATE

The study of magma dynamics and magma ascent in volcanic systems is theoretically possible using U and Th isotopic series disequilibrium. The possibility is best illustrated by an example where magma leaves the source region at depth, and there is a fractionation of U and Th in the melting process. Equilibrium is generally assumed for the short-lived isotopes of the decay series in the source region. Such isotopes would include  $^{226}\text{Ra}$ ,  $^{210}\text{Pb}$ ,  $^{228}\text{Ra}$ , and  $^{228}\text{Th}$  with half-lives of 1600, 22, 5.77, and 1.9 yr, respectively. With melt separation following U-Th fractionation during melt formation, the ( $^{230}\text{Th}$ - $^{226}\text{Ra}$ ) and ( $^{232}\text{Th}$ - $^{228}\text{Ra}$ ) ratios will reach equilibrium after about 8000 and 30 yr (~5 half-lives), respectively. If magma reaches the surface with a  $^{226}\text{Ra}/^{230}\text{Th} = 1.0$  and a ( $^{228}\text{Ra}/^{232}\text{Th}$ ) other than 1.0, it can be concluded that the fractionation took place between 8000 and 30 years before erupting. If both ratios are out of equilibrium, it means that the fractionation occurred <30 yr earlier.

To make use of disequilibrium dating in estimating magma ascent rates, some knowledge of U-Th fractionation is required. Where and when did it occur, and were there secondary perturbations? Obviously, if a fractionation occurred during magma genesis in the upper mantle and the magma produced moved to a mid-crustal storage region for some period of time before eruption, the time evolved according to the disequilibrium detected includes more than just the time of ascent.

Data for the Mount St. Helens 1980 eruption products illustrate the nature of the problem as well as the potential of the disequilibrium dating method. All samples analyzed contain an excess of  $^{226}\text{Ra}$  over  $^{230}\text{Th}$ , but none contains an excess of  $^{228}\text{Ra}$ . This implies a magma formation event more than 30 and less than 10,000 yr before the eruption. Indications of an excess of  $^{210}\text{Pb}$  over  $^{226}\text{Ra}$  indicate that magma formed between 30 and 150 yr before the eruption. Obviously, the magma was not continuously ascending during this entire period because, as mentioned earlier, there is good evidence that the 1980–1986 eruption initiated from a magma storage zone at 8- to 11-km depth. In such a situation, the ascent rate derived from the disequilibrium data is a minimum rate unless there is reason to believe the U-Th fractionation occurred in the crustal magma chamber, which in this case there is not.

To make better use of disequilibrium dating in estimating magma ascent rates, the focus needs to be on elemental fractionations that occur in the magma storage region or as magma begins to ascend; that is, a fractionation initiated by crystallization or degassing. It does appear possible to use disequilibrium dating to make estimates of the time evolved from mantle separation to eruption for midocean ridge basalts. Again, however, the interpretation of these data is complicated by uncertainties as to when and where the magma actually separated from the residual mantle, and by possible mixing processes and storage time which might have occurred during magma ascent.

---

### XI. SUMMARY OF MAGMA ASCENT RATE ESTIMATES

The estimates of average magma ascent rates for silicic to intermediate composition lava extrusions are fairly well constrained in the range of 0.001 m/s for very slowly ascending magmas, to 0.015 m/s for more rapidly ascending extrusive magmas (Table I). These estimates come from a variety of observations made at different volcanoes, and it is important to remember that they are average rates. Ascent surely must vary over the vertical extent of the conduit carrying the magma, because the density and viscosity of the magma vary considerably over this length, particularly in water-rich magmas. One topic for future study is the nature of changes in flow within volcanic conduits. It is rather interesting that observations made for basaltic composition magma extrusions give essentially the same range of average ascent rates as those obtained for more silica-rich magmas.

The assessment of magma ascent rates during explosive eruptions is more complex because there is almost certainly a much greater variation in the ascent rate from the base of the conduit to the surface. The magma leaves the top of the conduit at essentially sonic velocities for truly explosive eruptions. This high rate of ascent is achieved as a result of the low density and rapid expansion of the gas phase in these gas-rich magmas. Deep in the conduit, little of the gas is exsolved, the magma is more dense, and depending on the size and shape of the conduit, flow rates are much lower.

In our view, some of the more profitable areas for study of magma ascent lie with investigations of the behavior of the various magmatic volatiles, the rates of

TABLE I Magma Ascent Rate Estimates from Different Observations<sup>a</sup>

Volcano	Observation	Explosive ascent rate (m/s)	Extrusive ascent rate (m/s)
Mount St. Helens	Groundmass crystallization (IV)	≥0.2	0.01–0.02
Mount St. Helens	Hornblende rims (V)	>0.18	0.04–0.15
Mount St. Helens	Calculation from mass eruption rate (VI)	1–2	0.01–0.1
Mount St. Helens	Seismicity Movement	0.6	0.007–0.01
Soufrière Hills	Hornblende rims (V)	>0.2	0.001–0.012
Mount Unzen	Magnetite zonation	Not present	0.002
Hualali, Hawaii	Xenolith transport (VIII)	Not present	>0.01
La Palma, Canary Is.	Olivine zonation (IX)	Not present	>0.06

<sup>a</sup> Observations are numbered according to section of paper in which they are discussed.

their diffusion in melts, the properties of the different composition gases, and the processes by which gas is lost from magmas during ascent.

## GLOSSARY

**andesite** Volcanic rock with 53–63% silica content ( $\text{SiO}_2$ ) having a viscosity when molten that is typically intermediate to that of basalt and rhyolite.

**basalt** Volcanic rock with 44–50% silica content that in conjunction with typically higher flow temperatures results in relatively fluid magmas.

**Brinkman number** A dimensionless ratio giving the relative importance of the rate of heat production produced by viscous heating to the rate of heat loss by conduction of heat to cooler boundaries.

**caldera** Crater or surface depression resulting from collapse of an underlying magma chamber roof during withdrawal of magma.

**coextrusion** Process of simultaneously forcing two or more distinct magmas to flow in magmatic plumbing.

**conduit** A pipelike pathway for the transport of magma

that evolves by preferential channeling (process involving both melting and solidification) of flow within a dike.

**contact** Boundary or surface separating hot magma from cooler host rock.

**dike** A vertically oriented, sheetlike magmatic pathway formed by injection of magma into a thin fracture that fills and propagates within the brittle crust of the Earth.

**exsolution** The transition of a volatile component (e.g.,  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ) from solution in a magma to a gas phase. The formation of a gas phase results in significant driving forces for magmatic transport.

**lava** Molten rock expelled at the Earth's surface by volcanic processes.

**lithostatic** Change in static pressure with depth or pressure gradient associated with the overburden of crustal rock. Lithostatic pressures for a given thickness of crustal rock are approximately 2.5–3 times greater than pressures encountered in a layer of water having the same thickness.

**magma** A mantle- or crust-derived, physically and chemically complex mixture of molten rock, solids (e.g., crystalline or refractory fragments), and gases (e.g.,  $\text{CO}_2$  or  $\text{H}_2\text{O}$ ).

**magmastic** Change in static pressure with depth change in a fracture or reservoir filled with magma. Because magma densities are similar to crustal rock densities, lithostatic and magmastic densities are also comparable.

**phenocryst** One of the larger, more distinct crystals in a rock with an otherwise fine-grained texture.

**Reynolds number** A dimensionless quantity characterizing the relative importance of inertial or momentum related forces to viscous forces in fluid flow. In magmas viscous forces usually dominate, resulting in a Reynolds number that is much less than 1.

**rheology** The study of the deformation and flow of fluids.

**rhyolite** Volcanic rock with more than 68% silica having exceptionally sluggish flow characteristics owing to its high silica content and typically lower emplacement temperatures.

**seismicity** The detectable seismic activity that is associated here with the transport of magma.

**silicic** Having or being characterized by a high silica content.

**subliquidus** State of magma in which crystalline solids exist in an otherwise liquid regime. This state is associated with higher viscosities than magmas that are purely liquid (liquidus).

**thermal diffusivity** A quantity characterizing the ability of a material to allow heat to be transported by conduction (thermal diffusion) alone. The diffusivity is the ratio of the thermal conductivity to the product of the material density and the specific heat.

**viscosity** The resistance of a fluid to flowing in response to applied pressure forces. The higher the viscosity, the more resistant a fluid is to flowing.

**volatiles** A compound such as CO<sub>2</sub> and H<sub>2</sub>O that can exist as a gas at magmatic temperatures and pressures characteristic of the shallow crust. The exsolution of volatiles results in the existence of a gas phase that is important for driving the transport of magma.

**xenolith** A piece of mantle or crustal rock picked up by flowing magma.

depth at different locations on the Earth. Magma-induced fracturing permits magma to flow between different crustal locations (e.g., between a magma chamber and a sill or dike), and occasionally these pathways intersect the Earth's surface, causing eruption of lava in a spectacular event. In this chapter we consider those physical processes that permit this remarkable phenomenon involving the transport of viscous, molten rock across many kilometers of much cooler crust in thin fractures that promote solidification.

## I. THERMAL AND DYNAMIC ASPECTS OF DIKE FORMATION IN THE COOL CRUST

Volcanic dikes or sheetlike intrusions result when pressurized magma is forced into and along a crack, causing the propagation of a fracture. Dikes may be propagated more effectively if hot gases from the magma fill the advancing crack tip. It is possible that a pressurized gas pocket at the top of a magma chamber might prevent magma from flowing into a long crack that is being propagated upward by the gas (Fig. 1). Because of the low viscosity and low density of the vapor or gas, any gas or vapor propagated fracturing that results would not be subject to pressure losses associated with either the high viscosity of magma or the weight of the high-density magma column. This latter effect involving the weight of magma in a fracture decreases the pressure that can be transmitted to a crack tip by about 280 atm for every kilometer of fracture height. Of course, for gas pressure to be adequate to drive fracturing, the lid of the magma reservoir must not allow gas to bleed off faster than it can be produced in or channeled to the reservoir from greater depth. We know that some shallow reservoirs may be quite permeable to gas flow as indicated by losses of several hundred metric tons of sulfur dioxide (SO<sub>2</sub>) per day from the central pit crater, Halemaumau, which lies directly over the magma reservoir of Kilauea volcano on the island of Hawaii. Gas or vapor propagated fracturing can still be significant in such a leaky system whenever gas is produced faster than it is lost. This may occur when a fresh, volatile-rich supply of magma arrives at a chamber and pressure and temperature conditions are appropriate for exsolution of a separate gas phase.

Thin sheetlike fractures serve only as temporary pathways for magma as it traverses the cooler crust. This is because flow in dikes will become localized into channels

**T**HE ERUPTION OF a volcano signals the rather rare and successful arrival of very hot magma, which is prone to solidification as it traverses the comparatively cool crust of the Earth. Besides the negative impact of lower crustal temperatures on the probability of reaching the surface, magmas may not be transported by the most direct route. A magma may start its journey by being squeezed from a zone of melt as a result of the formation of pressure imbalances caused by density differences between the melt and surrounding crust. At this early stage of the magmatic journey, flow is likely to be by plastic deformation of the mantle or deeper crust to make way for the invading magma. However, at shallower levels, the cooler crust makes a transition from plastic deformation to fracturing in response to the intrusion of magma. Such a transition varies with

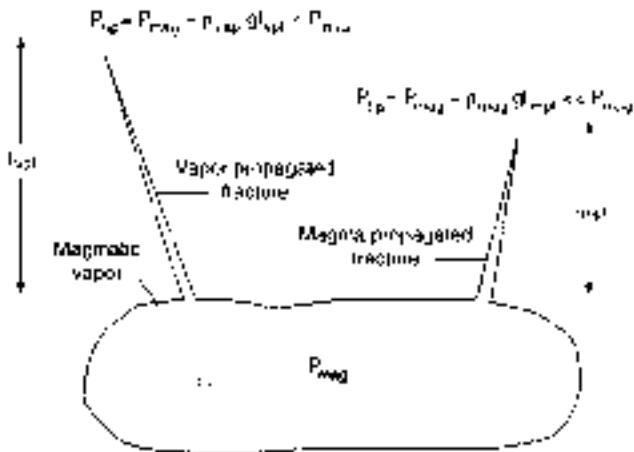

FIGURE 1 Sketch of fracture propagation by vapor and by magma. Presence of a vapor layer at the top of a magma chamber prevents flow of magma in a propagating fracture. Only vapor or gas can flow into the fracture in this case. Low viscosity of vapor permits it to more effectively penetrate the crack tip and process zone. Small vapor density,  $\rho_{\text{vap}}$ , minimizes pressure losses owing to the weight of vertical column of vapor. Thus, the pressure at the crack tip,  $P_{\text{tip}}$ , is almost equal to the magmatic pressure  $P_{\text{mag}}$  in the chamber even if vertical distance of fracture  $l_{\text{vfp}}$  approaches several kilometers. By comparison, the weight of more dense magma  $\rho_{\text{mag}}g l_{\text{mfp}}$  in magma propagated fracture will substantially reduce pressure that can be applied to the crack tip. [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

and cease within a few hours owing to solidification unless further breakup or melting and removal of crustal wallrock occurs to produce centralized vents or conduits with enhanced rates of flow. In some cases a *critical initial width* may determine whether a portion of a dike is blocked eventually by the freezing of magma or enlarges to become a centralized conduit. In portions narrower than the critical width, solidification or blocking will occur while the melting of dike walls to produce more thermally robust conduit-like structures will occur in portions of the dike that are wider than the critical width.

It is not just the rate of heat loss into the wallrock of a dike that determines whether a magma can survive its journey to the surface. The distribution of the heat that remains in the magma as it moves through the dike is an issue of equal importance. To see this, consider magma flowing at an average velocity of 1 m/s in a dike 2 m thick. A simple energy balance argument shows that the bulk or average, across-dike, magma temperature falls less than 20°C over a distance of 10 km, assuming a 5 kW/m<sup>2</sup> rate of heat loss to the host rock, a rate of

cooling that is appropriate just after the initiation of a dike in the cold host regime. If the average temperature was the only consideration, it could be readily concluded that the magma would not solidify. However, for simple laminar flow with no mixing to eliminate temperature differences arising in the magma between the center of the dike and its edge, the wall temperature can fall sufficiently low at the contact between the magma and wallrock that solidification occurs. Determination of the wall temperature is considerably more complicated than the estimation of the bulk temperature by the overall energy balance; it requires the solution of a coupled flow and temperature problem. This coupling involves the temperature dependence of the magma viscosity and the production of heat in the magma by the conversion of flow energy as a result of the high viscosity of magma. This latter effect is usually called *viscous dissipation*.

The simplest models of magma transport deal with only laminar flow in plane parallel dikes. However, idealized plane parallel flows are unlikely to occur in nature and might be thought to represent only singular examples of magmatic transport. To better appreciate the effect of small deviations from plane parallel flow in the extreme geometry of a dike (length/width  $> 10^3$ ), one need only consider that the highest temperature region of the flow is at most a few meters from the boundary of the dike where heat loss occurs. Magma flowing at an average velocity of 1 m/s in a 2-m-wide, 2-km-long dike has a residence time in the dike of 2000 s. If the flow also has a transverse (cross-stream) component of only 0.0005 m/s, just 1/2000 of the longitudinal (along-dike) velocity component, the hottest magma will move from the centerline to the wall during its residence in the dike. Alternatively, the role of a transverse flow can be estimated in terms of the cross-stream flow required to transport the same amount of heat as conduction. The quantity  $\rho c_p u d$  represents an effective thermal conductivity, where  $u$  and  $d$  are the characteristic cross-stream velocity and cross-stream transport distance,  $c_p$  is the specific heat at constant pressure, and  $\rho$  is the magma density. One finds that a transverse velocity of only  $10^{-4}$  to  $10^{-3}$  m/s is required to transport an amount of heat equal to that carried from the center to the edge of the dike by conduction alone.

Numerous possibilities exist for producing small, but significant transverse flows in a dike. These include boundary roughness, the rise of small, centimeter-scale vapor or gas bubbles in the magma as well as the occasional large ones, flow-induced sorting of solids (e.g., crystals) in the magma, and turbulence. Small deviations from a parallel wall geometry, such as the gradual necking down of a dike toward the outlet, will also produce

transverse motions, tending to raise boundary temperatures and delay or prevent solidification at the wall.

Realistic laboratory experiments involving magma are difficult to carry out because of the very high temperatures, pressures, and large scales that are usually involved. However, computer models of magmatic processes have become increasingly common and much of the following discussion is based on simulations of magmatic transport that involve numerically solving equations describing the heat and mass transport in flowing magmas. Before we can quantify the transport processes mentioned, we must first more carefully define the magmatic plumbing that is characteristic of crustal volcanism. We will tend to be conservative in our descriptions in the sense that we exclude from consideration those “easy” models that allow magma to get to the surface readily but are also atypical.

age 1 m in width while feeder widths for the Columbia River flood basalts average 6 m and exceed 23 m. The average width of silicic dikes is greater than that of basaltic dikes. A silica-rich, rhyolite dike intersected by drilling at 400–600 m beneath the volcanic Inyo Domes in California was found to vary from 6 to 33 m in width. It is possible that dikes may widen near the surface owing partially to the explosive release of volatiles from the rising magma. For the following discussion, the assumption of meter-thick dikes at depth is reasonable for basalts and may be a little conservative for the more viscous silicic magmas such as andesites. The processes that we describe here are particularly important for aiding magma to reach the surface in dikes of this thickness.

---

## II. PHYSICAL MODEL OF MAGMA FLOW IN A DIKE

### A. Dimensions

What are the physical dimensions of the dikes that play a role in magma transport? The geometric parameters defining a dike are its characteristic vertical length and width. A dike's vertical length is not well constrained by observations. Presumably, the length of a dike is determined by the depth to significant concentrations of magma. The disappearance of seismicity as a result of crustal weakening associated with large volumes of magma and inferences made from surface bulges caused by the intrusion of magma at depth place the magma storage zone supplying Kilauea volcano at a depth of 2–6 km beneath the surface. A comparable depth for magma under Mauna Loa volcano, which is also on Hawaii, can be inferred from the surface tilt resulting from the accumulation of magma in a crustal reservoir. Similar depths to magmas in the more viscous, siliceous systems such as under the Long Valley Caldera are predicted by seismic studies. In the models presented here, we assume reasonable dike lengths of 2–4 km.

The characteristic width of dikes is a parameter that is easier to determine, at least at the surface. The average widths of dikes in a swarm in Iceland are about 3.5 m. In Mull, Scotland, the average width was found to be 1.5 m, with the maximum width exceeding 50 m. Dikes comprising the Independence swarm in California aver-

### B. Magma Rheology

Another important physical property strongly influencing flow in a dike is the viscosity of magma and its dependence on temperature. At the surface, it is observed that the relatively low viscosity of basalts is conducive to at least moderate flow velocities (1 m/s) and to the production of transverse flow by the effects mentioned earlier. The novel lava lake experiments of Herbert Shaw and his colleagues at the U.S. Geological Survey give us some information about subliquidus viscosities of Hawaiian basalts near atmospheric pressure. For basalts flowing in dikes, the dynamic viscosity can be predicted from

$$\mu \text{ (Pa s)} = 1.0 \times 10^{-6} \exp[26,170/(T + 273)], \quad (1)$$

where  $T$  is the magma temperature in degrees centigrade. At 1200°C, a reasonable temperature for a Hawaiian basalt flowing in the crust, the viscosity,  $\mu$ , is predicted by Eq. (1) to be about 52 Pascal-seconds (Pa s), which is roughly equal to the viscosity of glycerin kept in a freezer. Over the temperature range of interest, Eq. (1) tends to yield greater viscosities than some more recent laboratory measurements. Lava lake measurements represent upper limits on the viscosity of a Hawaiian basalt at any given temperature since it has lost most of its water content during its flow to and residence on the surface. High-pressure experiments involving a basaltic melt with a reconstituted water content of 2.7 wt% do show a substantial decrease in estimated viscosity (~3 Pa s at 1200°C). However, Hawaiian basalts tend to be “dry” with dissolved water contents of about 0.3 wt% so the viscosities of basalts flowing in dikes are

between 3 and 52 Pa s at 1200°C. Again, we will be conservative by using Eq. (1), which predicts basaltic viscosities that are higher than average for Hawaiian magmas.

For more viscous magmas, an empirical viscosity-temperature relationship has been obtained by Tom Murase of the University of Tokyo and Alexander Mc Birney from the University of Oregon for medium-silica-content, andesitic lavas from Washington's Mt. Hood volcano. It is approximated by

$$\mu (\text{Pa s}) = 8.47 \times 10^{-8} \exp[35,000/(T + 273)], \quad (2)$$

with temperature,  $T$ , given in degrees Celsius. For an andesite, the viscosity at 1100°C is estimated to be about 200 times greater than for the Hawaiian basalt. Again, this value of the viscosity may be an upper limit since the presence of water in the melt can substantially lower the viscosity of an andesite, which often contains more water than a basalt. The temperature dependence of the viscosity assumed in Eqs. (1) and (2) is most appropriate above the liquidus temperature where no crystals exist as well as just below, say, 50 degrees, where few crystals are present.

### C. Magmatic Heat Loss and Flow Rates

Initially, hot magma owing along a propagating crack comes into contact with host rock at the ambient or native temperature. Just seconds after emplacement, the temperature at the magma-wallrock contact is the average of the magmatic and ambient temperatures. If heat movement is by conduction only in both the host rock and dike, that is, magma stops owing in the dike, this boundary temperature would exist until the temperature of the magma at the center of the dike falls below its initial value (Fig. 2). But if magma is owing, a thermal boundary layer will rapidly develop in the magma at the boundary. This boundary layer is simply a region in the flow where heat moves to the boundary mainly by conduction and is characterized by a gradual change in temperature between the magma and wallrock. The purely conductive (diffusive), time-dependent temperature distribution that develops in the host rock, which is characterized by thermal diffusivity  $\kappa$ , will not match the thermal boundary layer that is established in the flow. At a fixed location along the dike, the boundary layer conductive length scale, that is, the thermal boundary layer thickness, will tend to approach a constant value in time while the host regime conduction length

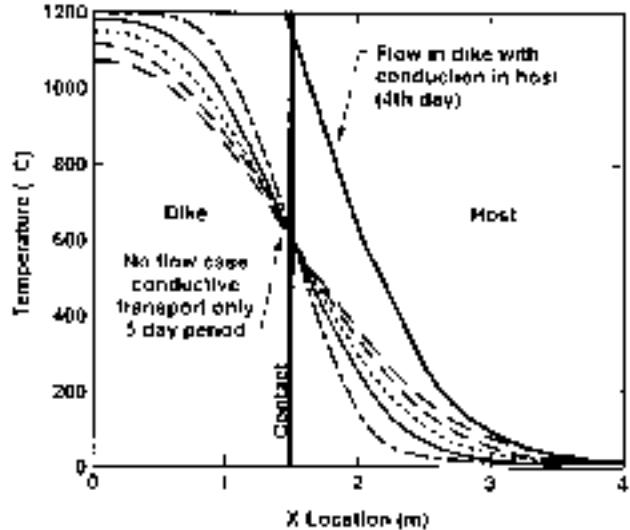

FIGURE 2 Comparison of temperature profiles in magma and in adjacent host rock for cases in which magma is stagnant in a 3-m-thick dike and when it is flowing. Stagnant magma loses heat to the host rock by conduction only. Group of curves intersecting the dike/host contact at 600°C (average of 1200°C dike and 0°C host temperatures at time of emplacement) illustrates thermally diffusive (conductive) temperature profiles during the first 5 days of cooling. The symmetry of this conduction solution about the contact is destroyed if magma is flowing. The thermal boundary layer in the magma is much thinner after 4 days than the thermally conductive layer in the host. This asymmetry results in much higher temperatures at the contact. [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

scale given by  $\sqrt{\pi\kappa t}$  grows indefinitely with time  $t$ . Figure 2 shows this difference after 4 days between the thickness (about 0.05 m) of the flow-induced boundary layer and the conduction length scale in the host rock (about 1.5 m). Because of this difference in thermal conduction length scales, heat is supplied to the boundary more effectively than it can be removed. After emplacement, the boundary temperature will rapidly increase above the average of the host regime and bulk magmatic temperatures and approach some value near the initial magmatic temperature.

A large difference in thickness between the magma thermal boundary layer and the host rock thermal conduction layer causes the host rock to act like a large thermal resistor in series with a small one (the dike boundary layer) and determines the heat flow out of the dike. Now the host rock behaves like the dominating thermal resistance controlling the heat flow from the dike. A typical rate of heat loss is 1 kW/m<sup>2</sup>, which

is appropriate about 8 days after emplacement of the dike into cold host rock (Fig. 3). On the other hand, 3 kW/m<sup>2</sup> is more appropriate for a day-old dike in cold host rock (Fig. 3). These values of heat loss to the host rock may actually be somewhat high for established volcanic regions. The continuous flow of hot magmatic gases through the crust overlying a magma reservoir, as in the case of Kilauea, can substantially increase the temperature of the host rock above ambient values and significantly reduce the heat loss rate from the magma to the host regime. In addition, preheating of the crust by injections of magma that do not reach the surface may produce a "thermal highway" for later injections of magma that do flow to the surface without solidifying.

The typical average flow speeds of basaltic magma in dikes vary from <1 m/s to >3 m/s. These values are consistent with the range of mass fluxes deduced from eruptions and also typify the range of magma ascent rates required to offset the setting velocity of dense ultramafic xenoliths or host rock fragments that have been transported to the surface in basaltic magmas. Less is known about flow velocities in andesitic dikes, but

large-scale eruptions probably require flow velocities exceeding several tenths-of-a-meter-per-second.

### III. COMPUTERIZED MAGMA TRANSPORT

As mentioned, it is very difficult to carry out meaningful laboratory experiments simulating the transport of magma in the Earth's crust. In principle, the important aspects of magma transport can be scaled down to a laboratory model. In practice, the likelihood of finding the right combination of materials having the correctly scaled thermal and fluid mechanical properties at temperatures and pressures readily achievable in the laboratory is remote. The occasional lab experiments that are done never simulate the full behavior of a magmatic plumbing system. Computer models of magma transport do not necessarily share this drawback. As computers have become increasingly powerful, more and more studies of magma storage and transport have been carried out as numerical simulations. Such models have gradually become more realistic as computer programs have become more sophisticated in treating the dynamics of temperature-dependent magmatic flow.

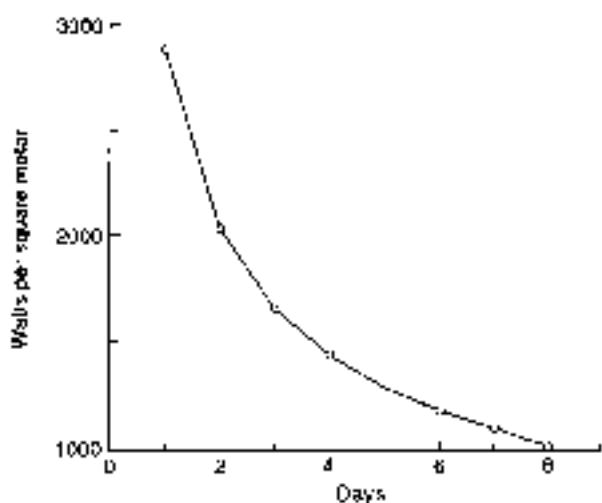

FIGURE 3 Rate of heat loss at the dike wall versus time. As the host rock is gradually heated by magmatic flow, the rate of heat loss decreases. This estimate of the rate of heat loss is given by  $Q = k(dT/dx) = k(\Delta T/\sqrt{\pi kt})$ . The thermal conductivity  $k = 1.26 \text{ W/m K}$  is appropriate for wallrock at elevated temperatures, while the thermal diffusivity  $\kappa$  is assumed to be  $7 \times 10^{-7} \text{ m}^2/\text{s}$ . The initial temperature contrast between the magma and country rock  $\Delta T$  is taken to be  $1000^\circ\text{C}$ , which is likely to be too large for a volcanic region already subjected to some preheating. Thus we would expect our estimates of the rate of heat loss to bound those values characteristic of volcanic regions. [Reprinted from Carrigan et al., 1992 by permission of the American Geophysical Union.]

#### A. Flow of Basaltic (Lower Viscosity) Magma in Dikes

The simplest dike is one with parallel boundaries. A 2-km-long by 1-m-thick dike containing basaltic magma flowing at a maximum speed of 1 m/s suffers a decreasing boundary temperature with distance downstream as illustrated by Fig. 4 (lower curve) assuming that heat is lost at a rate of 1 kW/m<sup>2</sup>. Here the temperature at the boundary falls approximately  $70^\circ\text{C}$  in just the first kilometer of flow. At this rate, solidification at the boundary of the dike will occur. Curiously, the "mixing cup" temperature of the magma at each downstream location remains nearly constant over the first few kilometers as shown in the figure. The mixing cup temperature, which is close to the bulk temperature, is the temperature that would be measured by a hypothetical extraction of all the magma flowing across a given horizontal plane and then mixing it up. A lot of flow energy can be converted to heat as a result of the high viscosity of magma in a high-shear environment. This fluid-dynamic viscous heating effect is analogous to the me-

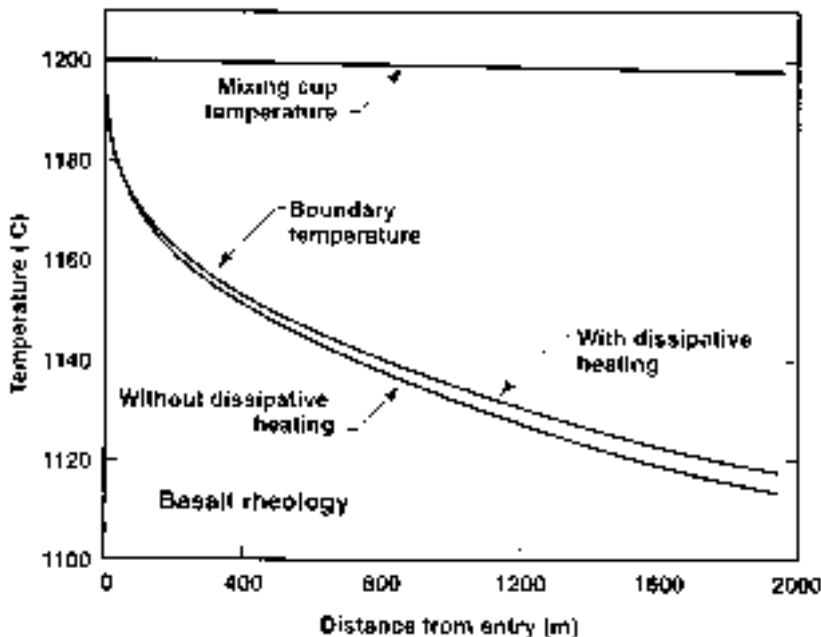

FIGURE 4 Boundary and mixing cup temperatures for a Hawaiian basalt flowing at an average velocity of 0.67 m/s (constant flux inlet condition) in a dike with  $1 \text{ kW/m}^2$  cooling at the walls. The mixing cup temperature decreases by only a few degrees over a distance of 2 km as indicated by the nearly horizontal line. However, the boundary temperature decreases by about  $70^\circ\text{C}$  even with viscous dissipative heating. [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

chanical effect of rubbing two sanding blocks together to generate heat. The upper curve shows the variation of temperature with distance downstream from the inlet when viscous heating is included. With this additional heating effect taken into account, the boundary temperature is slightly higher at each location downstream compared to dike flow without viscous dissipation.

### B. Potential Role of Viscous Dissipation

A dimensionless ratio of dike parameters called the Brinkman number,

$$\text{Br} = \mu v^2 / k \Delta T, \quad (3)$$

is an indication of when viscous dissipation becomes significant compared to the rate of heat loss by conduction. The parameter  $\Delta T$  is the temperature difference between the magma–wallrock contact and centerline of the dike,  $k$  is the thermal conductivity of the magma,  $v$  is its velocity, and  $\mu$  is the dynamic viscosity of the magma. The Brinkman number represents a measure of the rate of heat production by viscous dissipation relative to the amount of heat conducted to the boundary

of the dike. In more or less constant viscosity flows, Br must exceed a value of about 2 for viscous heating to affect significantly the shape of the cross-stream temperature distribution. For basalt losing heat at a rate of  $1 \text{ kW/m}^2$ , this value of Br requires an average flow velocity of a few meters per second. For an average velocity of 2 m/s, the mixing cup temperature actually remains equal to the inlet temperature with increasing distance along the dike. If the rate of heat loss is increased to  $2 \text{ kW/m}^2$ , the mixing cup temperature is maintained at the inlet value for an average flow velocity of 2.7 m/s, that is, the heat loss is entirely offset by viscous dissipation. However, the boundary temperature still falls as the thermal boundary layer grows with distance along the dike. Thus, even in basaltic dikes where the volume of magma is actually getting hotter owing to viscous dissipation, solidification along the boundaries can still occur in the absence of transverse flow. While viscous dissipation can produce more heat than is lost through the boundaries, cross-stream conduction alone is not adequate to carry enough heat to the boundaries to keep them from cooling.

For basalts, we have seen that the problem of cooling at the boundaries of a dike is not a lack of heat in the magma. Rather it is the distribution of heat or tempera-

ture that develops as the loss of heat progresses during flow downstream. It is necessary to look to natural mechanisms for stirring the magma as a means of redistributing this heat in the cross section of the dike.

### C. Effect of Rising Gas Bubbles

Because of the release of gas trapped in magma chambers and exsolution of volatiles in rising magma undergoing decompression, the flow of magma may become at least a two-phase problem. (In some cases, the presence of phenocrysts or entrained wallrock fragments could require the treatment of three phases, that is, we must sometimes consider magma as a mixture of solids, liquids, and gases.) For the vertical flow of gas and basaltic magma, the transition from single-phase to two-phase behavior occurs when gas bubble sizes are of the order of 0.01 m. While the separated flow of larger bubbles prevents them from being wholly preserved in lavas at the surface, with 0.02–0.03 m being the observed maximum, the sizes of volcanic bombs or eruptive fragments of lava suggest the common occurrence of bubbles greater than 0.10 m, and 1-m-diameter bubbles may be occasionally observed. In some cases, gas expelled from the magma chamber can create a rapidly rising gas bubble with dimensions comparable to the dike thickness (Fig. 5a). This is called the *slug-flow regime*. Such voids may also be produced by the coalescence of smaller bubbles consisting of volatiles that come out of solution in the rising magma. The buoyancy of a large bubble causes it to rise relative to the surrounding magma. Some of the flow lines in the magma must thus be diverted from the center of the dike toward the boundaries (Fig. 5a). For bubble-rise rates approaching tens of centimeters per second, the resulting cross-stream flow will easily increase dike boundary temperatures to mixing cup values.

The effects of centimeter-size bubbles rising relative to the bulk flow (Fig. 5b) can be determined from computer models by using an eddy thermal diffusivity that allows for the “drift” motion of the fluid caused by the passage of gas bubbles in the flow. For magmas, a bubble-eddy diffusivity  $\kappa_b$  of the form

$$\kappa_b = k_b \alpha \frac{d_b}{2} V_b \quad (4)$$

can be applied where  $k_b$ ,  $\alpha$ ,  $d_b$ , and  $V_b$  are, respectively, an empirical constant having a value of about 1.2, the bubble void fraction, the mean bubble diameter, and the relative bubble rise rate. A crude estimate of the

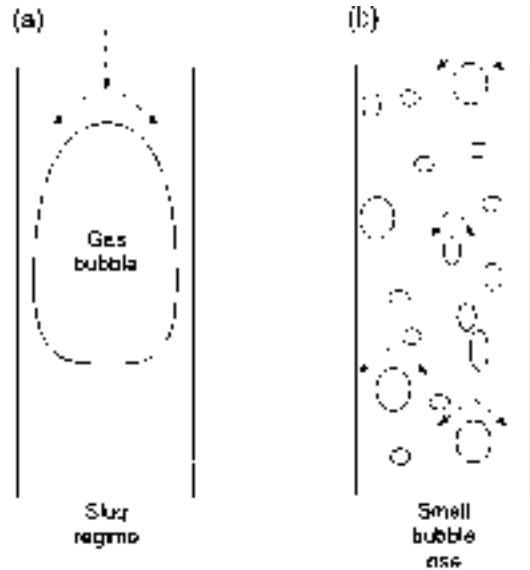

FIGURE 5 In actual dikes and conduits, lateral mixing can be effectively accomplished by the presence of rising gas bubbles produced from accumulated gas in chambers or exsolving volatiles. Both (a) large and (b) small bubbles induce cross-stream velocities in magma as they rise relative to the magma. An effective thermal conductivity given by Eq. (6) can be used to simulate the effect of the rise of small bubbles on heat transport to the walls of the dike. [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

relative rise rate of a bubble appearing in Eq. (4) is given by the Stokes' velocity:

$$V_b = \left( \frac{1}{18} \right) \frac{d_b^2 g}{\mu_{\text{magma}}} (\rho_b - \rho_{\text{magma}}), \quad (5)$$

in which  $g$  is the gravitational acceleration. An effective thermal conductivity  $k_{\text{eff}}$  that takes into account bubble-induced transverse or cross-dike motions can then be written as

$$k_{\text{eff}} = (1 - \alpha)k_{\text{magma}} + (1 - \alpha)\rho_{\text{magma}}c_{\text{magma}}\kappa_b, \quad (6)$$

where  $c_{\text{magma}}$  is the specific heat of the melt taken to be 1.05 kJ/kg K (0.25 cal/g °C). This effective thermal conductivity replaces the magma thermal conductivity in magma transport simulations. Note that  $k_{\text{eff}}$  is temperature dependent. We take into account that near the boundary, where the temperature is lower, the higher magma viscosity decreases the Stokes' rise rate  $V_b$ . As a result,  $\kappa_b$  also is less at the boundary, which means that the eddy thermal conductivity is less effective at the boundary than at the middle of the dike for transporting heat.

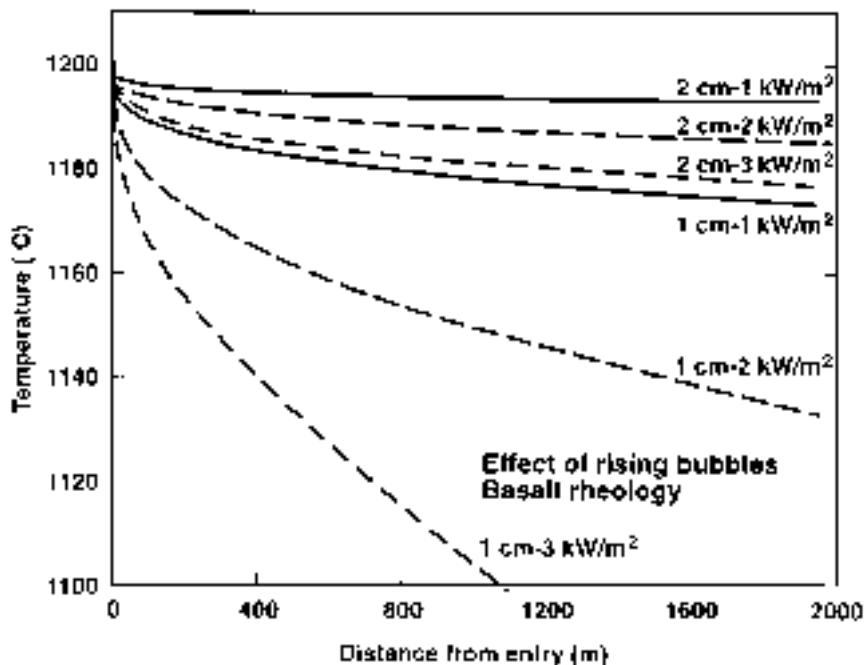

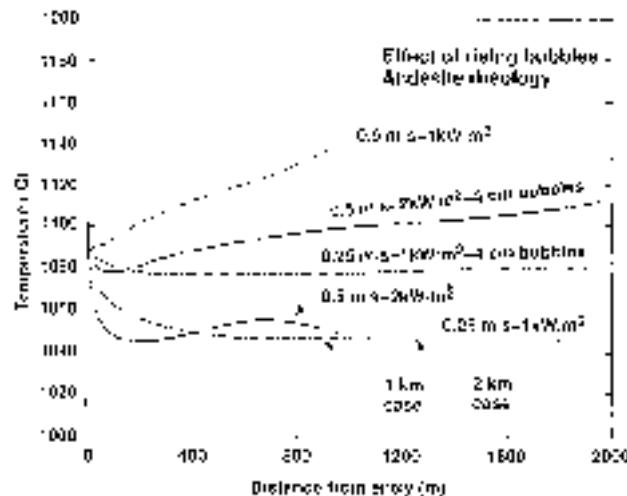

FIGURE 6 Rising bubbles in basalt strongly affect boundary temperatures of the dike. If gas bubbles occupy a 10% volumetric fraction of the dike and have a mean diameter of 2 cm, they substantially increase the effective thermal conductivity as a result of the transverse motion that they induce so that the temperature drop is only 22°C at the boundary after 2 km of flow in a dike with a large 3  $\text{kW/m}^2$  rate of heat loss. For a 1  $\text{kW/m}^2$  rate of heat loss, the temperature drop on the boundary after 2 km is a mere 7°C. Boundary temperature is rather sensitive to bubble size. Reducing mean bubble size from 2 to 1 cm in the 3  $\text{kW/m}^2$  case produces a much larger temperature drop as illustrated by the bottom dashed curve. [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

Figure 6 shows the variation of boundary temperature along a basaltic dike for different rates of heat loss and bubble size. For a void fraction of only 10% and mean bubble diameters between 1 and 2 cm, there is a large increase in boundary temperature at any given downstream location compared with cases that do not include bubble rise. There is also a significant dependence of the boundary temperature on the mean bubble diameter  $d_b$ . For a dike with an average flow velocity of 0.67 m/s (1 m/s maximum flow rate), losing heat at the rate of 1  $\text{kW/m}^2$ , the boundary temperature drops only 7°C over 2 km compared to 80°C for the case without bubbles shown in Fig. 6. Even with a heat loss rate of 3  $\text{kW/m}^2$ , the boundary temperature drop is just 22°C after 2 km. This suggests that basaltic magma could flow about 10 km before the onset of solidification at the boundaries. For a bubble diameter of just 1 cm, the figure shows that a temperature drop of almost 100°C occurs after only 1 km in the 3  $\text{kW/m}^2$  cooling case. When bubbles are not important, other mechanisms for inducing cross-dike motions in the magma flow are boundary surface roughness, which breaks up the thin

thermal boundary layer, and the occasional onset of turbulence in less viscous flows that results in higher boundary temperatures and reduced pressure gradients.

#### D. Effect of High Viscosity on Magma Transport

What about higher viscosity andesitic flows in a 1-m-wide dike with viscous heating and bubble flow? Figure 7 gives boundary temperatures versus distance along the dike for a number of different cases. For a maximum flow velocity of 0.5 m/s (average flow velocity of 0.33 m/s) and a heat loss of 1  $\text{kW/m}^2$ , the boundary temperature increases downstream owing to viscous heating even in the absence of rising bubbles. Assuming bubbles make up 10% of the dike volume, rising boundary temperatures occur for a heat loss rate of even 2  $\text{kW/m}^2$ . Without bubbles, the boundary temperature oscillates with distance along the dike if a heat loss rate of 2  $\text{kW/m}^2$  is used for the 0.5 m/s maximum velocity

**FIGURE 7** The effect of bubbles and viscous heating is shown for a 1-m-wide andesitic dike assuming a variety of magma flow velocities and heat loss rates. Due to viscous heating, boundary temperature rises along the dike for a maximum flow velocity of 0.5 m/s (average velocity = 0.33 m/s) and 1 kW/m<sup>2</sup> rate of heat loss (top dashed curve) and for 2 kW/m<sup>2</sup> rate of heat loss (upper solid curve) if 10 vol% content of bubbles having a mean diameter of 4 cm is present. Neglecting bubbles with 2 kW/m<sup>2</sup> heat loss and 0.5 m/s maximum flow velocity results in the bottom oscillatory solid curve. Halving both the flow velocity and rate of heat loss assumed in the previous case with bubbles (upper solid curve) produces the nearly constant temperature boundary given by the curve at 1080°C (dot-dash). If the effect of rising bubbles is not included in the latter case, the boundary temperature drops to a more or less constant value of 1040°C (bottom dot-dash and dotted curves). [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

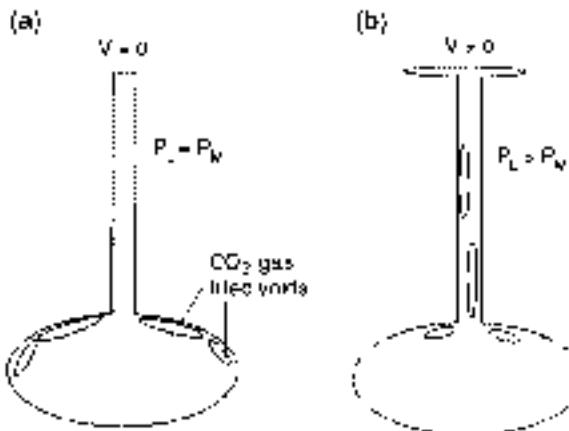

case. This may be a result of interplay between viscous dissipation and the temperature-dependent viscosity. The effect of bubbles on the thermal regime reduces the pressure gradient required to drive the flow at an average velocity of 0.33 m/s from 36.6 to 31.5 MPa/km (about 366–315 atm/km). At the lower 1 kW/m<sup>2</sup> loss rate, more or less constant boundary temperatures can be achieved if the maximum flow velocity is 0.25 m/s (average flow velocity of 0.17 m/s). However, even at this lower flow rate, the pressure gradient required to push andesite through the dike exceeds 20 MPa/km (about 200 atm/km) for a 1-m-wide dike. Generally, long andesitic dikes are observed to be much wider than 1 m and, for a given mass flux, the required driving pressure gradient is extremely sensitive to the dike width, being proportional to 1/width<sup>3</sup>. Thus, we expect that larger dikes will require a substantially lower driving pressure gradient for a given mass flow.

However, during the initial period of flow in a dike, we expect that magma must be forced through fractures that have widths of somewhat less than 1 m. It is difficult to imagine an andesitic magma propagating at any significant rate along a very thin dike because of the large pressure gradients required. In a 0.2-m-wide dike with an average flow velocity of 0.1 m/s, the magma can only flow about 500 m before the bulk temperature falls 100°C, assuming a heat loss rate of 5 kW/m<sup>2</sup>. This is a reasonable heat loss rate for a fracture in cool host rock. The required pressure gradient for this flow exceeds 30 MPa/km. For andesitic magma to travel without solidification in a dike several kilometers long would require an even larger pressure gradient. Nevertheless, andesites and even more silicic and viscous rhyolitic magmas propagate significant distances. A two-magma lubrication process, to be discussed later, involves the simultaneous transport of magmas of differing viscosity. It reduces the pressure gradient needed to transport the most viscous magma to the surface and may explain how some rhyolitic magmas are able to reach the surface.

#### IV. PRESSURE GRADIENTS REQUIRED FOR MAGMATIC FLOWS

##### A. Lower Viscosity Basaltic Magmas

The pressure gradient required to drive a 0.67 m/s average flow corresponding to a 1 m/s maximum flow rate in a 1-m-wide dike with a heat loss of 2 kW/m<sup>2</sup> is less than 0.5 MPa/km (about 5 atm/km). To maintain the same flow rate in a dike decreasing from a 1- to 0.5-m thickness over a distance of 2 km requires a pressure gradient of about 1.7 MPa/km. These driving pressure gradients are not particularly large. The lithostatic (i.e., the vertical pressure distribution of overlying crustal rocks) load in the crust increases with depth by about 25 MPa/km. For the sake of discussion, let us assume that a pressure condition on the inlet of the chamber applies and has a value equal to the depth times the lithostatic pressure gradient. For a 4-km depth,  $p_{in} = 100$  MPa and at the surface  $p_{out} = 0$ . For the magma column in the dike, we assume that the density is roughly comparable to that of the surrounding rock so that the load pressure is about the same as the lithostatic value at any level. Figure 8a shows this situation in which the lithostatic column balances the magmastic column (i.e., the vertical pressure distribution in magma). There is no excess pressure gradient to drive the flow and hence

**FIGURE 8** Chamber gas entering a dike or conduit can upset the balance between the lithostatic pressure  $p_L$  and the magmastic pressure  $p_M$  and drive magmatic flow. (a) Initially, gas accumulates in the magma chamber. Because the lithostatic pressure field (pressure regime in host rock) is approximately balanced by the magmastic pressure field (pressure regime in dike or conduit) the pressure gradient for driving magma through the dike is small to vanishing and no flow occurs. (b) If, however, gas enters the dike from the chamber, the average density of the magma in the dike falls and  $p_M$  becomes less than  $p_L$  at every level in the dike. A pressure difference then exists for forcing magma in the dike to the surface. Thus chamber gas (and exsolution of volatiles at shallow levels within the dike) can play a critical role in initiating and maintaining an eruption. [Reprinted from Carrigan et al., 1992, by permission of the American Geophysical Union.]

no flow. Now, suppose that chamber gas is leaked into the dike and rises upward toward the surface (Fig. 8b). If the gas bubbles displace only 10% of the volume of the dike, the pressure at the bottom of the magmastic column suddenly falls 10 MPa below the lithostatic value. This means that only a 10% void space caused by the presence of gas bubbles in the dike gives rise to a 2.5 MPa/km driving pressure gradient that exceeds the driving requirements of our computer simulations. Our calculations suggest that the average flow velocity would exceed 3 m/s in a 1-m dike and would produce enough viscous heating to more than offset a 2 kW/m<sup>2</sup> rate of heat loss.

The modest 10 vol% bubbles that drive the system in this example will not be distributed uniformly in the magma column. In water-rich systems, the bubble content increases rapidly during the last 1000 m of ascent due both to rapid decrease of water solubility in melt and vapor expansion. In CO<sub>2</sub>-rich systems, expansion of the gas phase is the main contributor to the upward increase in the bubble fraction, because CO<sub>2</sub> is

relatively insoluble in melt at crustal pressures. In the general case, when both components are present, the chamber gas will be enriched in CO<sub>2</sub> and the gas evolved during dike formation will be rich in H<sub>2</sub>O. Depending on water content, the expansion of the rising magma by vapor exsolution and expansion can become so great that the melt phase disintegrates near the Earth's surface, that is, the magma fragments to a dusty gas of ash in vapor. These are the conditions that promote explosive eruptions. Thus, once overpressuring of a magma chamber has induced dike propagation to the near surface and the onset of explosive activity, the drastic reduction in density in the upper part of the column of magma will make flow in the dike self-sustaining. Furthermore, the volume fraction of bubbles in the dike and not the bubble size determines dike flow velocity. Thus small bubbles can be as effective as large ones in inducing magma to flow in the dike. The presence of separated gas and liquid phases in a dike will also facilitate its propagation by increasing the available driving pressure gradient (through lowering the average density of the column) and decreasing viscous drag by replacing magma in the narrowing tip of the dike where fracturing is occurring.

## B. Magmatic Coextrusion and Transport of More Viscous Magmas

Compared to basaltic flows, andesitic and rhyolitic flows in a dike need extremely high driving pressure gradients. It has been mentioned that a thin (0.2-m) andesitic dike may require a driving pressure gradient that is greater than 30 MPa/km. This value exceeds the lithostatic gradient, which in some cases represents a maximum value for the available driving pressure gradient. However, under certain circumstances, the driving pressure gradient can be substantially reduced for mixtures of magmas. If even a small amount of a lower viscosity magma plates the walls of a dike, it can contribute to decoupling the flow of a higher viscosity component from the walls. Because most of the shear and energy dissipation take place near the walls, where the low-viscosity magma is now located, the pressure gradient required to drive the high-viscosity component through the dike is substantially decreased. In effect, the lower viscosity magma lubricates the passage of the higher viscosity magma. Consider a 10-m-wide dike with a higher viscosity crystal-rich rhyolitic core region rising in the center of the dike. Further, assume all the shear occurs in 1-m-wide layers of lower viscosity, crystal-

poor rhyolitic magma adjacent to the boundaries. In 1990, the author and Professor J. C. Eichelberger at the University of Alaska used geologic and drilling studies to show that volcanic domes in the Inyo volcanic system in California were formed by such a core/wall layer arrangement of magmas flowing simultaneously in a dike about 600 yr ago. The dynamic viscosities of the flowing core and wall layer magmas are  $3.6 \times 10^6$  and  $1.6 \times 10^4$  Pa s, respectively. The total pressure drop in the core/wall layer flow at an average velocity of 0.05 m/s over 1 km can be shown to be only 0.18 MPa (1.8 atm). If just the more viscous, crystal-rich, rhyolitic magma flowed in the same dike, the required pressure drop for driving the flow rises to about 21 MPa. This is about the largest value that could be produced in a very low density magmatic foam by the lithostatic pressure gradient.

The lubrication of the dike walls by lower viscosity magma is not something that happens by chance when two magmas of differing viscosity flow together. In fact, two-component flows will always tend to be self-lubricating in this manner. As the two layers flow along the channel, the lower viscosity layer will gradually flow around the higher viscosity component encapsulating it (Fig. 9). This encapsulation of the higher viscosity component results in self-lubrication of the flow since the lower viscosity component now occupies all zones of strong shear near the walls, while the higher viscosity component is relegated to a zone of weaker to vanishing shear in the center of the flow. This encapsulation/self-lubrication process is robust and is used in industry for transporting viscous oil in pipelines by injecting water as well as for the formation of composite plastic extrusions.

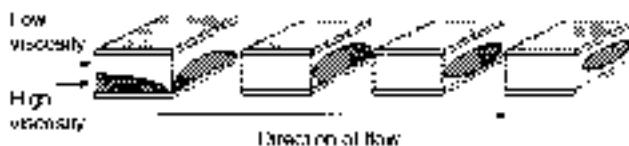

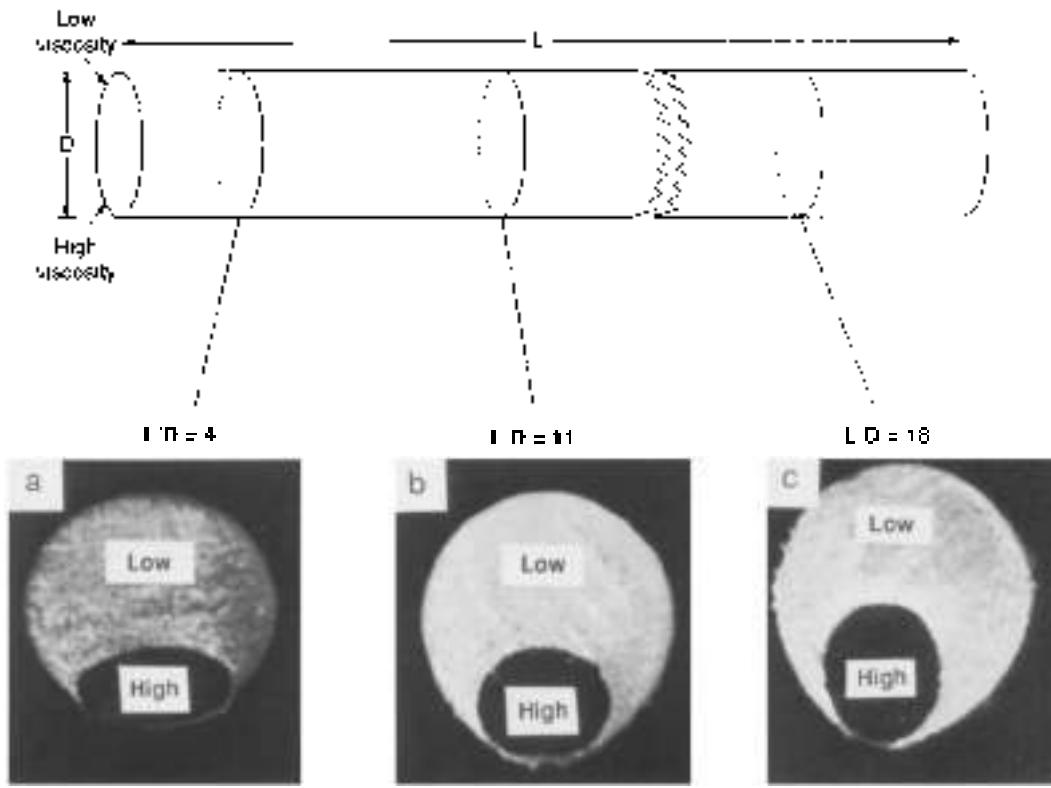

FIGURE 9 A channel sectioned at different locations along the direction of flow of two liquid layers with different viscosities that are injected side by side illustrates the progressive nature of the encapsulation or self-lubrication process. After entering the channel, the initially flat interface between the layers begins to be distorted. The interface between the two liquids increasingly bends back on itself at each successive station downstream as the lower viscosity component (light shading) of the flow encroaches on the contact between the wall and the higher viscosity component (dark shading). Eventually, the higher viscosity component is completely isolated from the high shear, wall region by the lower viscosity liquid. [Reprinted from Carrigan, 1994, by permission of Academic Press.]

Why encapsulation occurs has often been explained in terms of the minimization of the energy dissipated by viscosity in the process of pumping a given mass flux of two different liquids in a channel or pipe. A higher viscosity core and a lower viscosity annular (near wall) zone produces lower dissipation for a given mass flux than the opposite arrangement of higher viscosity at the wall and lower viscosity in the core. This core-annular distribution is also superior, with respect to the driving pressure gradient, to the side-by-side arrangement in which two different viscosity layers are fed together (one on top of or on the side of the other) into a pipe or channel. However, there is some evidence that if the zone of lower viscosity at the wall of the tube gets too thick ( $>30\%$  of the tube radius), the core-annular flow regime can break down.

Of all the laboratory encapsulation experiments, coextrusion experiments involving molten polymers have dynamics that are probably most like those characterizing the transport of magmas. The dynamics of magma transport are dominated by magma viscosity. Depending on parameters such as temperature, volatile content, and crystal content, the rheology of magma is typically found to vary from purely Newtonian (vanishing dependence of viscosity on shear rate) to a shear thinning power law behavior (viscosity depends mathematically on shear rate raised to some power). The flow of molten polymers in capillary extrusion dies is also dominated by viscosity. As in the case of magmas, polymers can also exhibit both Newtonian and power law behavior. In both polymeric and magma mixtures, surface tension can be neglected relative to viscous effects.

Another feature of polymer coextrusion experiments that is common to magma flow in a dike or conduit is that any inertial forces in the flow can be neglected compared to viscous forces. Thus, the Reynolds number which represents the ratio of inertial (momentum-related) to viscous forces is much less than unity for both the coextrusive magmatic and polymeric flows of interest. The similarities in the physical properties of the molten materials and in the dynamics of the flow systems strongly suggest an excellent correspondence between the coextrusion experiments and the simultaneous flow of two magmas in a dike.

The results of a coextrusion experiment (Fig. 10) performed by Professor C. D. Han of the Polytechnic Institute of New York illustrate the effects of viscosity differences on the side-by-side flow of two polymers having different viscosities. Using cylindrical dies of different aspect ratios, it was found that the lower viscosity component (low-density polyethylene) gradually flowed around the higher viscosity component (polystyrene) to

**FIGURE 10** A coextrusion experiment involving two molten polymer layers injected side by side into tubular capillary dies having different length to diameter ( $L/D$ ) ratios illustrates the encapsulation of the higher viscosity component. The ratio of the viscosities indicated for the two layers varies from 0.14 to 0.34 over the range of extrusion rates studied. Careful examination of the extrusion at  $L/D = 4$  shows that the lower viscosity component has already almost completely flowed around the higher viscosity component. With greater distances downstream the higher viscosity component migrates away from the wall toward the center of the flow. [Adapted from C. D. Han, *J. Appl. Polym. Sci.* **17**, 1289. Copyright © 1973 with permission of John Wiley & Sons, Inc. Reprinted from Carrigan, 1994.]

completely encapsulate it. While the higher viscosity component never became centered in the lower viscosity encapsulant for dies with length-to-diameter ( $L/D$ ) ratios of up to 18, it was fully encapsulated (separated from the die wall) within only 4 diameters of the die inlet. In polymer experiments the exact details of the encapsulation/self-lubrication process, such as the interface shape, may vary in a way that depends on the rheology of a particular melt system.

Another set of experiments by Minagawa and White (1975) at the University of Akron produced similar results for side-by-side extrusion both in a tubular (conduit-like) die and in a rectangular (dike-like) die. The coextrusion experiment using tubular geometry (Fig. 11a) illustrates the gradual bending around of the interface between the melts as the higher viscosity (dark) component is encapsulated by the lower viscosity com-

ponent with increasing distance down the tube. As a result of the high shear, the contact area between the higher viscosity component and the tube wall gradually decreases with distance down the tube. Encapsulation would eventually isolate the higher viscosity layer from the wall, as in the case of Han's experiment, if a longer tubular die had been used. The rectangular slot experiments (Fig. 11b) varied both the viscosity ratio of the layers and their initial orientation at the inlet of the slot. When both components have the same viscosity (viscosity ratio equal to one), no encapsulation occurred so that the interfaces remained essentially flat at the outlet for both the horizontal and the vertical initial orientations. When both layers had different viscosities (viscosity ratio different from 1), the interface between higher and lower viscosity components curved around so as to isolate the higher viscosity melt from the wall of the slot.

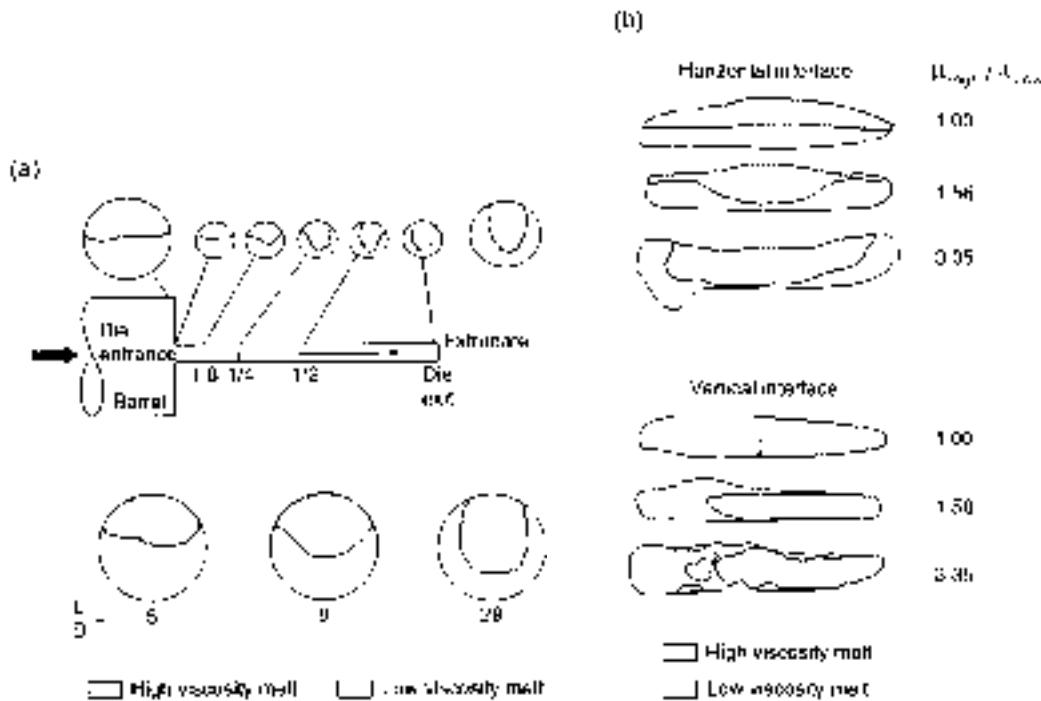

FIGURE 11 (a) Another coextrusion experiment with side-by-side initial conditions illustrates the bending of the interface and the gradual isolation of the higher viscosity component from the wall with increasing distance downstream (normalized by the pipe diameter  $D$ ). The viscosity ratio is 1.56. (b) In a rectangular, dikelike channel, side-by-side injection is studied for two different orientations of the interface between the two layers and for different viscosity ratios. The aspect ratio (downstream length : thickness) is 15. For viscosity ratios of unity, significant interfacial distortion does not occur. The maximum encapsulation for given length of the channel takes place when the interface is parallel to the shortest dimension (thickness) of the channel. This is the anticipated orientation that will give rise to encapsulation in the inyo chain model for magma withdrawal through a dike. ## V. THE ERUPTION OF THE INYO CHAIN OF VOLCANIC DOMES

In an effort to understand the subsurface processes leading to the formation of a chain of young volcanoes in California's Long Valley Caldera, J. C. Eichelberger, who was at Sandia National Laboratories at the time, and his colleagues embarked on a scientific drilling program in the 1980s. A major goal of their work was to understand the origin of the volcanoes or domes and the feeder dike that connected them. Obsidian Dome is one of the three composite volcanoes that is thought to have erupted more or less contemporaneously about 600 yr ago along a north-trending line that crosses the northwestern boundary of the caldera (Fig. 12). The hypothesis that a common dike connects all three domes was partially validated by the intersection of a shallow, rhyolitic dike between Obsidian Dome and Glass Creek Dome. It was found that at least three physically distinct

magmas have contributed to the formation of the composite domes.

Deadman Dome, the southern-most flow in the chain, consists of a coarse, crystal-rich rhyolite (70–74%  $\text{SiO}_2$ ) that overlies a rhyolite of lower crystal content, which also tends to have a slightly lower silica content (71.5%). The middle flow in the chain, Glass Creek Dome, lies on the rim of the caldera. Like Deadman Dome, it consists of a coarse, crystal-rich rhyolite overlying a finer rhyolite with lower crystal content. Obsidian Dome lies beyond the rim of the caldera and consists of a fine, low crystal content rhyolite overlying a fine, low crystal and low silica rhyolite or rhyodacite. Since any increase in crystal content or silica ( $\text{SiO}_2$ ) content means higher viscosity, lower crystal and silica content rhyolites are expected to encapsulate higher crystal and silica rhyolites, and such layering sequences are observed in the domes.

Figure 13 illustrates how the progressive breaching of the sloping roof of a zoned chamber could produce the observed gross compositional variations during a

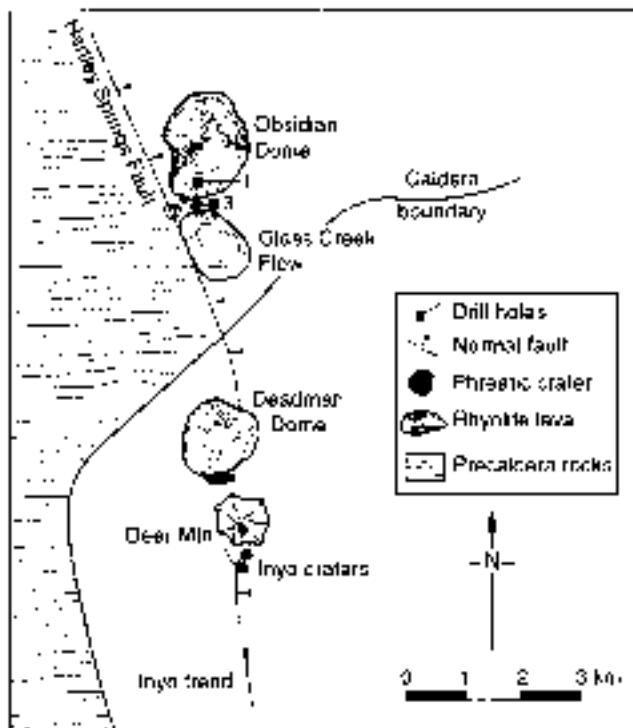

FIGURE 12 Map view of Inyo domes with associated volcanic and geologic features. The numbered squares on and by Obsidian Dome indicate the locations of scientific drill holes. [Figure adapted from Eichelberger et al., *J. Geophys. Res.* **93**, 13,208, 1988, with the permission of the American Geophysical Union. Reprinted from Carrigan, 1994.]

sustained period of increased pressure in the chamber. The formation of a common dike may have started by a breach in that portion of the roof in contact with a layer of coarse, crystal-rich, high-silica rhyolite. Owing to its very high viscosity, the magma does not allow a dike to reach the surface. At the same time, the dike also propagates horizontally, breaching the chamber roof along the line indicated in Fig. 13. This horizontal breaching continues until the lower silica and crystal content rhyolitic layer begins to be withdrawn in addition. Because of its lower viscosity, this magma encapsulates the crystal-rich rhyolite, successfully lubricating its rise to the surface to form the composite Deadman Dome lava flow by the simultaneous venting of both crystal-rich and crystal-poor lavas. Elevated pressures in the magma chamber continue to cause breaching of the chamber roof along the line. Because of the nearness of the dike to both the crystal-poor and crystal-rich rhyolite magma layers, both magmas are withdrawn simultaneously and encapsulate to form a composite dike that once again reaches the surface to form the compos-

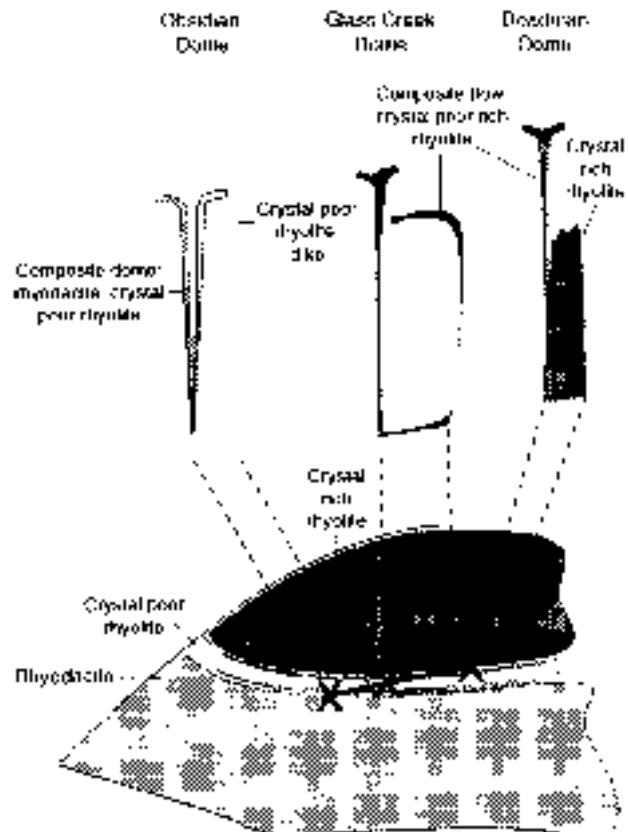

FIGURE 13 Using an encapsulation model for two-component magma transport, a multicomponent transport model is described for the contemporaneous formation of three 600-yr-old composite lava flows in the Inyo volcanic chain. If a breach in the magma chamber roof is initiated over the crystal-rich rhyolite, the high viscosity would tend to prevent this magma from reaching the surface. As the breach progresses down slope, it crosses into a zone of lower viscosity, crystal-poor rhyolite. This magma lubricates the rise of the higher viscosity, crystal-rich component and results in the composite Deadman Dome lava flow (X's indicate points over which lava flows have formed). The continued breaching of the roof causes the composite dike to finally "bud" a conduit that reaches the surface to form the Glass Creek Dome having a similar composition to Deadman Dome. The breach continues its descent across the crystal-poor rhyolite zone and produces a rhyolite dike that does not reach the surface. A rhyodacitic layer is finally sampled by the dike as it crosses a compositional boundary and provides lubrication for the rhyolite to erupt to the surface to form Obsidian Dome as the magma chamber pressure wanes. [Reprinted from Carrigan, 1994.]

ite Glass Creek Dome consisting of the same types of magmas as Deadman Dome. Continuation of the breach moves it into the zone of crystal-poor rhyolite away from the zone of crystal-rich rhyolite so that the dike now consists of a uniformly crystal-poor rhyolite. This

is in agreement with the cores obtained from drilling the dike near Obsidian Dome. Finally, the breach in the roof approaches and begins to draw the contents from the less viscous rhyodacitic zone. Lubrication of the crystal-poor rhyolite by the rhyodacite results in the budding of a conduit to form the Obsidian Dome flow.

---

## VI. CONCLUSIONS AND IMPLICATIONS FOR VOLCANISM

We find that basaltic models of dike flow that include deviation from laminar or unmixed flow produce higher temperatures at the dike walls than laminar models and support the notion that dikes of meter thickness or less can remain viable pathways over lengths of kilometers and do not need to solidify. If magma flow in a 1-m-thick dike is constrained to be laminar, our models suggest that solidification should begin on the sidewalls within several kilometers of the inlet. We also find that the heating of basaltic magma by viscous dissipation could offset the total rate of heat loss from the dike, but boundary temperatures would still continue to fall, leading to solidification along the walls.

Even though the Reynolds number may be too small for turbulence to occur in many cases, laminarity is likely to represent an unlikely state for magmatic flow since several mechanisms encourage both mixing and cross-stream heat transfer in dikes. From our models, we found gas-bubble-augmented flow to be very effective in producing a near isothermal regime in basalts. While still significant, it is less effective in causing cross-stream flow in andesitic magmas owing to the high melt-phase viscosity. Gases present in magma are also likely to be important for fracture propagation during the initial emplacement of the dike. Computer simulations show that the thermal boundary layers are sufficiently thin (typically 0.1 m) that disruption and local mixing should be expected as a result of boundary roughness.

An understanding of how more viscous, silicic magmas propagate distances of kilometers presents a challenge. Viscous heating can offset heat loss for bulk magma velocities in the range of 0.2–0.3 m/s. Boundary temperatures level out and become more or less constant whether or not lateral mixing occurs. Viscous heating near the wall is evidently sufficient to offset heat losses without requiring heat to be transported from the core flow. However, driving pressure gradients for these flows exceed lithostatic values. Increasing the dike width

does have a strong effect on decreasing the pressure gradient required to drive a given mass flux. But, how do silicic dikes propagate significant distances before their width has achieved its maximum value? The required pressure gradients seem too high for the amount of crustal penetration achieved. A crystal-rich rhyolitic magma flowing in a 10-m-wide dike requires a very large driving pressure gradient of 21 MPa/km. If encapsulation of crystal-rich rhyolite occurs by a crystal-poor rhyolite, as evidently happened in the feeder of the Deadman volcanic dome, the driving pressure gradient can be reduced to a mere 0.18 MPa/km. It is possible that extraordinarily viscous magmas often reach Earth's surface successfully only because of lubrication by a lower viscosity component, which substantially decreases the required driving pressure gradient.

## GLOSSARY

- annular flow** One of four two-phase flow regimes, in which magma lines the conduit walls and gas flows in a central jet.
- bubbly flow** One of four two-phase flow regimes, in which the gas phase appears as bubbles suspended in a continuous magma phase.
- degassing** The process by which magma loses its dissolved volatile species as pressure decreases.
- dispersed flow** One of four two-phase flow regimes, in which magma takes the form of fragments in a continuous gas phase.
- fragmentation** Process by which bubbly magma breaks up, generating magma fragments and a continuous gas phase.
- laminar flow** Flow regime where viscous effects dominate and flow trajectories are parallel to the conduit walls.
- Reynolds number** Dimensionless parameter that defines the relative importances of viscous and inertial forces during flow.

**slug flow** One of four two-phase flow regimes, in which large gas pockets, which are almost as large as the eruption conduit, rise through magma.

**turbulent flow** Flow regime where inertial effects dominate, such that the flow is well mixed by small-scale eddies.

**volatiles** Chemical species or compounds that are dissolved in natural magmas at high pressure and that appear as low-density gas at low pressures. The most common ones are water and carbon dioxide.

---

## I. INTRODUCTION

Magma spends time in the Earth's crust before erupting at the surface. In this chapter, we investigate how it evolves during ascent, what determines its flow conditions, and what sets the state and physical properties of the erupted mixture. We emphasize that the fate of an eruption is very sensitive to the last stages of ascent, at shallow levels in the Earth's crust. Our knowledge of eruptions is based primarily on surface observations and our ultimate goal is to relate eruption characteristics to processes that occur in the volcanic conduit at depth. Many different parameters must be known to predict accurately the fate of surface and atmospheric volcanic

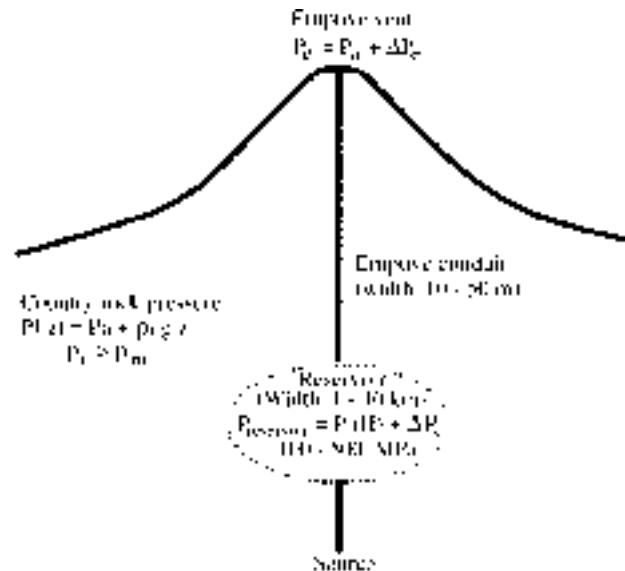

flows. For example, eruptions may last for long periods and may alternate between different regimes or types of behavior. In a common sequence, an eruption may start as a Plinian event, such that the erupted material rises to great height above the vent and is dispersed by high-altitude winds, but the eruption then switches to a pyroclastic flow phase, such that the eruption column collapses and generates dense flows cascading down the volcano's slopes. Specifying which behavior prevails requires knowledge of the eruption velocity, the mass fraction of gas at the vent, the vent dimensions, and the size of magma fragments. Another example is that an explosive eruption expels huge amounts of ash, pumice, and gases into the atmosphere with dangerous consequences to the environment and to the climate. To follow the dispersal of such products, one must know their size and this is determined in part by processes acting in the volcanic conduit.

## II. MAGMA ASCENT AND DECOMPRESSION

We start our journey in a reservoir or magma chamber, which is typically located several kilometers below the Earth's surface (Fig. 1). This depth may be greater than 15 km in a few cases, but usually does not exceed 10 km. As magma rises from depth, it undergoes a large pressure decrease. At a 10-km depth, for example, pressures are about 300 megapascals (MPa), or 3000 times the atmospheric pressure. Such a large pressure change has many consequences for the physical properties and flow of magma.

### A. Magma Composition and Volatile Content

At high pressure, magma contains volatile species in solution, the most abundant being water ( $H_2O$ ) and carbon dioxide ( $CO_2$ ). Magma is generated from a deep source, usually located below Earth's crust. The source material is an assemblage of different mineral phases that may contain various amounts of volatiles and is only partially molten. The primitive magma composition is thus a function of source composition and of the degree of partial melting. As this magma rises and collects into a shallow reservoir, it may melt country rock and may mix with other magmas stored in the plumbing system. Further, in a reservoir, it cools and crystallizes, which

**FIGURE 1** Schematic diagram showing the major components of a volcanic plumbing system. A magma at depth  $H$  in the Earth's crust reservoir empties into a thin eruption conduit. The reservoir pressure,  $P_{\text{reservoir}}$ , is equal to the “equilibrium” pressure due to the weight of country rock,  $P_i(H)$ , which is  $\rho_r g H$ , plus an overpressure  $\Delta P_r$ , which varies with time as a function of the input/output magma budget. The volcanic plumbing system feeds an eruption with an exit pressure that may not be equal to the atmospheric value. Parameter  $\rho_r$  is the crustal rock density,  $\rho_m$  is the magma density,  $P_a$  is the atmospheric pressure,  $P_v$  is the vent pressure, and  $\Delta P_e$  is excess vent pressure.

induces further chemical modifications. The final magma that becomes involved in an eruption is therefore the end result of a long sequence of events. Its composition and volatile content cannot be predicted from first principles and must be determined in each case.

Solubility dictates how much of a given chemical species can be dissolved in a liquid under given conditions. For each volatile species, solubility is a function of magma composition, temperature, and pressure. Temperature and composition are linked in nature as most magmas are near their liquidus (the point at which they start to crystallize), and hence it is simpler to think of solubility as a function of composition and pressure only. For a given composition, therefore, one may think in terms of pressure only. Under most circumstances, magmas are undersaturated in volatiles as they begin their ascent toward Earth's surface. During their rise, they reach the saturation threshold, such that the initial volatile content is equal to the solubility limit. As pressure decreases below this threshold, magma becomes supersaturated, volatile species can no longer stay in solution, and they start forming a separate phase as bubbles. As pressure decreases further, an increasing mass fraction

of volatiles exsolves and the gas phase expands. The solubility of volatile species can be given by the so-called Henry's law, which expresses concentration as a function of pressure. This simple form of the solubility law is not valid at large pressures but is a good approximation at pressures less than 200 MPa. For water in rhyolite magma, one has (Fig. 2):

$$C_g(P_g) = K_H \sqrt{P_g},$$

where  $C_g$  is the concentration of water in the magma,  $P_g$  is the pressure, and  $K_H$  is a constant. We can see from Fig. 2 that more than 5 wt% water can be dissolved in silicic magmas at typical crustal depths. One important fact is that, for this form of the solubility law, the exsolution rate is largest at small pressures and, hence, at shallow levels.

As pressure decreases, the magma loses its volatile constituents, which acts to increase its liquidus temperature. The effect is far from negligible and may in some cases amount to as much as 100 K for every percent of water. This has far-reaching consequences for magma. As a magma parcel degasses, it finds itself undercooled by significant amounts, which promotes crystallization. Under such conditions, the nucleation rate is large but the crystals have little time to grow. This results in a large density of very small crystals, referred to as *microlites* or *nanolites*. They act to change the magma properties and, in particular, may increase the viscosity significantly.

How gas pressure evolves during magma ascent dictates further volatile exsolution and phase relationships in the melt. At any level in the conduit, gas pressure is in general equal to neither the flow pressure (or bulk pressure) nor the surrounding rock pressure. Three different pressures are therefore involved. Gas bubbles grow in size because they contain an increasing mass of

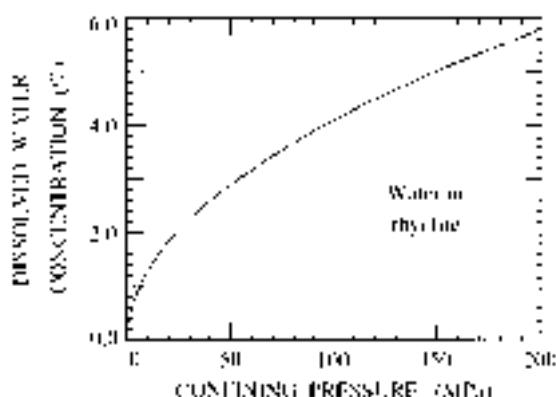

FIGURE 2 Solubility of water in a rhyolitic magma as a function of pressure.

volatiles by diffusion from the melt and because gas expands as pressure decreases. Such a volume change is achieved by deforming the liquid around the bubble and is driven by a pressure difference between gas and liquid. In other words, gas is overpressured with respect to the liquid. At the Earth's surface, this overpressure may be responsible for catastrophic expansion of lava, that is, an explosive event. The flow pressure is in general not equal to the country rock pressure, because it is determined by the starting pressure (the chamber pressure) and the head loss due to flow. A typical circumstance is that the flow is overpressured with respect to country rock, and this may lead to fracturing of country rock. In the field, researchers often see dykes, or thin magma-filled fractures, radiating outward from a central conduit. The opposite situation can also occur, and the conduit may "cave in," with dramatic consequences to the eruption.

### B. Gas Budget of an Eruption

For a given amount of magma, we can estimate the amount of gas that erupts simultaneously using solubility laws, initial volatile content, and assuming closed-system conditions, that is, that the gas and melt phases do not separate. This procedure may not give the correct answer because of three different effects. One is that equilibrium thermodynamics may not apply for large decompression rates: Exsolution and gas expansion are sensitive to the kinetics of bubble growth. Another factor is that the gas may have a significant velocity with respect to the liquid phase. A third factor is that gas may be added to or subtracted from magma. We have just seen that pressures in the flow and in country rock may not be equal to one another. If the flow pressure is larger than the country rock pressure, gas may be driven out of the conduit. Thus, an initially volatile-rich magma may end up as gas-poor lava at the surface. If pressures are smaller in the flow than in the surroundings, groundwater may be siphoned out of country rock into the rising magma.

### C. Decompression and Degassing

With falling pressure, gas starts to exsolve and collect into individual bubbles. Two independent processes are involved: bubble nucleation and growth. Studies of these processes have progressed rapidly in recent years and it has been shown that, in most circumstances, degassing may be approximated by conditions of local thermody-

namic equilibrium between the gas phase and the bulk liquid. Departures from such local equilibrium conditions are achieved at large eruption velocities. For our present purposes, it is sufficient to consider equilibrium relations. At any pressure  $P_g$  smaller than the saturation threshold, the local concentration of volatiles in the magma is equal to  $C_g$ , which is less than the initial concentration  $C_i$ . In a closed system, the difference between the two concentrations is taken up by the gas phase. The mass fraction of gas in the mixture,  $x_g$ , is approximately equal to

$$x_g = \frac{m_g}{m_T} \approx C_i - C_g,$$

where  $m_g$  is the mass of gas in a parcel of total mass  $m_T$ . This approximation is only valid if volatile concentrations are much smaller than 1, which is also required for Henry's law. If the system is not closed, but open to gas escape, the mass fraction of gas is smaller than this value. In a limit case, the mixture may lose all of its gas, and the mass fraction of gas is kept at zero throughout ascent. The density of the magma/gas mixture,  $\rho$ , is calculated as follows:

$$\frac{1}{\rho} = \frac{x_g}{\rho_g} + \frac{1 - x_g}{\rho_m}$$

where  $\rho_g$  and  $\rho_m$  are the densities of the gas and magma, respectively. At crustal pressures, a reasonable approximation for the equation of state of water is the ideal gas law:

$$\rho_g = \frac{MP_g}{GT}$$

where  $M$  is the molar mass,  $G$  the perfect gas constant, and  $T$  temperature. The volcanic mixture expands rapidly, such that gas eventually becomes the dominant phase by volume. Figure 3 shows how the gas volume fraction evolves for two different, but rather small, initial water concentrations. Even in those cases, gas takes up more than 80% of the mixture by the time it leaves the vent. Many magmas have higher volatile contents, and hence lead to erupted mixtures with as much as 98% gas by volume.

### III. FLOW DYNAMICS

How magma deforms is critical for understanding which flow velocities are reached for given pressure conditions in the plumbing system. At high temperatures, magma behaves as a Newtonian fluid, with the shear rate (the

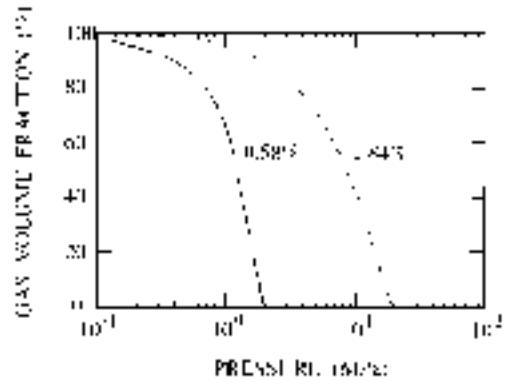

FIGURE 3. Volume fraction of gas for a magma parcel with given initial water concentration, as a function of pressure. Two different initial water concentrations are shown: 0.58%, corresponding to a saturation pressure of 2 MPa, and 1.84%, corresponding to a saturation pressure of 20 MPa. Note that in both cases the gas phase dominates over the melt phase in terms of volume.

gradient of velocity) being directly proportional to the applied stress. Flow behavior is described by a single parameter, viscosity, noted as  $\mu$ . However, the magma that rises in the conduit is more complicated because it is made of melt, gas, and possibly some suspended crystals. Crystals act to increase viscosity and, if they take up a sufficiently large fraction, change the flow behavior. At very large values of velocity, magma is deformed rapidly, so rapidly in fact that it may not respond viscously. In this case, magma behaves as brittle material and breaks into pieces. The viscosities of natural magmas vary within a very large range. The most fluid magmas are probably carbonatites, with viscosities of about 0.5 pascal seconds (Pa s; 500 times the viscosity of water). This general end of the viscosity range also encompasses one of the most common magma types: basalts. At the other end of the viscosity range, we find dry high-silica rhyolites, whose viscosities may exceed  $10^{12}$  Pa s. Such an extraordinary variation of physical properties has fundamental consequences for the movement and eruption of magma. Silicic lavas such as rhyolites and dacites are much more viscous than basalts. One important feature of magmas is that their viscosity varies dramatically with decreasing dissolved water concentration (Fig. 4). The rate of change of magma viscosity with falling pressure is largest at small water contents and, hence, at shallow levels.

#### A. Two-Phase Flow Regimes

Close to the Earth's surface, the ascending magma is a mixture of gas and liquid. How such a mixture flows

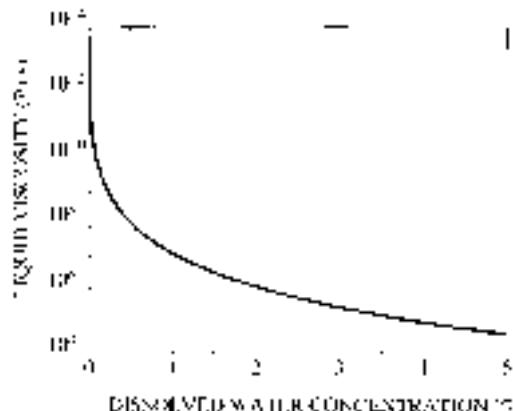

FIGURE 4 Viscosity of silicic melt as a function of dissolved water concentration. [Adapted from Hess and Dingwell, 1996.]

depends on the relations between the gas and liquid phases (Fig. 5). At small values of gas volume fraction, gas is contained in individual bubbles carried by the liquid, which corresponds to the *bubbly flow* regime. In this regime, the bulk behavior of the magma/bubble mixture depends on whether or not bubbles deform. At small velocity (small shear rate), surface tension keeps gas bubbles spherical. This impedes flow because shear gets focused in thin liquid regions between neighboring bubbles. At larger velocity (large shear rate), bubbles are elongated, which acts to lubricate the flow.

At larger values of gas volume fraction, individual bubbles may coalesce and generate large gas pockets, and the flow is in the *slug* or *intermittent* regime (Fig. 5). At still larger values of the gas volume fraction, the gas pockets extend over most of the conduit and the flow is best described as a central gas core with a thick film of liquid lining the conduit walls. In the fourth

regime, called *dispersed*, magma is in the form of small fragments carried within a continuous phase. This regime may be achieved in two different manners, depending on magma viscosity. In viscous silicic melts such as rhyolites or dacites, bubbles cannot move through magma and the *slug* and *annular* regimes are not possible. With decompression, a magmatic foam develops and becomes unstable near the surface. At this stage, bubbles burst, pulverizing magma into droplets. This has been called *fragmentation* and may involve several mechanisms, which are outside the scope of this chapter. For our present purposes, what matters is that the magma/gas mixture changes from a continuous liquid phase into a continuous gas phase. In low-viscosity basaltic melts, bubbles can migrate within magma and the flow is expected to go through the *slug* and *annular* flow regimes. With increasing decompression, the central gas jet becomes increasingly more powerful and eventually blows the film of magma lining the conduit walls. The end result is the same dispersed regime.

We can recognize the four different regimes in natural eruptions. Vesicular lava oozing out of a vent in an effusive eruption gives an example of the *bubbly flow* regime. This regime may be observed in all settings, regardless of magma composition and viscosity. "Strombolian" activity is characterized by the bursting of large gas pockets at the top of a magma-filled conduit and corresponds to the *intermittent* regime. *Annular* flow seems much less common and may be associated with fire fountaining, where "curtains of lava" are ejected out of basaltic vents. Strombolian activity and fire fountaining are restricted to low-viscosity magmas such as basalts. The *dispersed* regime is very common and corresponds to the *Plinian* and *pyroclastic* flow eruptions. These two eruption types are most common in silicic volcanoes but have also been achieved in basaltic ones. Fire fountaining may also be an example of this behavior.

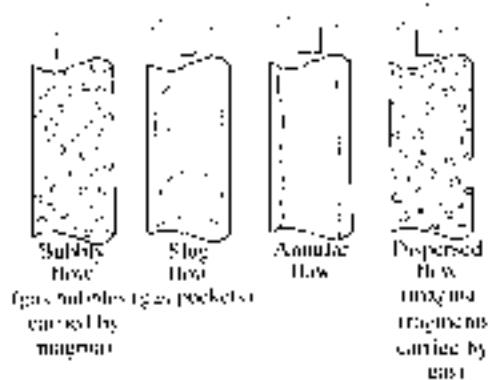

FIGURE 5 The four major types of flow regimes predicted for a mixture of gas and liquid. These four types of behavior can be observed in natural eruptions.

### C. Bulk Flow Conditions

It is convenient to think of flow in terms of a balance between different forces. In most cases of volcanological interest, we can neglect the motion of gas bubbles and it is sufficient to treat the ascending mixture as a material whose physical properties depend solely on gas content. For a given driving pressure, flow develops against the weight of the magma/gas mixture and the inertial and viscous stresses. If viscous forces dominate, flow is in a laminar regime, with flow trajectories parallel to the conduit walls. If, on the other hand, inertial forces are

more important, flow is in a turbulent regime, such that it is well mixed by energetic eddies. These two regimes differ strongly in their dynamics and velocity profiles and can be defined using a single dimensionless number called the Reynolds number:

$$\text{Re} = \frac{\rho W R}{\mu},$$

where  $W$  is a typical value for the velocity,  $R$  the conduit radius,  $\rho$  is the flow density, and  $\mu$  the mixture viscosity. Below a threshold value of about 100, flow is laminar and the radial velocity profile is parabolic with a maximum at the conduit axis (noted  $W_M$ ). The mass discharge rate is calculated to be

$$Q = \frac{\pi}{2} \rho W_M R^2.$$

In steady state, mass flux  $Q$  must remain constant and independent of height in the conduit. Thus, if the conduit radius does not vary by large amounts, quantity  $(\rho W_M)$  is constant. Volatile exsolution and gas expansion lead to a large reduction of density and hence to a very large increase of velocity (up to 100-fold). Thus, for magma rising through a conduit, density and velocity change by significant amounts due to volatile exsolution and gas expansion, but such changes counterbalance one another and the Reynolds number only varies as a function of viscosity. In general, mass discharge rates seldom exceed  $10^8 \text{ kg s}^{-1}$  and conduit radii are typically in a range of 10–100 m. For typical silicic magma viscosities (larger than  $10^6 \text{ Pa s}$ ), the Reynolds number is less than 10. This reasoning is only valid insofar as the relevant viscosity is that of magma. This is true for the bubbly flow regime, but not for the other regimes. In the dispersed regime, the mixture is made of gas and fragments. In this case, the relevant viscosity drops to very small values, less than  $10^{-3} \text{ Pa s}$ , and the Reynolds number jumps to very large values. We must therefore envision a volcanic conduit as being separated in two sections where the flow dynamics are totally different: a lower part where flow is laminar and an upper part with turbulent conditions (Fig. 6). For magma parcels rising through the conduit, the consequences are important. In the lower part, parcels that rise through the conduit center are subjected to large decompression rates, whereas parcels rising near the walls experience very small decompression rates. Degassing kinetics may therefore be markedly different. In the upper and turbulent part of the flow, however, we can treat the rising mixture as well mixed.

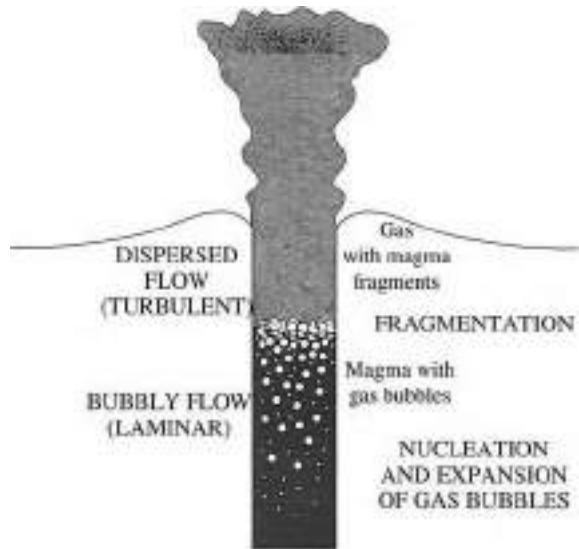

FIGURE 6 Diagram showing the main phases of magma ascent at shallow levels, such that the magmatic gas phase plays a key role.

#### IV. MASS DISCHARGE RATE AND ASCENT VELOCITY

We have so far treated a flow with prescribed characteristics. The next step is to predict those characteristics using fluid mechanical models. Many such models have been used by volcanologists to investigate different eruption types, but they can only be considered exercises because they require many inputs that remain poorly known. We can regard a volcanic system as a conduit with specified pressures at the two ends. The two critical inputs are the conduit dimensions and mixture rheology. To solve for the flow conditions, we use classical equations for the conservation of mass, momentum, and energy. In an eruption, the mass discharge rate rarely stays constant and we might frequently observe a sequence of increasing mass discharge rate followed by a waning phase, which eventually leads to the cessation of activity. We might also witness fluctuations of mass discharge rate. Such changes may be due to changes of driving pressure, magma composition, or conduit size.

##### A. Driving Pressure

The driving pressure difference can be calculated simply for a volatile-free magma, such that the magma density,  $\rho_m$ , remains constant over the whole conduit height.

Consider a magma column extending from a reservoir located at depth  $H$  to the vent. At the vent, the exit pressure may not be equal to the atmospheric pressure  $P_a$ , either because the flow has reached sonic velocities (see later discussion) or because a lava flow has built up over the vent. The pressure difference between the top and bottom of the magma column is

$$\Delta P_1 = \rho_m g H + \Delta P_e,$$

where  $\Delta P_e$  is the vent overpressure (Fig. 1). For a lava flow, the vent overpressure is due to the weight of overlying lava, and is  $\Delta P_e = \rho_m g b$  for lava thickness  $b$ . The pressure difference across the magma column is then

$$\Delta P_1 = \rho_m g (H + b).$$

This can be compared to the pressure difference between the surface and the top of the magma reservoir:

$$\Delta P_2 = \rho_r g H + \Delta P_c.$$

This pressure is equal to the lithostatic pressure, that is, due to the weight of the overburden, plus a pressure differential  $\Delta P_c$  due to the fact that country rock may deform. The driving pressure is  $\Delta P = \Delta P_2 - \Delta P_1$ . If it is zero, the magma column is in static equilibrium and there is no flow. In the lava flow case,

$$\Delta P = (\rho_r - \rho_m) g H + \Delta P_c - \rho_m g b.$$

This shows three terms. The first represents magma buoyancy, showing that magma is driven upward if it is less dense than country rock. The two other terms may vary with time and hence may be held responsible for variations of mass discharge rate. The chamber overpressure,  $\Delta P_c$ , changes as a function of input of magma from depth and output into the eruptive conduit. If the output exceeds the input, the overpressure diminishes, and the mass discharge rate decreases. In the opposite case, the chamber may become increasingly overpressured. The last term on the right-hand side is the weight of lava over the vent, which depends on the dynamics of lava flow at the surface. If a thick lava flow develops, this term may become significant and may even lead to the cessation of activity. One striking example is that of Montagne Pelée in 1902, which grew a tall spine exceeding 300 m in height after its climactic eruption.

## B. Conduit Geometry

The conduit is a critical component that, for obvious reasons, is difficult to observe over the whole distance between reservoir and vent. Its walls are not straight and smooth and its shape is poorly known. The conduit

may not remain the same during a single eruption. For example, if the flow is very energetic, it may be enlarged by erosion or reduced by foundering of the walls. In a slow eruption, it may be choked by the chilling of magma against the walls. It is therefore difficult to predict *a priori* the value of mass discharge rate. Basaltic eruptions may occur out of fissures, several hundred meters long and a few meters wide. For silicic magmas, direct observations during an ongoing eruption are seldom possible but we might observe fossil conduits in a variety of geologic settings with widths of 10–100 m. At Mount St. Helens, following an explosive event that left the vent free of lava, it was possible to measure a conduit radius of about 30 m. Toward the surface, volcanic conduits seem to flare upward. Observations of fossil conduit walls show that they are fractured and have highly irregular outlines. The fractures may contain ash and pyroclasts, showing that the ascending material has leaked into the country rock. Gas escaping from the conduit feeds the ubiquitous fumaroles found on volcanic slopes and craters.

## C. Flow Rate

In laminar flow conditions, the horizontal profile of ascent velocity is parabolic (the “Poiseuille” profile) starting from zero at the walls and reaching a maximum at the conduit axis. Assuming that the conduit has a circular cross section with radius  $R$ , the mass flux at some arbitrary height  $z$  in the conduit is

$$Q = \frac{\pi R^4}{8\mu} \left[ -\frac{dP}{dz} - \rho g \right]$$

where  $dP/dz$  is the vertical pressure gradient. Assuming that the mixture viscosity and density are constant over the whole conduit, and equal to the values for pure magma, we obtain

$$Q = \rho_m \frac{\pi R^4 \Delta P}{8\mu H} = \rho_m \frac{\pi R^4}{8\mu} \left[ (\rho_r - \rho_m) g + \frac{\Delta P_c - \rho_m g b}{H} \right]$$

where we find the driving pressure  $\Delta P$  calculated earlier. This shows that the mass flux is highly sensitive to the conduit radius. It also shows that, for given pressure conditions and conduit dimensions, the mass flux is inversely proportional to magma viscosity. This explains why basaltic lavas are in general erupted at higher velocities than silicic lavas. This equation also shows how pressure conditions affect the flow rate, but is in general inadequate because of viscosity and density changes. In this case, the “local” equation at height  $z$  still holds,

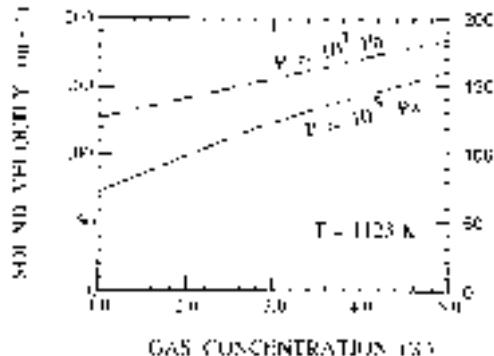

FIGURE 7 Sound velocity in a mixture of gaseous water and magma, as a function of water content. Two curves are shown for two different values of pressure.

however, and may be rewritten as an equation for the pressure gradient:

$$-\frac{dP}{dz} = Q \frac{8\mu}{\pi \rho R^4} + \rho g$$

This shows that the pressure gradient is the sum of the head loss due to viscous stresses and the weight of the magma. This also shows that an increase of viscosity implies an increase of pressure gradient. Conversely, an increase of radius implies a decrease of pressure gradient.

At large Reynolds number, the dynamics are different and the ascent velocity is almost constant in a horizontal cross section. The eruption velocity tends toward that of sound waves propagating through the mixture:

$$W_s = \left[ \frac{dp}{dz} \right]^{-1/2}$$

The values of this threshold velocity are given in Fig. 7. In a straight conduit, this is the maximum velocity that can be achieved, which corresponds to *choking*, a self-explanatory term. Many volcanic eruptions contain sufficient amounts of gas to be in such conditions, with two important consequences. One is that the exit velocity is independent of magma viscosity and, for all practical purposes, independent of magma composition and conduit dimensions. The second consequence is that the flow does not exit the vent at atmospheric pressure and expands dramatically above it. In this regime, the mass discharge rate is given by

$$Q = \pi R^2 \rho W_s,$$

which differs from the laminar flow equation given earlier in two important ways. One is that the mass discharge rate is much less sensitive to the conduit dimensions than in laminar conditions and the other is that it is independent of magma viscosity. Thus, the mass discharge rate varies within a restricted range.

#### D. Model of Magma Ascent with Degassing

We can solve the equations of motion from the reservoir to the surface including the effects of a major rheological change at fragmentation, when the rising mixture changes from a bubbly liquid to a gas carrying suspended magma fragments. In this calculation, the *closed-system* approximation is used, such that the exsolved gas does not escape to the country rock, and the viscosity of the magmatic phase varies as a function of dissolved water content as illustrated in Fig. 4. Here, for the sake of example, fragmentation is taken to occur at some threshold value of the gas volume fraction (70%). The evolution of flow pressure in the conduit is characterized by three distinct regions (Fig. 8). From the base of the conduit to the saturation pressure, when exsolution begins, the flow pressure decreases linearly due to both the weight of the magma and viscous shear. Between the exsolution and fragmentation levels, pressure decreases rapidly, due to the large increase of magma viscosity. Above the fragmentation level, friction is much smaller than before because the ascending mixture is basically a gas, implying that pressure decreases at a reduced rate. Figure 8 illustrates that magma ascent involves marked changes of physical properties and flow regime. It also indicates that flow pressures are in general not equal to pressures in the surroundings. Toward the surface, the flow pressures are predicted to be significantly smaller than those in country rock. This is due to two factors. One is that the density of the gas/magma mixture is very small, which implies a small head loss. The other

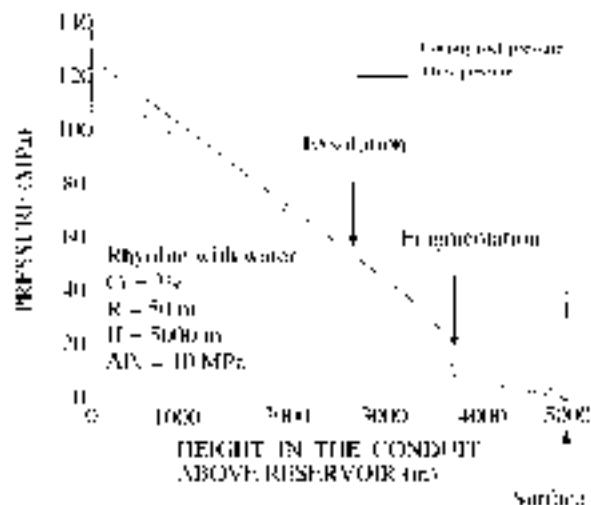

FIGURE 8 Flow pressure as a function of height in a conduit for rhyolitic melt. The dashed curve shows the pressure distribution in the country rock. [Adapted from Massol and Jaupart, 1999.]

is that fragmentation has occurred, implying a reduced wall friction. If we allow for extensive gas escape toward country rock, we might obtain a completely different solution. In a limiting case, the magma loses all of its gas to the surroundings and therefore flows almost as a pure liquid in laminar conditions. The end result is a flow pressure that remains above country rock pressures.

### E. Postfragmentation Events

After fragmentation, the rising mixture is made of a continuous gas phase carrying magma fragments. At this stage, flow velocities are very large and magma fragments spend little time in the conduit before ejection into the atmosphere. However, several processes modify the structure of the flow prior to eruption at the surface. Magma fragments expand and probably burst, generating smaller fragments. Additionally, the fragments collide against one another and may break up. Thus, the size of fragments keeps on evolving. Fragment collisions and fragmentation are also held responsible for electrical charging effects and for the spectacular lightning effects commonly observed in volcanic atmospheric plumes. As the volcanic mixture rises toward the surface, it may lose some gas to fractured and permeable country rock. This key process is difficult to understand in detail because it involves many different ingredients: a continuous gas phase through the magma, gas wetting the conduit walls, permeable country rock, and horizontal pressure gradients. Such a variety makes it difficult to assess in each and every case. One key aspect is that its importance depends on the balance between ascent velocity and horizontal “leakage” velocity: A fast eruption leaves no time for large amounts of gas to escape.

---

### V. CONCLUSIONS

As magma rises in a conduit, the gas and flow pressures are not equal to pressures in the surrounding rocks and must be calculated with a dynamic flow model. Such models are required to understand how volcanic eruptions may occur in different regimes, and how they may switch from one regime to the other. They also enable us to use surface observations to obtain constraints on the characteristics of the deep plumbing system. Finally, they help us unravel the various changes brought on magma near the surface. The models emphasize that

the key phases of magma evolution occur at shallow levels: gas becomes very abundant at small pressures, implying large velocity changes. Gas leakage is also most significant near the surface because it is there that country rock fractures are numerous and open to flow. Although the models are based on sound physical principles, they suffer from two basic deficiencies. One is that the dimensions of the plumbing system are not known at depth, and the other is that the fragmentation process remains ill understood. Thus, present research is being oriented in two directions. One is to study fragmentation, which may be done in the laboratory and by comparing field data with theoretical predictions. Another direction is to use natural tracers to follow directly the ascent process. Pumice and ash samples, which are quenched fragments of vesicular magma, provide a record of degassing and expansion conditions that can be deciphered using dynamic models.

# ERUPTION

Eruptions are exciting. It is almost impossible to think of a volcano without contemplating the awesome power displayed during an eruption. But what exactly is an eruption? How long do eruptions last? How long does a volcano remain dormant between eruptions? Have volcanoes always erupted as they do now and where they do now? These are just a few of the fundamental questions addressed in this section.

We begin with an overview chapter, Earth's Volcanoes and Eruptions, which serves as an introduction to the various types of eruptions that occur at the Earth's surface and how they vary with geographic location. The theory of plate tectonics is used to explain the present day distribution of active volcanoes, which are defined as those historically active or active within the last 10,000 years.

It is sobering to remember that our own history is pitifully short compared with the lifetime of an average volcano. It is quite possible for a volcano not to have erupted at all since humans began documenting their surroundings, but to be simply dormant right now, between periods of activity. The longer ago that an eruption took place, the harder it is to gather evidence of what exactly took place; the products of the eruption are subject to the same erosion processes as any other rocks. Therefore, the further back in geological time that we look, the larger the eruptions need to have been for us to identify them. On the other hand, large eruptions are now less common than small eruptions, and this has probably always been true. Products from huge caldera forming eruptions therefore will be found not in the most recent volcanic deposits, but buried deep in the geological record.

Detailed analysis of all the available evidence from the last 10,000 years has led the authors to deduce the approximate frequency at which we can expect eruptions of various sizes. For example, small eruptions, such as that at Nevada del Ruiz in Colombia in 1985 killing 23,000 people, occur typically several times a year, although fortunately usually without such tragic consequences. The Mount St. Helens event of 1980 occurs on average once each decade. It is unclear, however, how frequent much larger eruptions are.

Almost as important as predicting the onset of volcanic activity, and certainly more difficult, is predicting when an eruption will cease. With a few notable exceptions, such as Stromboli in the Aeolian Sea offshore Italy, which has been erupting steadily for at least 2500 years, the average eruption duration is about 7 weeks. Some last for only a day and the longer the dormant period, the larger the final eruption.

Just as earthquakes can be defined using scales of magnitude and intensity, so can volcanic eruptions. Estimates of the magnitude and intensity of eruptions can be made for very large events millions of years ago using a comparison of the distribution and volume of erupted products (ash and lava) with those of smaller, recent

events. In the chapter Sizes of Volcanic Eruptions, David Pyle defines eruption magnitude and intensity and illustrates the use of these properties for understanding the mechanisms driving the colossal eruptions of the past.

Finally in this section, Haraldur Sigurdsson addresses how the rate of volcanism has varied through geological time. Because there have been no really large caldera forming eruptions since humans have been on Earth, it might be inferred that such things will not occur in the future. However, we know that large eruptions occur less frequently than smaller eruptions. In the chapter Volcanic Episodes and Rates of Volcanism, Sigurdsson considers the last 65 million years of Earth history and puts into geological and geographical perspective the fluctuations in the magnitude and intensity of volcanism over this time. Evidence shows that there have been several episodes of increased volcanism worldwide in the past and a possible link with climate change. Whether climate change is a cause or an effect of variations in the rate of volcanism remains an intriguing question.

## I. INTRODUCTION

Most volcanoes are slumbering, deceptive agents of change. They may offer benefits such as scenic beauty and geothermal energy, but they may also turn swiftly violent, causing tragic destruction and fatal consequences. Volcano lifetimes are long compared to ours, and most of those lifetimes are spent in repose. However, because our memories (and histories) tend to be short, volcanic violence too often takes us by surprise. In recent decades, though, we have seen major advances in understanding how volcanoes work. These have been spurred in part by dramatic natural events, such as the 1980 eruption and debris avalanche at Mount St. Helens, or the climatic impact of eruptions like Mexico's El Chichón (1982). But these advances also result from improvements in global communication, remote sensing, and interdisciplinary cooperation. In light of these advances, this chapter attempts to answer these questions: Where are the world's volcanoes? What do they do? How often do they do it?

Understanding the impact and hazards posed by volcanic activity requires information on the frequency, duration, magnitude, and rates of volcanism in both space and time. We will review what we have learned, with primary emphasis on the past few thousand years. This record is short, by geologic standards, but it is a rich and important source of information on all but the largest eruptions affecting our planet. It provides our best numerical basis for extrapolating the observations and measurements of contemporary eruptions to better understand those of both the past and the future. Our review draws on two Smithsonian resources: (a) our reporting of current volcanic activity around the world and (b) our computerized, retrospective database of historical and other dated volcanism during the past 10,000 years (Holocene time). The first began in 1968 as the Center for Short-Lived Phenomena, but was moved, reorganized, and renamed as the Scientific Event Alert Network (SEAN) in 1975. Further concentration on volcanology led to its being renamed the Global Volcanism Network (GVN) in 1990, and it continues today with a monthly *GVN Bulletin* and other outlets. The database began in 1971 and has grown steadily, through careful compilation of information from a multitude of sources, to cover more than 1500 volcanoes of the world and 8000 dated eruptions.

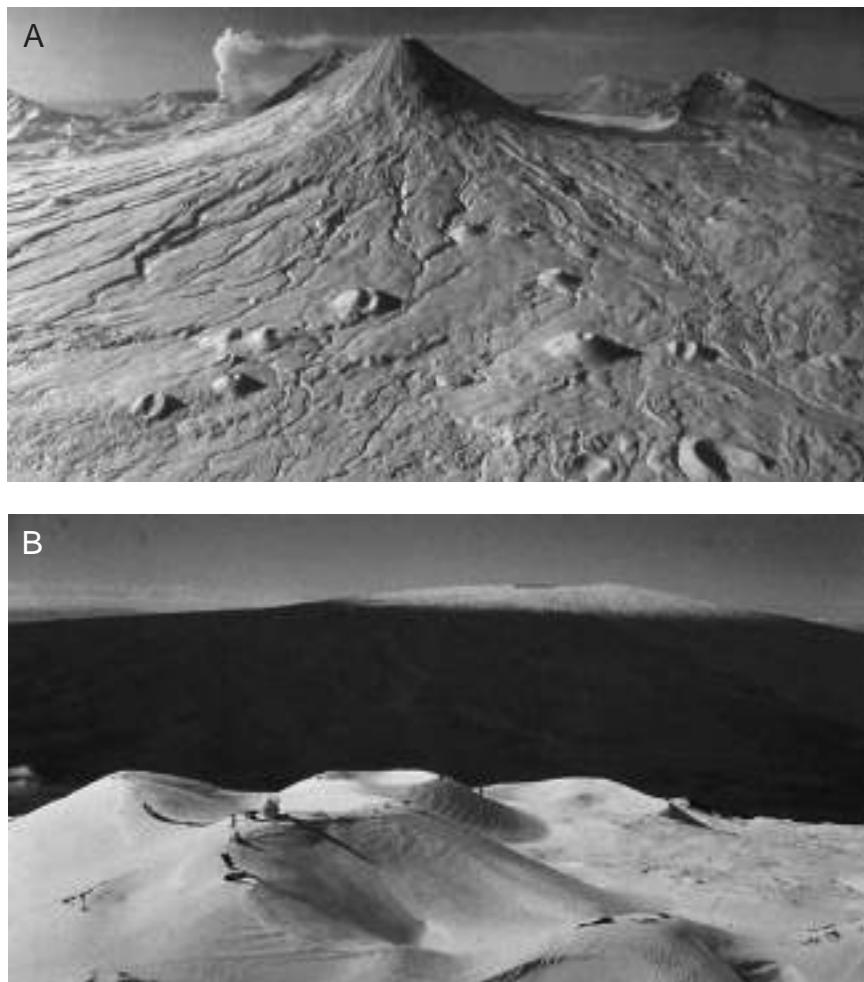

## II. VOLCANOES

Most volcanoes are not majestic, symmetrically conical, snow-capped giants. They in fact range widely from small cinder cones to huge piles of lava, standing 10 km above the ocean floor. Some, like Yellowstone in the United States or New Zealand's Lake Taupo, do not even identify themselves by rising above the surrounding landscape. Volcanoes reflect the varied processes that shaped them, and with a wide range of plumbing sys-

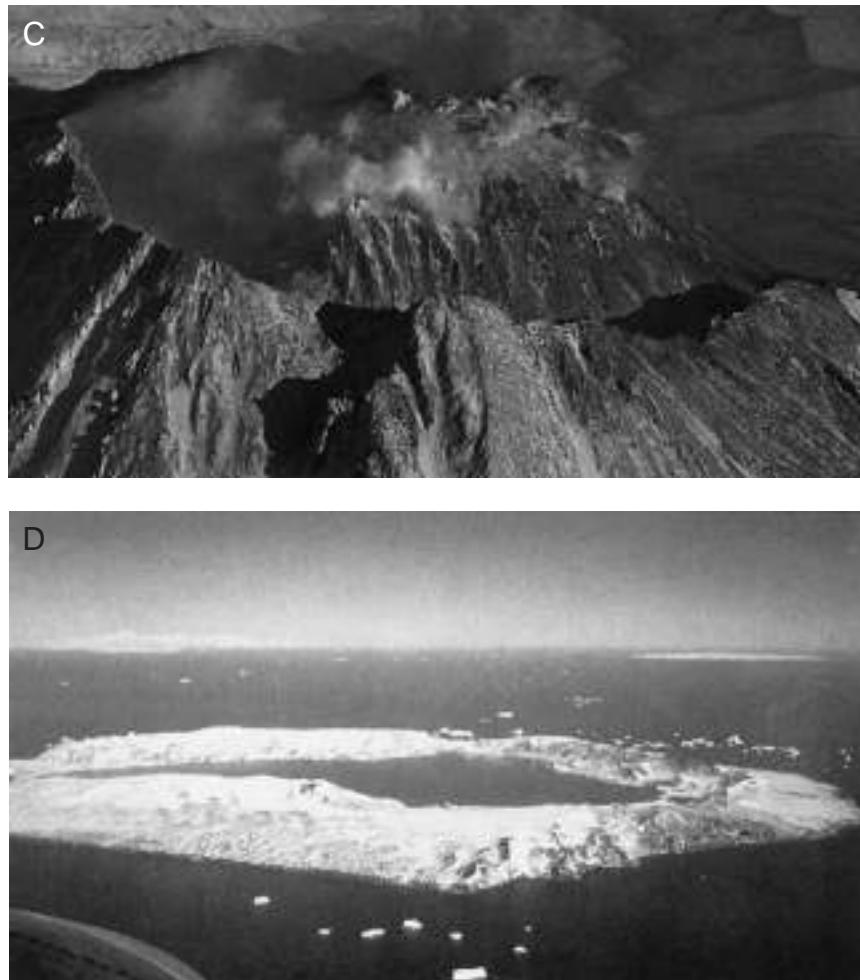

tems, supply rates, magma types, and eruption styles, it is not surprising that a wide range of features results. Furthermore, volcanic processes include many that destroy and modify earlier constructions, adding to the variety of forms that fall under the name *volcano*.

### A. Types

Volcanoes are born when subsurface magma, normally less dense than surrounding rock, rises buoyantly toward

**FIGURE 1** Volcano shapes reflect the wide range of variations in lava chemistry, vent orientation, gas content and eruptive style. (A) Stratovolcanoes include towering symmetrical cones like Kamchatka's Kliuchevskoi (center) and irregular compound volcanoes like Ushkovsky (right). Kliuchevskoi's frequent eruptions originate both from the central vent and from radial fissures that produced the flank cinder cones in the foreground. (Photograph by V. A. Podtabachny; courtesy of Anatolii Khrenov, Institute of Volcanology, Petropavlovsk; also see color insert.) (B) Shield volcanoes grow through the repeated effusion of thin lava flows to form Earth's largest volcanic edifices. Their volumes can exceed those of stratovolcanoes by several orders of magnitude. Here the low-angle slopes of Hawaii's broad Mauna Loa volcano, rising 9 km above the seafloor, forms the horizon. In the foreground, a cluster of cinder cones, among Earth's smallest volcanic features, caps the summit of an older shield volcano, Mauna Kea. (Photograph by Don Swanson; U.S. Geological Survey.)

**FIGURE 1 (continued)** (C) A steaming lava dome has grown incrementally through the extrusion of viscous lava inside the breached crater of Kamchatka's Bezymianny volcano. The horseshoe-shaped crater formed as a result of a massive volcanic landslide during a 1956 eruption remarkably similar to that at Mount St. Helens in 1980. (Photograph by Yuri Doubik; Institute of Volcanology, Petropavlovsk; also see color insert.) (D) Large volcanic calderas, formed by inward collapse following the eruption of large volumes of magma, are among Earth's most dramatic volcanic features. A 7-km-wide caldera flooded by the iceberg-laden waters of Antarctica's Bransfield Strait truncates the summit of ring-shaped Deception Island. (Photograph by Juan Bastias; courtesy of Oscar Gonzalez-Ferran, University of Chile.)

the surface. In its path upward, magma understandably exploits local fracture systems and, where long, linear fractures are present, a “curtain of fire” fissure eruption may result. Alternatively, magma may follow the line of weakness formed where two vertical fracture planes intersect, resulting in a pipelike vertical conduit building a symmetrical cone (Fig. 1A). Many gradations and complexities exist, even changing during the course of a single eruption. The supply of magma to the surface is commonly irregular, even sporadic, and if the supply ceases for too long the next batch will be forced to find another route to the surface because the old conduit will have been blocked with cooled, solidified magma.

Thus fields of numerous small cones are formed or (again depending on supply rate and plumbing systems) large mountains dotted by smaller cones.

Perhaps the most influential factor in shaping volcano landforms, though, is the manner in which gas exits the magma. As magma nears the surface, the attendant decrease in pressure permits exsolution of dissolved gases, which then drive the eruption vertically (the only direction in which it is free to expand). Both gas content and viscosity vary widely in magmas, and the more gas-rich, viscous, and lower temperature compositions common to continental margin magmas tend to explode violently, fragmenting the liquid into countless small

particles that cool swiftly as volcanic tephra. This process can form small cones of ash, layer upon layer, or (depending on the violence and longevity of the explosions) thin, widely dispersed ash layers. In contrast, gas separates more easily from the less viscous, hotter, and less gas-rich magmas of both spreading centers and oceanic islands, where lava flows passively from vents to form gentle slopes as on Hawaii (Fig. 1B). All gradations of products exist—from gentle flows, through near-vent spatter, to scoria, cinder, ash, and pumice—with resulting volcanic shapes depending on the gas content, magma chemistry, and eruptive style. Often the most violent explosive eruptions are followed by slow, “toothpaste tube”-like extrusions of viscous, degassed magma to form steep-sided domes in the vent (Fig. 1C).

The wide variety of initial constructional shapes is further expanded by additional processes during a volcano's lifetime. For example, a lateral shift in the plumbing system of a simple stratovolcano turns it into an asymmetric compound volcano. Destructional processes such as major slope failure (as at Mount St. Helens in 1980) or caldera collapse (as at Crater Lake, 6800 yr ago) may dramatically change a volcano's shape, and erosion is a relentless modifier in most parts of the world. Such varied processes lead inevitably to the enormous diversity of volcanic forms on the planet.

## B. Distribution

Volcanoes are not randomly distributed on Earth's surface. The global volcano map (inside back cover) shows the distribution of about 1500 terrestrial volcanoes with probable activity in the last 10,000 years. This broader time interval provides more uniform coverage of active volcanism than the regionally variable historical record, and includes most volcanoes likely to erupt again. Tectonic setting, discussed in more detail later, clearly plays a major role in volcano distribution. Although some volcanoes are scattered, most are concentrated in linear belts, and these belts have accounted for >94% of known historical eruptions. The belts total 32,000 km in length and (assuming a generous 100-km belt width) cover less than 0.6% of the Earth's surface. Most are adjacent to deep oceanic trenches, and it is clear that subduction of one plate beneath another (where oceanic crust is being consumed at converging plate margins) causes most of the volcanism that we see. The complementary tectonic process of rifting (the creation of new crust at diverging plate margins) takes place largely on the deep ocean floor, unwitnessed by humans. The left

half of Fig. 2 shows the small proportion of the world's historically documented eruptions that have taken place in the ocean rift environment (and in the intraplate environment, where hot spots deep in Earth's mantle feed molten rock to the surface through any plate passing overhead). It is possible, however, to use relative plate motions to calculate the budget of new lava reaching the Earth's surface each year and these estimates are shown in the right half of Fig. 2. Oceanic ridge volcanism overwhelmingly dominates the planet and, although most of it poses no threat to humans, this dominance must be remembered in a global perspective.

The geometry of Earth's tectonic plates means that the distribution of volcanoes by nations is also quite uneven. This national aspect has gained significance as attention to volcanic hazards—with attendant governmental expenditures for monitoring and other studies—has grown. Fully 80% of the world's population lives in, and presumably pays taxes to, nations with responsibility for at least one Holocene volcano. For some these volcanoes are in a distant overseas protectorate, while for others they loom over the nation's most populous city. Figure 3 shows the distribution of volcanoes by nation in terms of activity during several intervals: the past 10,000 years, variable lengths of historical documentation, and the 20th century. Indonesia leads the world in the number of historically active volcanoes, but many citizens would be surprised by the prominent position of the United States (including the Marianas and American Samoa, as well as Alaska, Hawaii, and the Cascades). The resources for dealing with volcanic hazards are also unevenly distributed, with more than

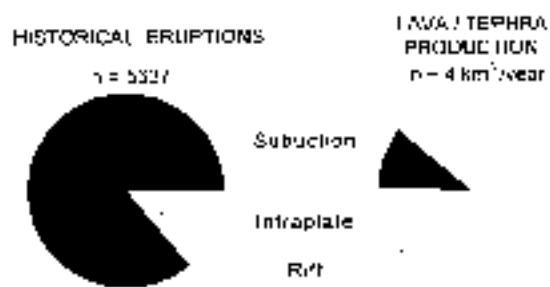

FIGURE 2 Volcanism distributed by tectonic setting (see text and inside back cover map of the world). Pie diagram on left shows proportion of documented historical eruptions from subduction zones (black), midocean ridges (stipple), and hot spot settings (white). Pie diagram on right shows proportion of annual magma budget in the same settings (with same symbols) to emphasize the dramatic contrast between the volcanism that we see and that we don't. Data for right diagram from Crisp (1984) and left from Smithsonian.

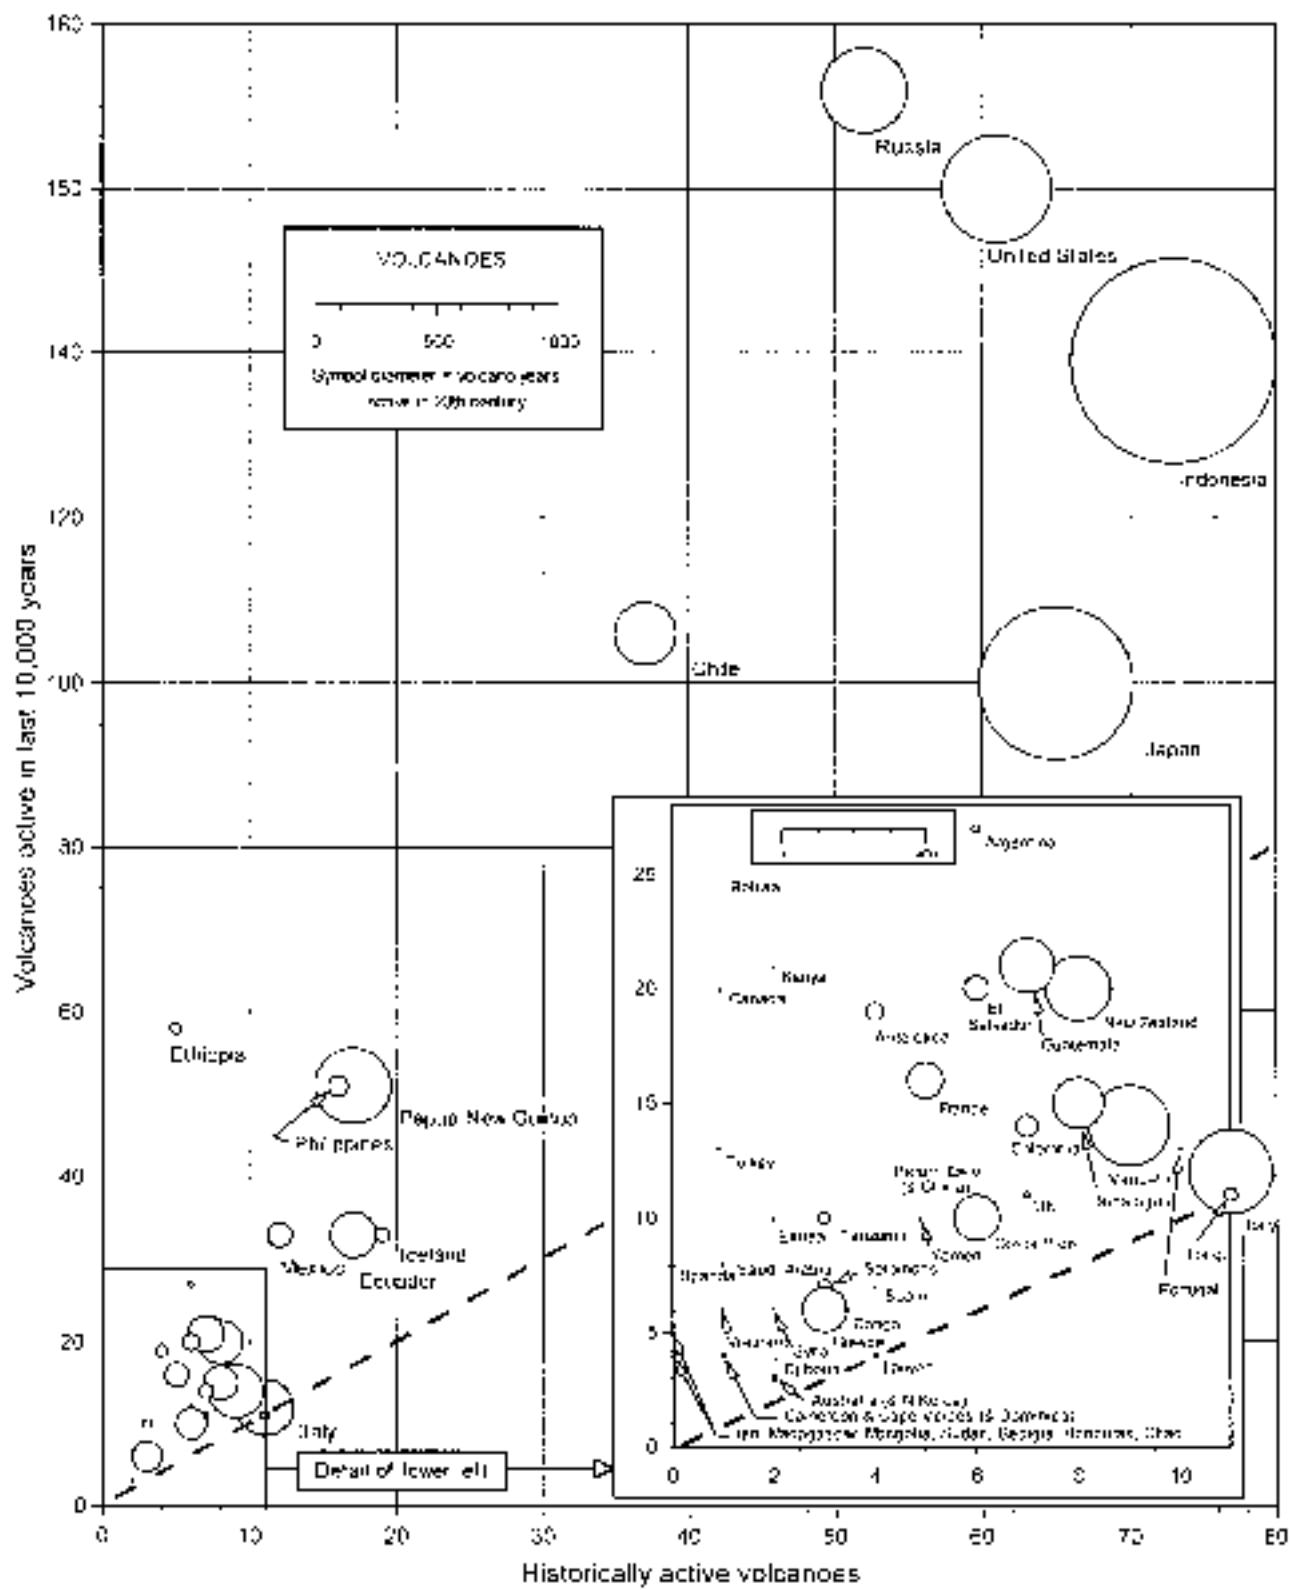

FIGURE 3 Volcano distribution by nation. The 56 nations shown here contain 98% of the world's historically active volcanoes and another 25 contain at least one volcano active in the last 10,000 years. Distance from the dashed line may indicate a short historical record, relatively thorough study of young-but-not-historical volcanoes, or a combination of the two. Circle diameter shows the wide range in volcanism within this century, a measure of the public awareness of volcanism evident in living memories. For this measure, we count all 20th-century years in which each volcano has erupted, and sum the counts for each nation.

half of the world's volcanoes located in nations with a per capita GDP (gross domestic product) of less than one-fifth that of the United States. But volcanoes disrespect national boundaries. Ashfall can be devastating to a downwind nation (e.g., Argentina during the 1991 eruption of Chile's Cerro Hudson); many airlines are threatened by ashclouds from major explosive eruptions along well-traveled flight paths (e.g., great circle routes to Japan over Alaska); and climatic effects of unusually large eruptions can be serious on the opposite side of the globe (e.g., June snowfalls—and crop failures—in New England following the 1815 eruption of Indonesia's Tambora). Clearly volcanic hazards are an international problem, calling for cooperation and resource sharing between nations.

### C. Number

How many active volcanoes are there in the world? The answer to this common question depends on use of the word *active*. At least 20 volcanoes will probably be erupting as you read these words (Italy's Stromboli, for example, has been erupting for thousands of years); roughly 60 erupted each year through the 1990s; 165 in the full decade 1980–1989; 550 have had historically documented eruptions; at least 1300 have erupted in the Holocene (past 10,000 years); and some estimates of young seafloor volcanoes exceed a million. Because dormant intervals between major eruptions at a single volcano may last hundreds to thousands of years, dwarfing the relatively short historical record in many regions, it is misleading to restrict usage of *active volcano* to recorded human memories: We prefer to add another identifying phrase (e.g., *historically active* or *Holocene volcano*).

The definition of *volcano* is as important in answering the number question as the definition of *active*. Usage has varied widely, with the term *volcano* being applied to individual vents, measured in meters, through volcanic edifices measured in tens of kilometers, to volcanic fields measured in hundreds of kilometers. We have tended toward the broader definition in our compilations, allowing the record of a single large plumbing system to be viewed as a whole, but this approach often requires careful work in field and laboratory to establish the integrity of a group's common magmatic link. The problem is particularly difficult in Iceland, where eruptions separated by many tens of kilometers along a single rift may share the same magmatic system. A "volcanic field," such as Mexico's Michoacan-Guanajuato field (comprising nearly 1000 cinder cones, derived from a single magmatic system, dotting a 200- by 200-km area) may be counted the same as a single volcanic edifice. Perhaps

the most honest answer to the number question is that we do not really have an accurate count of the world's volcanoes, but that there are at least 1000 identified magma systems—on land alone—likely to erupt in the future.

### D. Tectonic Setting

Although differences between broad volcano groups were recognized by early volcanologists, the conceptual development of plate tectonics in recent decades has provided a framework for such studies. Much attention has been devoted to understanding the features common to specific tectonic settings and how they relate to processes of magma origin, modification, transport, and eruption.

#### 1. Subduction

The most common eruptions observed by humans, and by far the most dangerous to human populations, are those from volcanoes overlying the world's subduction zones. Because of their explosive nature, these are also the eruptions most likely to affect our climate.

As an oceanic plate descends into the hotter, higher pressure interior, it is dehydrated and fluids from it rise into the overlying mantle wedge. In this complex region of shear and melting, new magma is born and rises in buoyant diapirs, but this rise is not steady. There may be many stops in subsurface chambers along the way, with early crystallizing minerals separating from the magma, and melting of surrounding rocks further changing its composition by contamination. This slow, complex, and varied route to the surface results, not surprisingly, in the eruption of complexly varied materials at different times and places.

In addition to compositional diversity and varied supply rates, a wide variation in the characteristics of subduction further contributes to the broad range of subduction zone volcanism observed. Segmentation of volcanic chains into discrete linear belts 100–300 km long, commonly offset by zones of more intense seismicity, has been recognized in Central America, the Cascades, the Aleutians, and the Andes. The geometry of subduction greatly influences the resulting volcanism. In the Andes, for example, volcanism is weak or absent above downgoing slabs that are inclined at only a gentle angle to the horizontal. We have found that relatively weak volcanism also correlates with thin overriding plates, with young downgoing slabs, with decreased angle between the direction of the downgoing slab and the bearing of the arc itself, and with low aseismic slip

rates (where great earthquakes indicate strong coupling between converging plates).

## 2. *Oceanic Ridge*

Although the majority of Earth's eruptions occur in this setting, these are the eruptions that we normally do not see. Balancing the downgoing material in subduction zones, new magma is added to the planet's surface along the 70,000-km oceanic rift systems. This magma is relatively homogeneous basalt, originating in the uppermost mantle and arriving at the surface in relatively primitive condition. Its extrusion is generally below 1–4 km of water, both shielding it from view and, with substantial pressure, inhibiting volatile release. The result is gentle, effusive eruption from a narrow zone (often only 1–2 km wide). There volcanoes range, with decreasing spreading rate, from flat fissure eruptions, through elongate shields, to discontinuous chains of central volcanoes constructed of fresh pillow lavas. Symmetrical central volcanoes are also found outside the rift itself, particularly near large offsets in the ridge system and near topographic highs of the faster spreading ridges; they outnumber subduction zone and hot spot volcanoes by several orders of magnitude. Hints of the behavior of ocean rift volcanoes can be found in Iceland, one of the few places where the world's rift system emerges above sea level. Here the historical record suggests that, although crustal spreading is probably steady, the rift zone's response to it is episodic: rift eruptions (and intrusions) lasting several years cause a few meters of separation every 100 years or so, rather than a constant few centimeters of separation every year.

## 3. *Hot Spot and Flood Basalts*

Hot spot volcanoes are believed to be formed by long-lived, relatively stationary plumes, anchored deep in the mantle and feeding magma to the surface through the overlying plate. As an area moves over a hot spot, magma production fuels active volcanism at the surface, but this declines and dies as the plate moves beyond, and a new volcano begins to form above the hot spot. Hawaii is the best known example of hot spot volcanism, and the variable volumes of the progressively older volcanoes to the northwest testify to the correspondingly variable magma supply as they have been carried in that direction by the Pacific plate during the last 70 million years. Steady feeding of relatively consistent basaltic magma to shallow chambers often yields a delicately balanced system ready to erupt over long time periods and therefore vulnerable to triggering influences such as earthquakes and fortnightly tides. Careful study of historical eruptions on Hawaii shows them to be largely random

phenomena, temporally, although large-volume eruptions tend to be followed by longer reposes. Distinctive stages in the long-term development of Hawaiian volcanoes have been recognized, the last of which takes place several million years after the volcano has been separated by plate motion from the feeding plume.

Stages in the development of the plume itself are believed by many to begin with the first batch of magma rising buoyantly through the mantle to reach the surface as a giant outpouring of flood basalts. Flood basalt provinces, such as India's Deccan plateau (60–65 Ma) and the Columbia plateau in the northwestern United States (around 15 Ma), have produced hundreds of thousands of cubic kilometers of lava and individual flows that covered thousands of square kilometers in just a few months or even days. Such catastrophic episodes are fortunately rare in the planet's history.

## 4. *Intracontinental*

This setting has much in common with the two tectonic environments described earlier in that some intracontinental volcanoes result from rifting and others from hot spots. Because of the complexities of the thick, siliceous continental crust that is inevitably involved in these eruptions, they are the most violent and least well understood forms of volcanism on the planet. Such eruptions can produce huge volumes of ash distributed over thousands of kilometers, such as the Cenozoic volcanoes of Colorado's San Juans, or the Pleistocene eruptions of Yellowstone. Studies of nonsubduction volcanism in the western United States emphasize the relatively long life of these centers (perhaps 5 million years, or 10 times the active life of many subduction zone volcanoes). Pulses of plate motion are thought to trigger magma formation and rise into the complex, extensional environment of the western United States, where 60 loci are identified by R. L. Smith as potential eruption sites in the future. Another regional review of intraplate volcanism covers eastern Australia and New Zealand, where the overall eruption rate has been slow but apparently continuous throughout the past 95 million years.

---

## III. ERUPTIONS

Looking at the distribution of volcanism through time again raises questions of definition: Is an individual explosion an *eruption* or should the word be used (as we tend to) for clearly linked events that may be separated by hours, days, or even months of surface quiet? Arrival of volcanic products at the Earth's surface is normally

termed an *eruption*, but the historical record is often unclear. Steam venting is commonly only a by-product of subsurface heat, and is rarely dignified by the word *eruption*, but steam may be all that was seen by a sea captain reporting an “erupting” volcano 200 years ago. Volcanic heat is also the prime source of *phreatic* (or *steam-blast*) explosions in which heat and water combine to fragment preexisting volcanic materials and hurl the resulting tephra into the sky. These events can be quite violent, however, and are rightfully called *eruptions*, even without the direct involvement of new magma.

Gas is an unequivocal volcanic product, but the gentle, continuous emission of fumarolic gases—common to most volcanoes—is not considered an “eruption.” Occasionally, though, large quantities of gas are suddenly vented—as in the fatal eruption of the Dieng volcano complex on Java in 1979. In 1984 and 1986, the African nation of Cameroon suffered catastrophic expulsions of CO<sub>2</sub> resulting in many fatalities by suffocation. The origin of the African events is controversial, but the evidence suggests that they resulted not from an eruption, but from the sudden overturn of crater lake water, with catastrophic exsolution of volcanic gas that had gradually accumulated in the bottom waters over the course of many years.

The great range of eruption types has already been mentioned. Among the various measures of eruption “bigness,” volume of products has been the most widely used by volcanologists. Eruptions of equal volume, however, may release quite different amounts of gas, with comparably different effects on climate. The larger eruptions inevitably receive the greatest share of scientific (and media) attention, but the steady pulse of smaller events adds up to significant contributions. In assessments of annual volcanic SO<sub>2</sub> production, for example, the steady, unspectacular contributions of the world’s fumaroles and small, ongoing eruptions are found to outweigh those of the less frequent larger eruptions. In any case, the range of eruption types is large, and there are many that, in the words of G. P. Scrope 135 years ago, “exhibit an infinite variety of phases intermediate between the extremes of vivacity and sluggishness.”

#### A. Durations and Culminations

Clearly some eruptions last for a very long time, like Stromboli’s 2500+-yr continuing pyrotechnic show. At the time of this writing (early 1999) the following 16 volcanoes have been erupting more or less continuously through the last 24 years (the reporting span of SEAN/

GVN) and are likely to remain active for some time: Stromboli and Etna (Italy); Erta Ale (Ethiopia); Manam, Langila, and Bagana (Papua New Guinea); Yasur (Vanuatu); Semeru and Dukono (Indonesia); Suwanose-jima and Sakura-jima (Japan); Santa Maria and Pacaya (Guatemala); Arenal (Costa Rica); Sangay (Ecuador); and Erebus (Antarctica). However, other eruptions end swiftly: 10% of those for which we have accurate durations lasted no longer than a single day (Fig. 4a), most end in less than 3 months, and few last longer than 3 yr. The median duration is about 7 weeks.

Of particular importance to volcanic hazard mitigation is the time interval between an eruption’s start and its culminating, paroxysmal phase. Several famous eruptions (e.g., Krakatau, 1883; Mount St. Helens, 1980; Pinatubo, 1991) have culminated months after the start of low-level eruptive activity, prompting the suggestion that volcanoes provide their own warning and that observatory monitoring of dangerous volcanoes is therefore unnecessary. To show the folly of this suggestion, we have looked at this time interval for the most explosive eruptions for which we have adequate data. These 252 eruptions (Fig. 4b) emphasize the sobering fact that many catastrophic explosions provide little advance warning. More than two-fifths of the eruptions reached their climax within the eruption’s first day (42%) and more than half (52%) within the first week. Where data are available, half of the first-day paroxysms (including Tarawera, 1886; Bandai-san, 1888; Hekla, 1947; and Shiveluch, 1964) came within only an hour of the eruption’s start.

The range of eruptive behavior is wide, however, and history’s largest explosive eruption, Tambora in 1815, provides sobering lessons about eruption duration. Mild eruptive activity over 3 full years was followed by a dramatic eruption, with cloud height estimated at 33 km, but even that was not its climax. After a lull of 5 days, the culminating eruptive cloud reached heights estimated at 44 km and caused 3 days of total darkness 500 km from the volcano. More than 60,000 people died as a result of this eruption. It is understandably difficult to sustain public awareness of hazards during long-term, low-level eruptive activity, but it is dangerous to assume that the worst is over after the initial explosive phase. Predicting an eruption’s end is even more difficult than predicting its beginning.

#### B. Patterns through Historical Time

Has global volcanism changed through time? A look at the number of volcanoes active per year, during the last

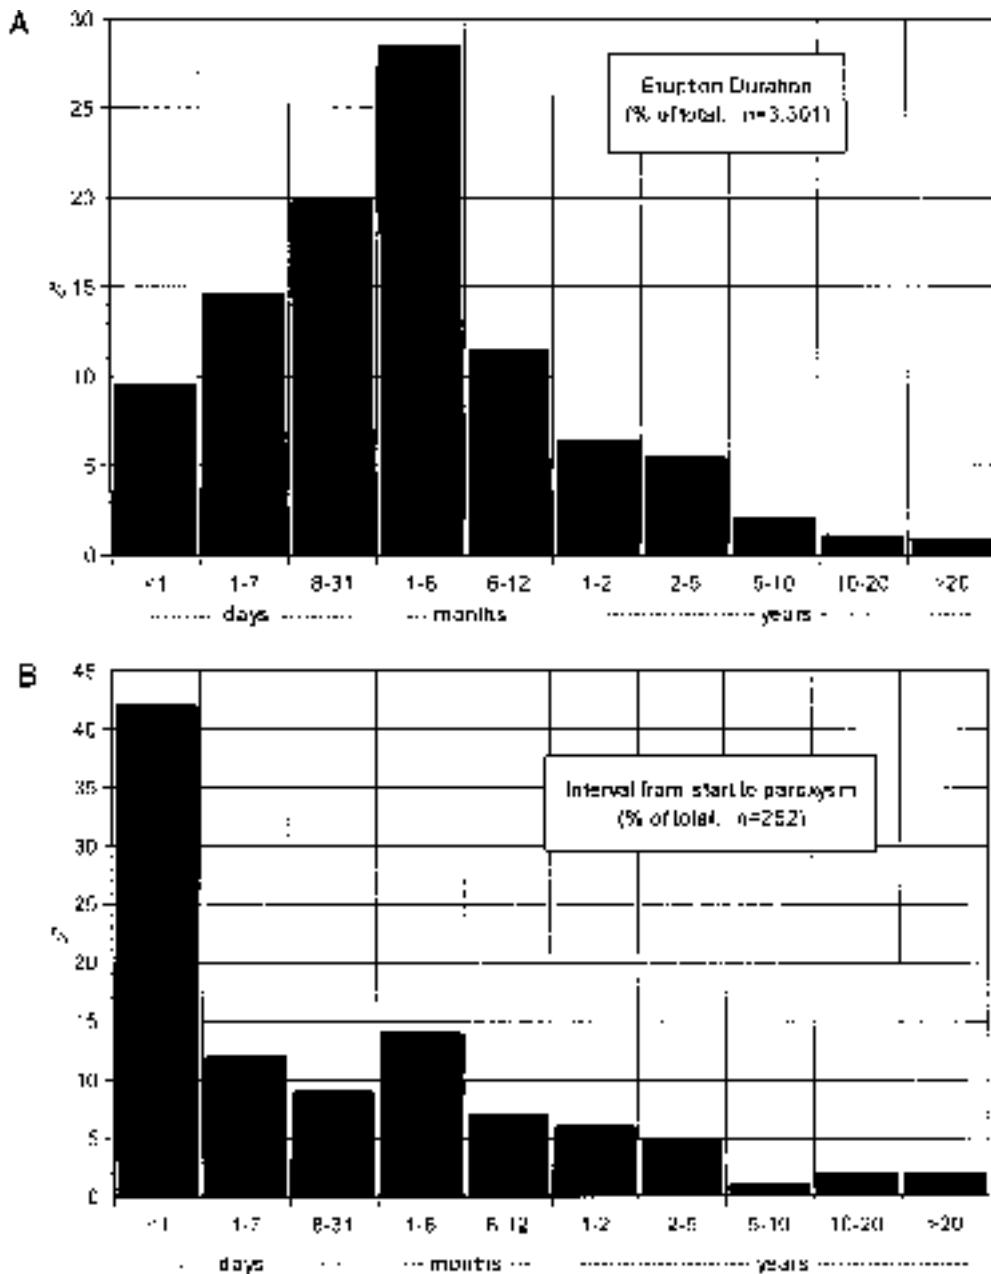

FIGURE 4 Eruption duration and development. (A) 3301 eruptions for which stop (and start) dates are known. (B) Interval between the eruption's start and its climactic phase for 252 highly explosive, well-documented, historical eruptions. These have a volcanic explosivity index (VEI) of 3 or above, indicating more than  $10^7 \text{ m}^3$  of tephra or, in the absence of volume estimates, described as "severe" or "violent."

500 yr, shows a dramatic increase, but one that is closely related to increases in the world's human population and communication. We believe that this represents an increased reporting of eruptions, rather than increased frequency of global volcanism: more observers, in wider

geographic distribution, with better communication, and broader publication. The past 200 yr (Fig. 5) show this generally increasing trend along with some major "peaks and valleys," which suggest global pulsations. A closer look at the two largest valleys, however, shows

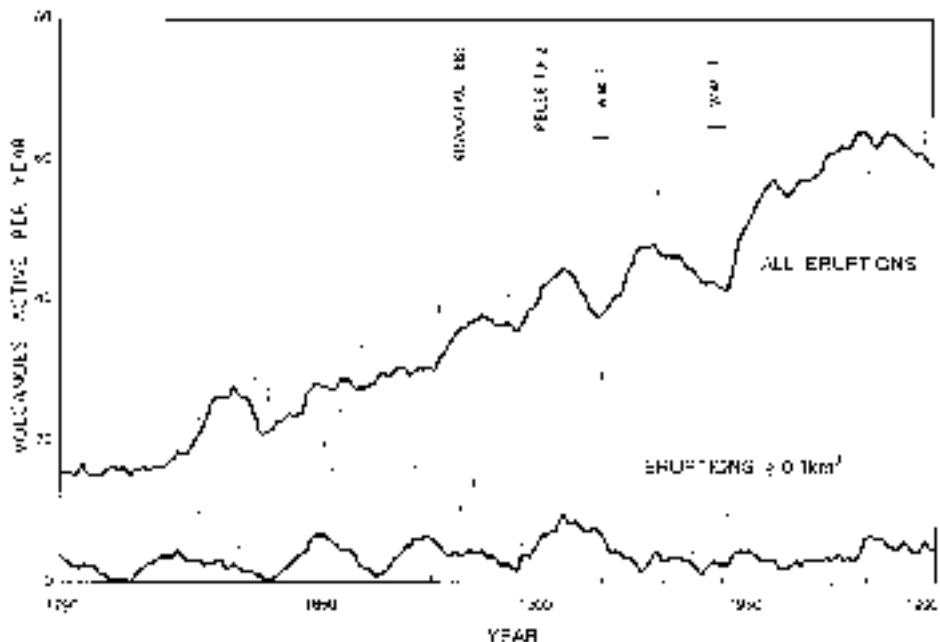

FIGURE 5 Eruption reporting since A.D. 1790. Total number of volcanoes erupting per year (thin upper line) and 10-yr running mean of same data (thick upper line). Lower lines show only the annual number of volcanoes producing large eruptions ( $\geq 0.1 \text{ km}^3$  of tephra or magma) and scale is enlarged (on right axis). Thick lower line again shows 10-yr running mean.

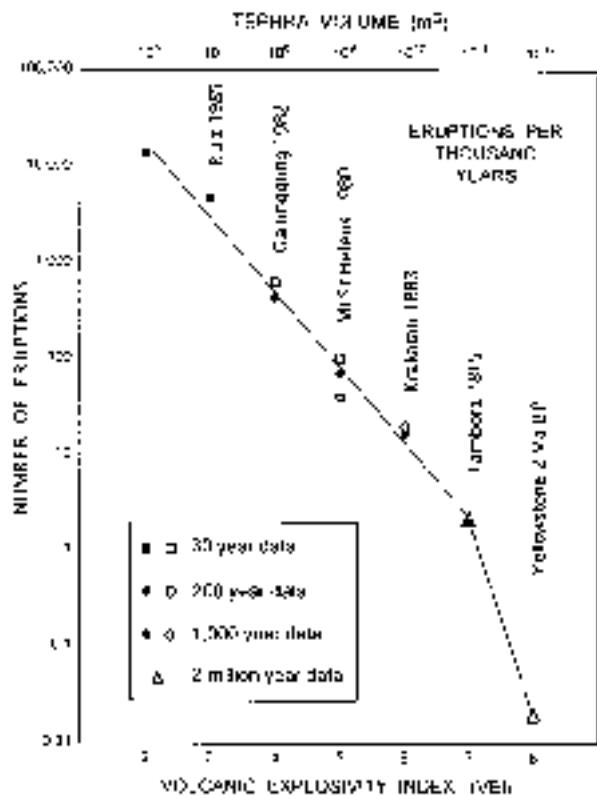

that they coincide with the two world wars, when people (including editors) were preoccupied with other things. Many more eruptions were probably witnessed during those times, but reports do not survive in the scientific literature.

If these apparent drops in global volcanism are caused by decreased human attention to volcanoes, then it is reasonable to expect that increased attention after major, newsworthy eruptions should result in higher-than-average numbers of volcanoes being reported in the historical literature. The 1902 disasters at Mont Pelee, St. Vincent, and Santa Maria (Fig. 5) were highly newsworthy events. They represent a genuine pulse in Caribbean volcanism, but we believe that the higher numbers in following years (and following Krakatau in 1883) result from increased human interest in volcanism. People reported events that they might not otherwise have reported and editors were more likely to print those reports. We felt confident enough of this interpretation to predict, in the first (1981) edition of our book, a similar increased reporting of volcanism after the 1980 eruption of Mount St. Helens. This did not happen, but we would like to think, by way of partial explanation, that reasonably comprehensive reporting of global volcanism is finally at hand. Note (in Fig. 5) that the number of erupting volcanoes has leveled off to between 50 and 70 per year during the past three decades.

Further evidence that the historical increase in global volcanism is more apparent than real comes from the lower plot of Fig. 5. Here only the larger eruptions (generating at least  $0.1 \text{ km}^3$  of tephra, the fragmental products of explosive eruptions) are plotted. The effects of these larger events are often regional, and therefore less likely to escape documentation even in remote areas. The frequency of these events has remained impressively constant for more than a century, and contrasts strongly with the apparent increase of smaller eruptions with time.

### C. Magnitude and Frequency (Global)

How much do eruptions vary in size? Like earthquakes, the frequency of eruptions decreases with increasing size: There are a lot of small ones, fewer medium-sized ones, and not so many large ones. We have borrowed from the seismologists' magnitude-frequency plots, using as our best measure of magnitude the volcanic explosivity index (VEI, see Sizes of Volcanic Eruptions chapter). This closely parallels the volume of erupted tephra, which increases by an order of magnitude with each larger VEI integer. In Fig. 6, the number of eruptions at and above each VEI increment is shown for

**FIGURE 6** Magnitude and frequency of Holocene eruptions. Cumulative number of eruptions during various intervals (going back in time from 1 January 1994) for each VEI class and normalized to “per 1000 years.” Eruptions of low explosivity (VEI 0 and 1) are not shown, and a logarithmic scale is used to allow resolution of the lower frequencies found with the larger eruptions. The best fit line is determined by an exponential regression model for VEI 2–7 using data points that are filled. Data points from Decker (1990) for VEI 7 and 8 are shown by open triangles. Well-known eruptions are labeled to illustrate each VEI class.

various time intervals in the recent past: 30, 200, 1000, and 2 million years. We have used longer time intervals for data from successively larger VEI groups because the smaller events have been adequately reported only in recent decades, whereas the larger events, being rarer, need a longer time interval for representative counts. This is a somewhat subjective process, but the intervals are chosen in the hope that they are long enough to be representative yet short enough to have reasonably accurate reporting. As discussed with Fig. 5, larger eruptions are more likely to have been accurately reported over longer periods, on a global basis, than smaller eruptions.

Another way of interpreting this plot is that subaerial eruptions producing at least  $10^6 \text{ m}^3$  of tephra (VEI ≥

2) take place at an average rate of once every few weeks somewhere on Earth. Those producing  $>10^7 \text{ m}^3$ , like the VEI 3 Ruiz event in Colombia that generated such fatal mudflows in 1985, take place several times a year. Eruptions the size of Mount St. Helens 1980 ( $10^9 \text{ m}^3$ , or  $1 \text{ km}^3$  and VEI 5) occur perhaps once a decade, and those like Krakatau in 1883 ( $>10 \text{ km}^3$ ) on the order of once a century. The historical record, however, fails to prepare us for the much larger eruptions of the past. The Toba eruption, only 74,000 years ago in Indonesia, produced nearly 10,000 times more magma ( $2800 \text{ km}^3$ ) than the Mount St. Helens eruption. Even larger eruptions are known from the older geologic record.

Simple extrapolation of the Holocene record in Fig. 6 is not warranted above VEI 7, however, and that value, we must remember, is based on a single data point. The shape of the magnitude–frequency relationship at this end is unclear, but Decker (1990) has attempted to improve it by plotting data from Newhall and Dzurisin’s compilation (1988) of caldera unrest during the past 2 million years. The caldera data set is incomplete, as the authors themselves are quick to acknowledge, and large assumptions are made in extending the historical data, but that extension is probably closer to the truth than extrapolation of the historical data. An eruption the size of Yellowstone’s about 2 million years ago, producing  $2500 \text{ km}^3$  of magma, is believed to take place every 100,000 years. Volcanic ash from this eruption was distributed over much of the western United States (including Los Angeles, Tucson, El Paso, and Des Moines) with compacted thicknesses of 0.2 m at distances of 1500 km from the source. Its impact was surely profound.

#### D. Interval and Magnitude (Individual)

While Fig. 6 illustrates the frequency of eruptions on a global basis, most people are more interested in how much longer a particular volcano will remain quiet and what kind of eruption will break that quiet. Such information can come only from detailed study and monitoring, as described elsewhere in this volume, but the volcanological record provides some guidance that is both useful and sobering. One of the certain contributors to large volcanic death tolls is the fact that the repose interval between eruptions is very much longer than the historical records in many parts of the world. Figure 7 shows the relationship between eruption interval and the proportion of historical eruptions in each VEI class. Most eruptions of low explosivity follow repose intervals of only 1–10 yr, but with increasing time intervals the

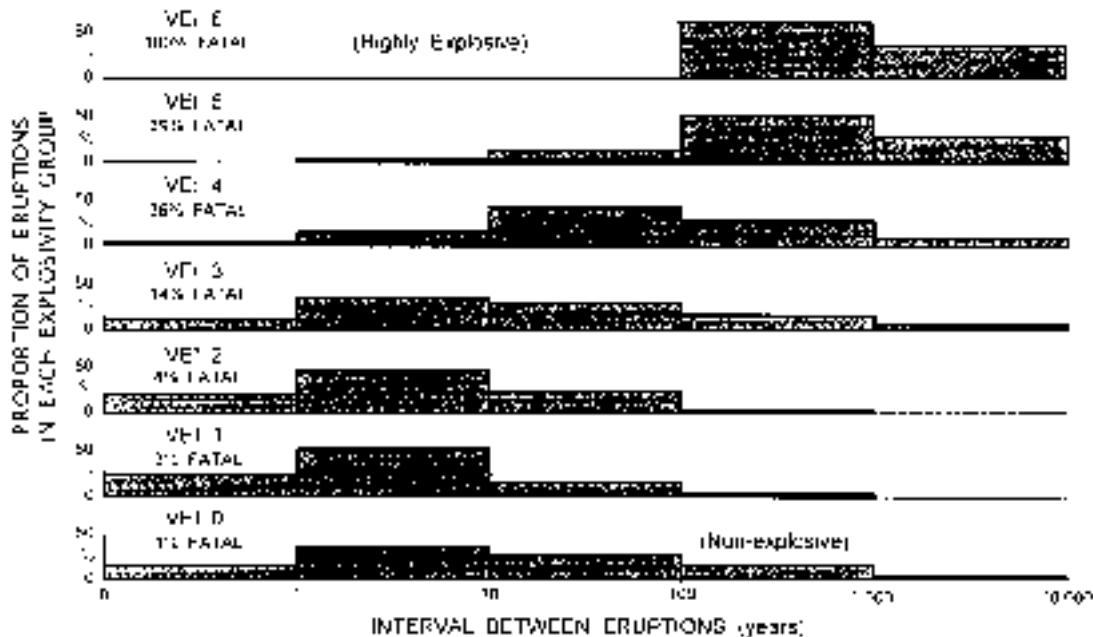

FIGURE 7 Explosivity and time intervals between eruptions. For each VEI unit, eruptions are grouped by time interval from start of previous eruption. The number of eruptions in VEI groups 0 to 6 are, respectively, 446, 677, 2991, 692, 230, 48, 16. For each group, the percentage of historical eruptions that have been fatal is also shown to emphasize the danger of large explosive eruptions from volcanoes that have appeared to be quiet for hundreds to thousands of years.

explosivity increases significantly. Long repose periods precede large eruptions, and in regions with short historical records the human population is commonly unprepared. The results are often tragic.

Humans have not been successful in controlling volcanoes in a substantive way and are not likely to be so in the future. We can, however, develop a more successful coexistence with volcanoes, neither fatalistically accepting their actions nor relying on last-minute attempts at control. To do this, we must emphasize understanding as the first element of prediction, and improve our human response to eruptions when they do occur. This requires understanding of the huge eruptions of the geologic past as well as the more frequent and more familiar events of our own lifetimes. With limited resources, volcanology should concentrate efforts on a limited number of dangerous volcanoes, but it would be a mistake to overemphasize the historical record in selecting them. For at least two centuries we have had an average of one or two eruptions per year from volcanoes with no previous historical activity. Other volcanoes have erupted after hundreds of years of quiet. Because their danger was not widely recognized, and because unusually violent eruptions are known to follow unusually long periods of quiet, these events included some of history's worst natural disasters. Table I lists

TABLE I Largest Explosive Eruptions of the 19th and 20th Centuries<sup>a</sup>

Year	Volcano	First historical?	Deaths
1991	Cerro Hudson (Chile)	No	0
1991	Pinatubo (Philippines)	Yes	>740
1982	El Chichón (Mexico)	Yes	>2,000
1980	Mount St. Helens (USA)	No	57
1956	Bezymianny (Kamchatka)	Yes	0
1932	Cerro Azul/Quizapu (Chile)	No	0
1912	Novarupta/Katmai (Alaska)	Yes	2
1907	Ksudach (Kamchatka)	Yes	0
1902	Santa María (Guatemala)	Yes	>5,000
1886	Tarawera (New Zealand)	Yes	153
1883	Krakatau (Indonesia)	No	36,417
1875	Askja (Iceland)	Yes	0
1854	Shiveluch (Kamchatka)	Yes	0
1835	Cosiguina (Nicaragua)	No	5–10
1822	Galunggung (Indonesia)	Yes	4,011
1815	Tambora (Indonesia)	Yes	60,000

<sup>a</sup> VEI  $\geq 5$ , or tephra volume  $\geq \text{km}^3$ . All but five were the first historical eruptions known from the volcano, and the high death tolls (in heavily populated regions) reflect that fact.

the most violent eruptions of the last two centuries—those with a VEI  $\geq 5$  (or  $\geq 1 \text{ km}^3$  of tephra). Notice that 11 of 16 were the first historical eruptions at that volcano (and for others, like Krakatau, earlier activity was not widely known). The study of volcanology tends to concentrate on volcanoes made famous by eruptions that were either destructively large or photogenically long lasting, but we must not neglect the nonfamous, thickly vegetated volcanoes that have had no historical activity. Like Lamington in Papua New Guinea and Pinatubo in the Philippines, they may be the most dangerous of all.

## GLOSSARY

- destructiveness index** The logarithm of the area covered by lava, pyroclastic flows, and surges, or buried under more than 100 kg/m<sup>2</sup> of tephra during an eruption.
- intensity** The mass eruption rate (kg/s). The **intensity scale** is based on the logarithm of the mass eruption rate.
- magnitude** The mass of material ejected during a volcanic eruption (kg). The **magnitude scale** is based on the logarithm of the erupted mass.
- volcanic explosivity index (VEI)** A widely used classification scheme to describe the size of explosive eruptions. This is based principally on the erupted mass or volume of a deposit.

**V**OLCANIC ERUPTIONS SPAN a huge range of volumes, eruption rates, and styles and vary

widely in their violence and destructiveness. Consequently, eruption size can be measured in a number of different ways. The two principal quantities that define the scale of an eruption are *magnitude*, the mass of material erupted, and *intensity*, the mass eruption rate. These two quantities can be determined more or less precisely for both modern and ancient eruptions, and for both effusive and explosive events. Studies of the sizes of past and present volcanic eruptions allow volcanologists to compare recent “smaller” eruptions, with the rare, but colossal, eruptions of past millennia. By so doing, we may learn more about the processes that control eruptions of all scales.

---

## I. SCALES OF ERUPTION SIZE

Because erupted masses and rates of eruption both vary by many orders of magnitude, a logarithmic scale is needed to categorise the sizes of volcanic eruptions, in much the same way as the Richter magnitude scale is used for earthquakes. The first attempts to devise such a scale used a single number (analogous to the Richter magnitude) to describe the size of an eruption. This scale placed an eruption into a magnitude class (I to IX) based on the logarithm of its bulk pyroclastic volume.

A revised scale, called the *volcanic explosivity index* (VEI), developed this concept. The volcanic explosivity

TABLE I. The Volcanic Explosivity Index<sup>a</sup>

VEI index	0	1	2	3	4	5	6	7	8
General description	Nonexplosive	Small	Moderate	Moderate–large	Large	Very large			
Qualitative description	Gentle	Effusive	← Explosive →		← Cataclysmic, paroxysmal →				
Maximum erupted volume of tephra (m <sup>3</sup> )	10 <sup>4</sup>	10 <sup>6</sup>	10 <sup>7</sup>	10 <sup>8</sup>	10 <sup>9</sup>	10 <sup>10</sup>	10 <sup>11</sup>	10 <sup>12</sup>	10 <sup>13</sup>
Eruption cloud column height (km)	<0.1	0.1–1	1–5	3–15	10–25	>25			

<sup>a</sup> Adapted from Newhall and Self, 1982.

index (Table I) uses an integer scale from 0 to 8 to describe both the volume and plume height of any given eruption. This index is based on both magnitude (erupted volume) and intensity (eruption column height) information. For example, a VEI 4 eruption is defined to have a bulk volume of 0.1–1 km<sup>3</sup> of tephra, and a column height of between 10 and 25 km. The volcanic explosivity index can be applied both to modern and ancient explosive eruptions. In practical use, the VEI value given to an eruption is based mainly on the volume of ancient deposits, and mainly on the *explosivity*, or column height, of observed eruptions. This index has been adopted by the Smithsonian Institution in their compilations of past volcanic eruptions and is widely used. This scale is not useful for eruptions of lava, which are primarily nonexplosive and therefore receive a default classification of 0 or 1 (Table I).

The underlying assumption of the volcanic explosivity index is that the magnitude and intensity of eruptions are related in some way, so that a single number can fully describe the different aspects of the size of an eruption. Subsequent work has shown that there is not a simple relationship between magnitude and intensity for many eruptions. Instead, two independent logarithmic scales are needed, one for magnitude and the other for intensity. By undoing the assumed link between erupted mass and eruption rate it becomes possible to describe and compare both explosive and effusive eruptions.

The magnitude scale is based on a logarithmic index of magnitude that is defined as follows:

$$\text{magnitude} = \log_{10}(\text{erupted mass, kg}) - 7.$$

For most eruptions, magnitudes defined in this way will be similar to their VEI. According to this scale, a “large” eruption, like Pinatubo, is of magnitude 6.0 or higher.

Similarly an intensity scale based on a logarithmic index of intensity is defined by:

$$\text{intensity} = \log_{10}(\text{mass eruption rate, kg/s}) + 3.$$

On this scale, an extremely vigorous eruption will have an intensity of 10–12, whereas a very gentle eruption might have an intensity of 4 or 5. One very useful property of these scales is that they can be used to describe both recent and ancient eruptions.

## II. MASS AND VOLUME OF VOLCANIC DEPOSITS

Determining the mass of a volcanic deposit is not a trivial matter. Lava flows can have highly variable thicknesses and a complex distribution pattern. Poorly consolidated tephra deposits have a low preservation potential, and can rarely be reconstructed in full without detailed work and some good fortune. Finally, both lava and tephra deposits have variable densities, but this needs to be known before the mapped volume can be converted to an equivalent mass. If all magmas and all pyroclastic deposits had the same physical properties, there would be no problem. However this is not the case. Molten rock that is free of gas bubbles typically has a density of between 2300 and 2700 kg/m<sup>3</sup>, depending on its composition. Tephra can have bulk densities between 600–800 kg/m<sup>3</sup>, in the case of ash fall deposits, and 1600–2000 kg/m<sup>3</sup> for block and ash flow deposits. Consequently, there is no single, simple correction factor that can be universally applied to convert from volume and mass. The same is true for lavas, which can erupt with vesicle contents as high as 20 or 30%, and bulk densities as low as 1800–2000 kg/m<sup>3</sup>.

To make comparisons between different deposits, deposit volumes are often converted to a *dense rock equivalent* volume. This is an estimate of the volume of dense, unvesiculated magma that erupted to form the pyroclastic deposit. The common usage of both bulk and dense rock equivalent volume scales is a source of confusion,

because it is not always clear which “volume” is being referred to. Dense rock volumes are also of little value unless the assumptions about the densities of both the bulk and dense deposit are stated. There is no such confusion with erupted mass, which is the reason why mass should be used as the basis for magnitude scales.

### III. MAGNITUDES OF VOLCANIC ERUPTIONS

The mass of ejecta thrown out during explosive eruptions spans at least 9 orders of magnitude (Table II). The smallest explosive events are rarely documented, and their deposits are even more rarely preserved. Discrete ash-venting episodes during an eruption, such as those at the Soufrière Hills, Montserrat, between 1995 and 1998, lasted a few tens of minutes and released just a few million kilograms of ash. Small ash-cloud events during the 1986 eruptions of Augustine, Alaska, similarly released a few tens of millions of kilograms of ash during discrete pulses of activity. The smallest of these events have a magnitude of less than 0. At the other end of the

scale, caldera-forming events like Tambora (A.D. 1815) or Toba (75 ka B.P.) have magnitudes of 7–9, and erupt  $10^{14}$ – $10^{16}$  kg of magma.

Eruptions of lava similarly span at least 8 orders of magnitude (Table III). At the smallest end, individual carbonatite flows at Oldoinyo Lengai volcano in East Africa range up from just a few cubic meters, or tens of thousands of kilograms. In contrast, 15 km<sup>3</sup>, or over  $10^{13}$  kg, of lava was erupted during the largest effusive eruption of the last 300 years at Laki, Iceland, in 1783–1784. Some eruptions of lava attain a large mass simply because the eruption lasts for a long time. The eruption of the Soufrière Hills volcano on Montserrat erupted over  $6 \times 10^{11}$  kg (a magnitude of 4.8) of andesite lava as a series of domes between November 1995 and March 1998. The even longer lasting eruption at Santiaguito, Guatemala, has squeezed out over  $2 \times 10^{12}$  kg of lava since 1922.

Examples from the geologic record extend to even more colossal scales. The 14.7-million-year-old Roza flow of the Columbia River basalts had a mass of at least  $3 \times 10^{15}$  kg (magnitude 8.5) and was a part of a flood-basalt flow field 100 times larger. Flows of a similar scale can be found in many of the other flood basalt provinces of the world.

TABLE II Magnitude, Intensity, and Power Output from Some Explosive Eruptions

Eruption	Total magnitude (kg)	Thermal energy release (J)	Total seismic energy release (J)	Peak eruption plume height (km)	Peak eruption rate, plume-forming phase (kg/s)	Power output (W)	Magnitude	Intensity
Toba, ca. 75 ka B.P.	$7 \times 10^{15}$	$7 \times 10^{21}$	—	—	—	—	8.8	—

#### IV. INTENSITIES OF VOLCANIC ERUPTIONS

The intensity of an explosive eruption, or the rate at which the ejecta leave the vent, is the main factor that controls the height of an eruptive plume. For a sustained eruption, the height reached by the eruption column is proportional to the fourth root of the intensity:  $H \propto I^{1/4}$ . The plume height in turn controls the dispersal of the volcanic clasts, so it is possible to infer the intensities of ancient eruptions from studies of the deposits. For recent eruptions, direct visual and satellite observations of the heights reached by eruption columns mean that the intensities of a wide range of eruptions can be determined. The intensities of selected explosive eruptions are summarized in Table II. The most powerful Plinian eruptions have intensities of between 11 and 12, corresponding to mass eruption rates of  $10^8$ – $10^9$  kg/s, and send plumes to between 25 and 55 km above the Earth's surface. The intensities of small ash eruptions can be as low as 5 or 6, with mass fluxes of just  $10^2$ – $10^3$  kg/s supporting weak plumes.

Explosive eruptions that undergo a transition from a plinian phase to an ignimbrite-forming phase may do so as a result of the increasing intensity of the eruption. In many cases these changes in intensity are linked to the increasing size of the eruptive vent, or the opening of new vents as ring fractures open up above the magma chamber. The intensity of many ignimbrite-forming

eruptions may have been as much as 1 or 2 orders of magnitude larger than the plinian phase (i.e.,  $10^9$ – $10^{11}$  kg/s). Increasingly good quantitative models are available that allow geologists to infer the paleointensity of ancient ignimbrite-forming eruptions. However, because not all explosive eruptions produce flows of any description, it is probably unwise to base an intensity scale on anything other than the peak intensity of the plume-forming phase.

The intensities of lava eruptions are rather more difficult to constrain than those of explosive eruptions, unless they are actually observed. Many effusive eruptions also show dramatic changes in intensity as the eruption progresses. The fissure-fed eruptions of Laki in 1783 and Hekla in 1991 both started with fire fountains sustained by a total flux of millions to tens of millions of kilograms of lava per second. As the eruptions progressed over subsequent days and weeks, the flux declined by 2 to 3 orders of magnitude. In these cases, the changes in intensity can be linked to changes in the pressure of the magma chamber at depth, or to transitions in the rheology of the erupting mixture. In contrast, during the 1995–1998 dome-forming eruption of the Soufrière Hills volcano, Montserrat, the rate of eruption of lava increased by about an order of magnitude as the eruption progressed, before coming to an abrupt halt in March 1998.

Instantaneous rates of eruption of lava measured at active volcanoes range from less than 2 kg/s (an intensity of 3.3) during the eruption of small pahoehoe flows at

TABLE IV Long-Term Eruption Rates of Lava: Lakes and Domes

Volcano	Period	Eruption type	Mean eruption rate ( $\text{kg s}^{-1}$ )
Soufrière Hills, Montserrat, West Indies	1995–1998	Lava dome	8000
Unzen, Kyushu, Japan	1991–1995	Lava dome	4000
Santiaguito, Guatemala	1922–1925	Lava dome	4500
Santiaguito, Guatemala	1925–1984	Lava dome	800
Mount St. Helens, USA	1980–1986	Lava dome	700
Merapi, Indonesia	1890–1992	Lava dome	80
Nyiragongo, Zaire	1901–1977	Lava lake	1000
Halemaumau, Hawaii	1823–1923	Lava lake	300
Erta 'Ale, Eritrea	1968–1974	Lava lake	160
Stromboli, Italy	Historical times	Lava pond	0.3

the Tanzanian volcano Oldoinyo Lengai in 1988, to more than  $10^7 \text{ kg/s}$  during the hour-long eruption of Nyiragongo in central Africa in January 1977. Some of the lowest intensities are recorded from eruptions that continue for years, or even longer (Table IV). Typically, dome-forming eruptions continue with an intensity of less than 5 ( $100 \text{ kg/s}$ ) to 8. The eruption of Stromboli, Italy, has an average intensity of less than 3.

Flood-basalt-forming eruptions, such as those that formed the Columbia River basalts in the northwestern United States, are thought to be the products of high-intensity eruptions. However, there is some disagreement over precisely how intense they may have been. There are two alternative reconstructions of the eruption that produced the  $1300\text{-km}^3$  Roza flow. An early reconstruction suggested an eruption duration of about 1 week, assuming that the flows were fully turbulent and erupted with an intensity of  $12.5\text{--}12.8 (3\text{--}6 \times 10^9 \text{ kg/s})$ . A later model suggested the eruption might have lasted for 10 years, assuming an intensity of 10 ( $10^7 \text{ kg/s}$ ), similar to that at Laki in 1783. These intensities are of a similar order of magnitude to those encountered during many violent explosive eruptions. However, an important difference between effusive and explosive eruption intensities is that eruptions of lava may take place along fissure systems tens or hundreds of kilometers long, while explosive eruptions tend to originate from vents only tens or hundreds of meters in size. Thus the rate of eruption per unit area of the vent is considerably lower for effusive than for explosive eruptions.

## V. THE RELATIONSHIP BETWEEN THE INTENSITY AND MAGNITUDE OF A VOLCANIC ERUPTION

The magnitudes and intensities of a range of different eruptions are summarized in Fig. 1. The scatter of the data shows that there is some decoupling of eruption rate and erupted mass, particularly for nonexplosive eruptions. In other words, eruption duration varies independently of either magnitude or intensity. For short-lived plinian eruptions, there is a fair correlation between the intensity of the plume-forming phase and the magnitude of the whole eruption. Although there is some overlap between the sizes of the most vigorous eruptions of lava and explosive eruptions, in general a given mass of lava will erupt at a lower intensity, over a longer period of time, than the same mass of tephra.

## VI. ENERGY OF VOLCANIC ERUPTIONS

Most volcanic energy is dissipated as heat. The thermal energy release will depend on both the temperature and composition of the material erupted, and ranges from approximately 1 MJ/kg for rhyolite erupted at  $800^\circ\text{C}$  to ca. 1.5 MJ/kg for basalt erupted at  $1150^\circ\text{C}$ . Rates of

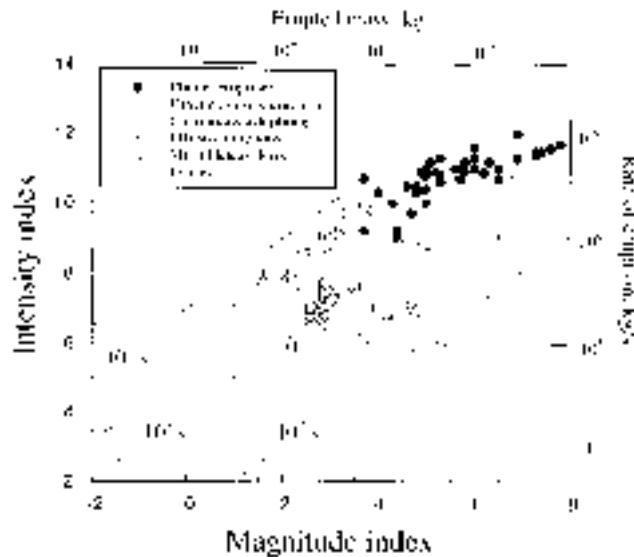

FIGURE 1 Plot of the magnitudes and intensities of selected recent and historical eruptions. Data from explosive eruptions are plotted as circles. Many Plinian eruptions include episodes of pyroclastic flow emplacement. The peak eruption rate during the flow-forming phases might be as much as 1 or 2 orders of magnitude higher than during the Plinian phase, but because this peak intensity is hard to infer, the intensity refers instead to the mass eruption rate during the plume-forming phase. Data from effusive eruptions are plotted as squares. For these eruptions the intensity is defined as the mean mass eruption rate; the peak intensity can be 1 or 2 orders of magnitude higher at the start of fissure-fed eruptions (Table III). The three labeled diagonal lines show the duration (in seconds) of an eruption of a given magnitude and constant intensity. In the case of Plinian eruptions associated with high-intensity pyroclastic flows, this duration is not the true duration of the eruption.

power output range from  $10^{13}$  to  $10^{15}$  W for typical Plinian eruptions and  $10^{10}$  to  $10^{12}$  W for large basaltic eruptions, with a total thermal energy release of  $10^{18}$ – $10^{21}$  J for eruptions of magnitude 5 to 7 (Tables II and III). For comparison, the total energy released by a shallow earthquake with a body magnitude of 7.5 is about  $10^{17}$  J, released at a rate of  $10^{15}$ – $10^{16}$  W.

The kinetic energy of the particles ejected from a volcanic vent rarely exceeds a fraction of a percent of the thermal energy release. Even for a violent eruption where the ejecta leave the vent at the local speed of sound, the kinetic energy release is only of the order of 50 kJ/kg. Seismic energy can be an important component of energy release. Many eruptions are accompanied by a total seismic energy release larger than  $10^{13}$  J (Tables II and III) but this is still several orders of magnitude smaller than the accompanying thermal energy release. Other forms of energy release that have been quantified, but are negligible, include the energy expended as atmospheric pressure waves, the potential energy required to raise the magma up the conduit, and the energy stored in the elastic deformation of the edifice.

## VII. OTHER MEASURES OF ERUPTION SIZE

Another parameter that gauges the size of an eruption is the *destructive potential*. If this is defined as the area within which human structures would expect to be com-

TABLE V The “Destructiveness” of Selected Volcanic Eruptions<sup>a</sup>

Eruption	Lava flows	Area ( $\text{km}^2$ ) covered by: Tephra fall ( $>100 \text{ kg/m}^2$ )	Pyroclastic flows, surges	Lahars	Total area ( $\text{km}^2$ )	Destructiveness index
Millbrig, Ordovician bentonite, USA	—	$>10^6$	—	—	$>10^6$	6
Kidnappers flow, New Zealand	—	—	45,000	—	45,000	4.7
Taupo, ca. A.D. 180	—	12,000	20,000	—	32,000	4.5
Novarupta, 1912	—	30,000	150	—	30,150	4.5
Pinatubo, 1991	—	1700	400	$>400$	$>2500$	3.4
Laki, 1783–1784	599	10	—	—	609	2.8
Mount St. Helens, 1980	—	10	600	100	710	2.9
Hekla, 1991	23	$<1$	—	—	23	1.4
Etna, 1991–1993	7.2	—	—	—	7.2	0.9

<sup>a</sup> Destructiveness index =  $\log_{10}$ (total area affected by lava, pyroclastic flows and surges, lahars and tephra accumulations exceeding  $100 \text{ kg/m}^2$ ).

pletely destroyed as a result of an eruption, this allows us to compare eruptions of different style and involving different materials. Accumulations of dry tephra that exceed 100 kg/m<sup>2</sup> (a dry, uncompacted thickness of 10–20 cm) can cause roofs and other structures to collapse. Areas covered by lava flows and lahars, or hit by pyroclastic flows and surges — of whatever thickness — will also effectively be devastated by an eruption. If the *destructiveness index* of an eruption is defined as the logarithm of the total area affected by lava, lahar, pyroclastic flows and surges, and tephra fall accumulations of more than 100 kg/m<sup>2</sup>, then it is straightforward to compare the relative impacts of different eruptions (Table V). Extremely destructive events, with a destructiveness index of >4, that lay waste to an area of more than 10,000 km<sup>2</sup>, are very rare. The Taupo eruption of ca. A.D. 180 probably rates as the most destructive of the past 2000 years. Examples from the geologic record are unlikely to exceed the scale of the 1000- to 2000-km<sup>3</sup> ash-fall deposits that can be found now as Middle Ordovician bentonites. The largest of these has a destructiveness index of 6 (Table V). Moderately to highly destructive events, with a destructiveness index >3, include eruptions of the scale of Novarupta in 1912 and Pinatubo in 1991. Of course, the human and economic impacts of individual eruptions depend on local factors, but the destructiveness index is a useful way of comparing such otherwise dissimilar eruptions as those at Laki in 1783 and Mount St. Helens in 1980.

---

#### ACKNOWLEDGMENT

Data on individual eruptions are the products of work by many people, most of which can be found in either of the two principal journals of volcanology. A full list of references can be obtained from the author.

## GLOSSARY

**catastrophists** A group of early geologists who maintained that the steady progression of geologic time was periodically disrupted by brief cataclysms.

**decompression melting** The generation of magma in the Earth's mantle that results from upwelling of solid mantle rock, leading to a decrease in pressure acting on the rock and spontaneous partial melting without the addition of heat. Melting as a result of decrease in pressure occurs because the melting point of mantle rock (peridotite) decreases with decreasing pressure.

**directionalism** The 19th-century concept that Earth's processes were gradually slowing down, due to progressive heat loss from the interior of the Earth.

**flood basalts** Vast outpourings of basaltic magmas, resulting in rapid buildup of extensive basaltic plateaus.

**hot spots** Regions of anomalously high rates of volcanism on the Earth, generally associated with great outpourings of basaltic magmas. Hot spots may originate from deep mantle plumes.

**ignimbrites** Pyroclastic deposits primarily formed by volcanic ash and pumice, resulting from great explosive eruptions that generate pyroclastic flows.

**LIPs** Acronym for large igneous provinces, which are massive outpourings and intrusions of basaltic magmas. They are typically localized and transient phenomena, normally lasting for only a few million years.

**mantle plume** The upwelling of a large region of anomalous mantle material through the Earth's mantle, made buoyant because of either a thermal or chemical anomaly. Mantle plumes may be the source of magmas for LIPs and for the currently active hot spots.

**subduction zones** Regions of plate convergence, where lithosphere is thrust back into the Earth's mantle. Processes within the subduction zone bring about melt generation in the mantle wedge and cause buildup of the overlying volcanic arc.

**tephra layers** Layers of volcanic ash particles, generally a few centimeters thick, consisting primarily of glass shards. They are extremely widespread, covering thousands of kilometers on land and in the ocean basins. Tephra (Greek for *ash*) is formed by fragmentation of primarily silicic magma during explosive volcanic eruptions, ejected to the atmosphere in high eruption columns and dispersed widely.

**uniformitarians** The group of geologists who believed that the rates of geologic processes in the past had been roughly comparable to those observed today.

**volcanic arcs** Long, arcuate belts of volcanic chains that are created above subduction zones. While most volcanic

arcs are island arcs, they are also important on convergent continental margins.

of geophysical studies of ocean ridges and oceanic plateaus, show that Earth's volcanism is decidedly episodic, although the causes and processes behind this episodicity of volcanism remain poorly understood.

## I. INTRODUCTION

In the 18th and 19th centuries, during the early days of the study of the Earth, geologists clashed over two fundamental views of the rates of geologic processes. On one side were the Uniformitarians, whose talismanic principle was "the present is the key to the past"; that is, the rates of volcanism and other convulsions in the Earth were steady state and had not varied greatly in their intensity during geologic time. On the other hand were the Catastrophists, who maintained that the steady progression of geologic time was punctuated by brief cataclysms or periodic catastrophes, when volcanism, mountain building, and major upheavals occurred, often resulting in species extinctions. In the late 18th and early 19th centuries, the Cartesian belief that the Earth was a gradually cooling body gained support, and this gave rise to the concept of *directionalism*: that Earth processes such as volcanism had been much more vigorous in the past and that our planet was eventually destined to lose its internal reservoir of heat, with the slowing down of geologic processes such as volcanic activity. As a result of the wide-ranging exploration of the Earth and its geologic history in the 20th century, we are now in a position to address the issue of the rates of volcanism and episodicity.

Recognizing that the current state of the Earth is not necessarily typical of all tectonic regimes in the past, it is important to study the long-term geochemical and tectonic evolution of the Earth system. This chapter examines the geologic record for evidence of episodes in volcanism. It focuses primarily on the Cenozoic, that is, the past 65 million years, where the geologic record of the rates of volcanism is most complete. Three categories of terrestrial volcanism are considered: (1) ocean ridge volcanism, where the magma production rates have been largely determined by geophysical techniques, primarily by paleomagnetic methods; (2) hot spot volcanism, producing oceanic plateaus (e.g., Iceland) or volcanic island chains (e.g., the Hawaiian-Emperor chain); and (3) explosive volcanic activity in volcanic arcs above subduction zones, where the rate of volcanism is primarily recorded by tephra layers in sediment cores from the ocean basins.

The results of extensive drilling of the sedimentary succession of the ocean basins near volcanic arcs, and

## II. OCEAN RIDGES

The crust that lines the ocean basins represents about 70% of the Earth's surface, and constitutes the most important product of volcanism on the planet. The formation of ocean basins is a consequence of plate motion, where the divergence of plates leads to upwelling of the underlying mantle and formation and segregation of basaltic melt (magma) from the rising mantle due to decompression melting, resulting in the volcanism that builds up submarine ocean ridges. The oceanic crust and lithosphere combined (ca. 80 km thick) form a boundary layer between the mantle of the Earth and the overlying hydrosphere. This boundary layer has probably been forming throughout most of the 4.5-billion-year history of the Earth, but most of the older oceanic crust has been returned into the mantle and destroyed due to the process of subduction. The rate of volcanic or magmatic activity in the ocean ridges is measured by the rate of plate generation, which in turn is calculated from the plate tectonic framework.

Rates of growth of a given plate depend on the length of the adjacent ridge and spreading rate. For example, the Antarctic plate is growing at the highest rate of  $0.561 \text{ km}^2/\text{yr}$ , being totally surrounded by spreading ridges. The worldwide aggregate length of spreading ridges is  $5.92 \times 10^4 \text{ km}$ , and they generate oceanic crust at the rate of  $3 \text{ km}^2/\text{yr}$ , with a mean half-spreading rate of  $2.5 \text{ cm/yr}$ . Because of the large range in spreading rate from ridge to ridge, and variable ridge length, the rate of ocean ridge volcanism varies from region to region on the Earth. However, as discussed later, the aggregate global rate has not varied greatly in the Cenozoic.

The currently exposed ocean floor formed by spreading has an area of  $297 \times 10^6 \text{ km}^2$  and is up to 180 million years old, that is, the oldest oceanic crust is of Jurassic age. The oldest remnants of oceanic crust are found in the western Pacific and along the east and west margins of the Atlantic Ocean. We do not know the history of oceanic plates prior to 180 Ma, because all of the older crust has been subducted, but if we assume that plate generation and subduction has been a steady-state process, then the currently preserved ocean floor represents only 5% of the ocean floor created during Earth history.

In such a steady-state scenario,  $5.94 \times 10^9 \text{ km}^2$  would have been subducted throughout Earth's history; taking 80 km as a lithosphere thickness, this is equal to  $4.75 \times 10^{11} \text{ km}^3$  return mass flow into the mantle, or corresponding to about 48% of the volume of the mantle. Thus about half the mantle has been recycled once through the ocean ridge and the subduction zone systems during the history of the Earth, if the rates have remained constant.

The  $3 \text{ km}^2$  of oceanic crust formed per year on ocean ridges is produced by the solidification of magmas, in part as volcanic rocks (basalts), and in part as plutonic rocks (gabbros, ultramafic rocks). With an average thickness of the order 6 km for the oceanic crust, the flux of basaltic magma from the mantle to the surface crustal layer at ocean ridges is about  $18 \text{ km}^3/\text{yr}$  (approx.  $5 \times 10^{13} \text{ kg/yr}$ ). The amount erupted as lava on the ocean floor is between 2 and  $4 \times 10^{13} \text{ kg/yr}$ ,

or about 1 order of magnitude greater than the rate of volcanism in island arcs and hot spots, as discussed later.

The rates of ocean crust generation just given refer to current steady-state production, and studies of magnetic anomaly patterns on the ocean floor have shown that production rate during the Tertiary has varied between about 17 and  $23 \times 10^6 \text{ km}^3/\text{million years}$ . The rate of global ocean crust production has, however, fluctuated much more significantly in the last 150 Ma (Fig. 1), with a notable maximum in the mid-Cretaceous. During this time, global ocean crust production (ocean ridge plus oceanic plateaus) was of the order 50–75% greater than current rates, largely due to high production of Pacific ridges in the period from 80 to 120 Ma. The mid-Cretaceous volcanic episode produced oceanic crust at a rate up to  $32 \times 10^6 \text{ km}^3/\text{million years}$  and represents the largest magmatic episode known on Earth.

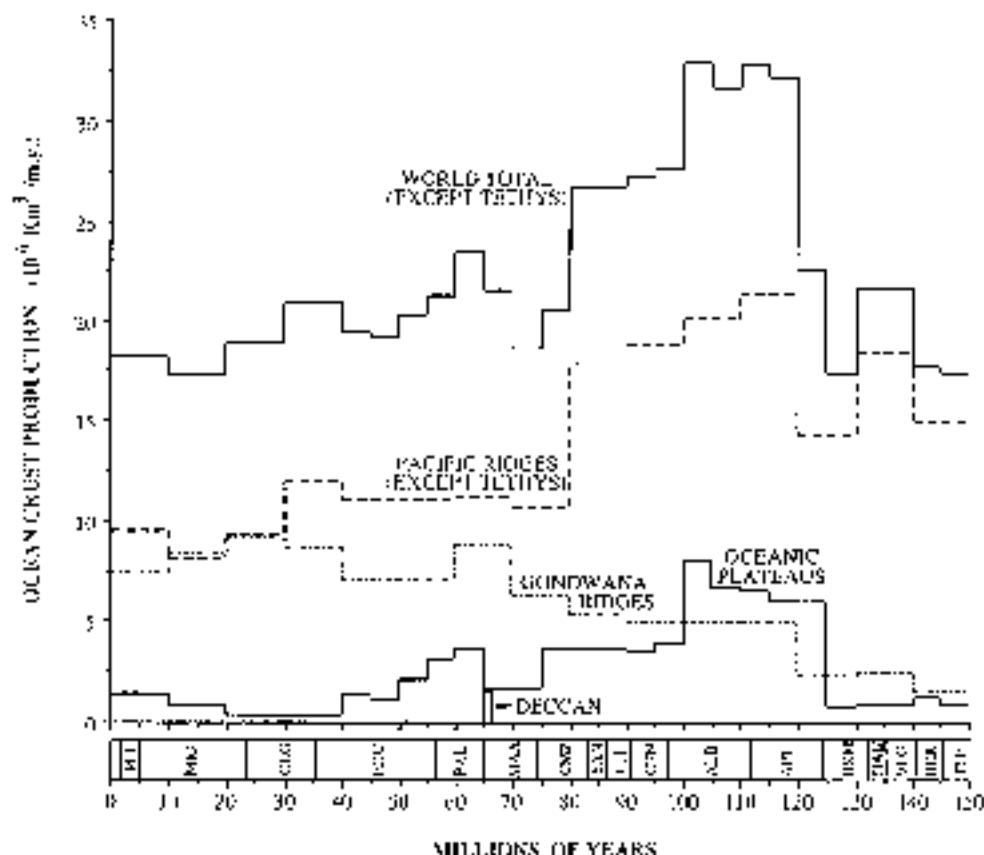

FIGURE 1 The rates of basaltic magma production and volcanism in the ocean basins of the Earth are measured by the rate of ocean crust formation. During the past 150 Ma the global rate has fluctuated mainly around  $15$  to  $25 \times 10^6 \text{ km}^3/\text{million years}$ , but during the mid-Cretaceous the oceanic crustal budget increased dramatically, with rates between 50% and 75% higher than present (Larson, 1991).

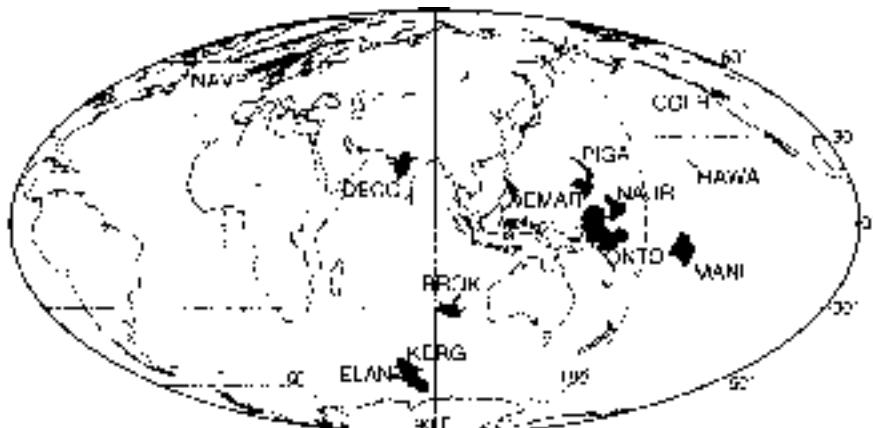

### III. LARGE IGNEOUS PROVINCES

Large igneous provinces (LIPs) are thick and extensive crustal regions, composed of mafic volcanic and intrusive rocks, that have formed by processes other than normal seafloor spreading. They occur in a variety of structural settings, as oceanic plateaus, submarine ridges, volcanic passive margins, seamount groups, continental flood basalts, and ocean basin flood basalts. They are often attributed to mantle plumes or hot spots, and they represent of the order 5–10% of the mantle output of magma today. However, in terms of magma production, they are episodic in nature, unlike the relatively steady-state activity of the ocean ridges. The volcanic components of LIPs are principally subaerial basaltic (tholeiitic) lava flows, but felsic and intermediate volcanic rocks also occur.

The largest LIPs are oceanic plateaus, forming broad, flat-topped volcanic regions that rise about 2 km above the surrounding seafloor (Fig. 2). Greatest of these is the Ontong Java plateau in the Pacific, covering an area of about 5 million km<sup>2</sup>. This great province is of mid-Cretaceous age, but it was erupted in a relatively short time span, from about 118 to 124 Ma, implying emplacement rates of tens of km<sup>3</sup>/yr. The Kerguelen plateau in the southern Indian Ocean is somewhat smaller but also a very impressive igneous province, some 2.3 million km<sup>2</sup> in area, emplaced about 110–114 Ma. The North Atlantic volcanic province, which is derived from a hot spot now centered beneath Iceland, has an area of more than 1.3 million km<sup>2</sup>, and was mostly emplaced between

55 and 58 Ma. Also notable are the Deccan traps in India (1 million km<sup>2</sup>), emplaced between 64 and 69 Ma and the Columbia River basalts of the western United States, erupted between 15 and 17 Ma. Thus they all have in common a relatively brief period of emplacement, and LIPs can be considered as transient magmatic episodes that significantly increase global magma production rates for a brief period (Fig. 3). In terms of Earth history, such events are truly catastrophic, and this raises the question of whether the emplacement and eruption of a large LIP will have far-ranging or perhaps global environmental consequences and affect biotic evolution, and many mechanisms have been proposed. The release of large amounts of carbon dioxide might raise significantly the global CO<sub>2</sub> levels in the Earth's atmosphere, which could potentially induce an enhanced greenhouse effect and global warming. Conversely, if the LIP volcanism is subaerial, then the emission of sulfur dioxide gas to the atmosphere could lead to stratospheric aerosol formation and global cooling events. While the nature and sign of the climate effects resulting from LIP emplacement remain controversial, we can state with confidence that their rapid eruption on the ocean floor will result in displacement of seawater and in turn a modification of global sea level. Thus it is estimated that the creation of the Ontong Java Plateau would have elevated sea level at least 10 meters.

LIPs occur in both oceanic and continental settings, intraplate and on plate boundaries, and their distribution is worldwide. The most prevalent hypothesis to account for LIP magmatism links them to mantle plumes or plume tails. This is supported by the fact that most but

**FIGURE 2** The location of some of the largest and best known LIPs on the Earth: Broken Ridge (BROK), Columbia River basalts (COLR), Deccan traps (DECC), East Mariana Basin flood basalts (EMAR), Elan Bank (ELAN), Hawaiian Islands (HAWA), Kerguelen Plateau (KERG), Manihiki Plateau (MANI), Nauru Basin (NAUR), North Atlantic volcanic province (NAVP), Ontong Java Plateau (ONTO), and Pigafetta Basin flood basalts (PIGA). (After Coffin and Eldholm, 1994.)

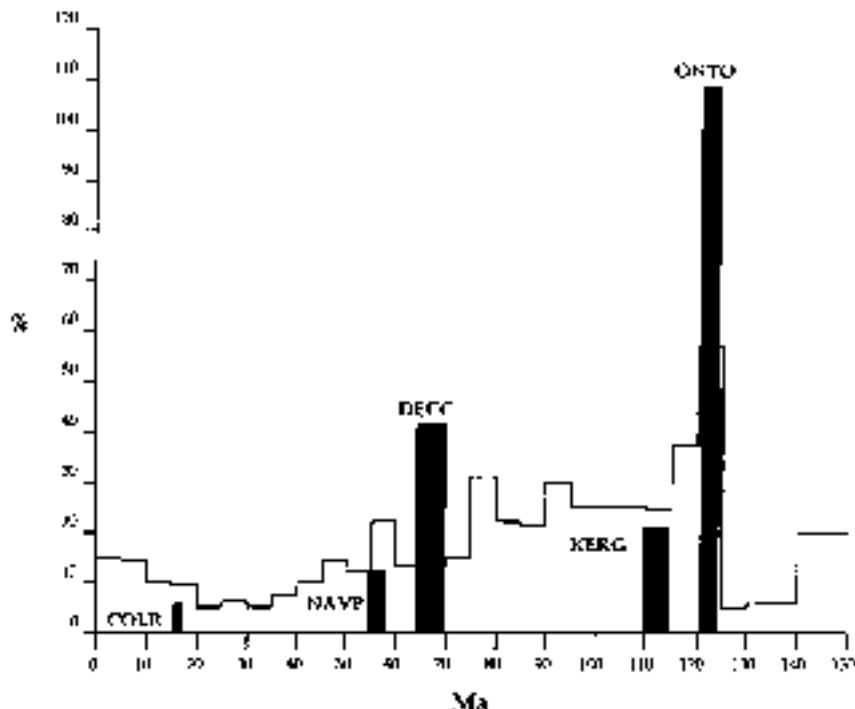

FIGURE 3 The crustal production rates of LIPs, as a percentage of midocean ridge crustal production rate versus time. The LIPs shown are Columbia River basalts (COLR), North Atlantic volcanic province (NAVP), Deccan traps (DECC), Kerguelen Plateau (KERG), and the Ontong Java Plateau (ONTO). Thin line is the global ocean crust production rate. (Adapted from Coffin and Eldholm, 1994.)

not all of the LIPs can be linked to hot spots, such as the link between the North Atlantic volcanic province and the Iceland hot spot, Deccan traps and the Reunion hot spot, and Kerguelen Plateau and the Kerguelen hot spot.

duction was at its peak, with a rate up to  $5 \text{ km}^3/\text{yr}$ , resulting in the formation of the Deccan traps in India. Melt production has steadily declined to the current rate of only about  $0.04 \text{ km}^3/\text{yr}$  in Reunion today. During the past 55 million years, the Iceland plume has pro-

#### IV. MANTLE PLUME MELT PRODUCTION RATES

If LIPs are produced by mantle plumes, then the huge emplacement of oceanic crust, such as that of the Ontong Java at rates up to  $12 \text{ km}^3/\text{yr}$ , must be viewed in the context of the dynamics of mantle plume activity. Comparisons with the currently active plumes are instructive, although they are all dwarfed by the huge LIP events in the early Cenozoic and mid-Cretaceous. The melt production rate of the Hawaiian plume in the Pacific Ocean has increased steadily in the last 35 million years to a value of about  $0.18 \text{ km}^3/\text{yr}$  today (Fig. 4). In contrast, the Reunion mantle plume in the Indian Ocean exhibits the opposite trend in melt production (Fig. 5). In its early stages (ca. 66 Ma), the Reunion plume pro-

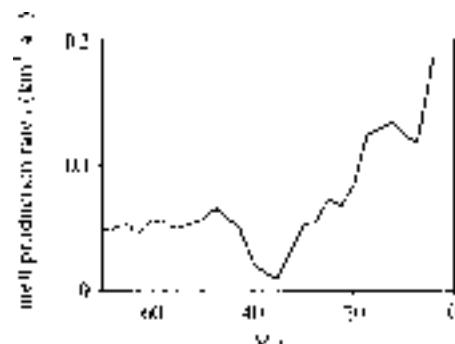

FIGURE 4 Basaltic melt production rate of the Hawaiian mantle plume has increased steadily in the last 35 million years, to a value of about  $0.18 \text{ km}^3/\text{yr}$  today. The rate is calculated from the volumes of individual seamounts and shield volcanoes above the mean seafloor level, and underplated material. (After White, 1993.)

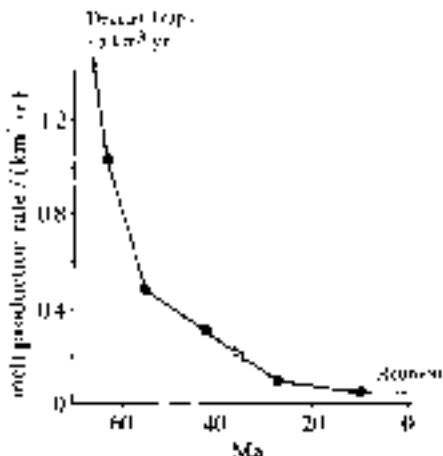

FIGURE 5 Variation in melt production rate with age along the trail of the Reunion mantle plume in the Indian Ocean. The rate was at peak of  $5 \text{ km}^3/\text{yr}$  about 66 million years ago, resulting in the extrusion of the Deccan traps on the Indian continent, but its production has steadily declined since, to the current rate of only about  $0.04 \text{ km}^3/\text{yr}$  on Reunion island today. (After White, 1993.)

duced the Iceland-Faeroes-Greenland ridge and extensive basaltic crustal formations on the rifted margins of the northern North Atlantic. A magma production rate of this plume has been estimated as  $0.24 \text{ km}^3/\text{yr}$ . It is clear from the above earlier discussion that melt production rates in currently active hot spots are at least an order of magnitude lower than those that occurred during peak production of the LIPs discussed earlier. When we consider together the evidence from LIPs and currently active mantle plumes, it appears that the peak magma production rate of a plume lasts only a few (2–5) million years, during which most of the magma is emplaced, and that rates build up and fall off exponentially with time.

The variations in melt production rates in mantle plumes are likely to be controlled by two factors. One is the intrinsic properties of the mantle plume (e.g., its potential temperature, magma flux, and dimensions); the other factor is the thickness of the lithosphere overlying the plume. As the plume rises within the mantle, melting will occur as a result of decompression, and the extent of melting is controlled in part by the thickness of overlying lithosphere. If the lithosphere is thick, decompression is insufficient to bring about extensive melting, and rise of the plume head is checked at great depth beneath the thick lithosphere. Where the lithosphere is thin, however, such as beneath a rifting continental lithosphere or beneath young oceanic litho-

sphere, large quantities of melt may be produced in response to decompression of the mantle as it ascends to regions of lower pressure.

It is clear from studies of currently active hot spots and from the emplacement of LIPs that this type of volcanism is highly episodic on the Earth, and the inception of such episodes is most likely related to the arrival of the heads of large mantle plumes at the base of the lithosphere. The origin of the mantle plumes remains in the realm of speculation, but they may originate from thermal or mechanical instabilities in the seismically anomalous and heterogeneous  $D''$  layer at the boundary between the Earth's core and the mantle, at a depth of about 2900 km (see Mantle of the Earth chapter).

## V. VOLCANIC ARCS

Explosive volcanism above subduction zones plays a fundamental role in the exchange of mass and energy between the solid Earth and the oceans and atmosphere. Just as variations in ocean ridge and plume activity discussed earlier have become the focus of intense study, there is a compelling need to examine long-term variations in volcanism associated with subduction zones, especially when we consider that such events have the potential for profound societal impact. In terms of environmental effects, episodes in volcanic arcs are likely to have a greater immediate impact than any variations in the rates of ocean ridge volcanism, because the former are dominantly subaerial, with discharge of potentially climate-modifying volatiles directly into the Earth's atmosphere. Large-scale siliceous eruptions that generate voluminous pyroclastic flows (ignimbrite deposits) represent the largest type of volcanic event known on Earth, and individual eruptions may discharge up to several thousand cubic kilometers of magma during a single event. Large ignimbrite eruptions occur relatively infrequently (one event every 20,000 years erupts a volume  $>1000 \text{ km}^3$ ), but significant uncertainties exist regarding variations in the rate of this type of volcanism on Earth or in a given volcanic province. Such events are of great interest, however, because of their potential for global environmental change.

Unlike the rates of seafloor spreading and oceanic crustal formation, the rates of island arc magma generation and volcanism are difficult to determine in a quantitative manner. The products of subduction zone magmatism contribute to the construction of the volcanic edifice of the arc, but a large fraction of the erupted

material is deposited in adjacent ocean basins (see chapter on Volcaniclastic Sedimentation around Island Arcs). Unraveling the land-based record of arc volcanism in a major ignimbrite province is hampered by the paucity and poor precision of many radiometric age dates, lack of mappable stratigraphic levels, and poor preservation of deposits. The evidence of major explosive volcanic eruptions is, however, well preserved in the marine environment adjacent to subduction zones as volcanic ash, or tephra layers, interbedded with deep-sea sediments. The marine tephra record is condensed in thickness compared with the terrestrial one, but it is more likely to be complete and easily dated by biostratigraphic methods and radiometric dating of phenocrysts found in the tephra layers. Thus the relative variations in the rates of explosive volcanism in arcs can be well determined from marine tephra layers, whereas the absolute values of magma production rate are poorly determined.

Estimates of Holocene rates of magma production and eruption in volcanic arcs are from 1 to  $5 \times 10^{12}$  kg $^{-1}$  yr $^{-1}$ . Most are probably underestimates, because they rarely take into account the large mass fraction of volcaniclastics deposited in adjacent sedimentary basins. Intuitively, one would expect that the volcanic production rate in an arc correlates with the rate of plate convergence; however, these rates do not appear to be simply related. If we examine the current estimates of extrusion rates (expressed as the volume rate per kilome-

ter of arc length) and rates of plate convergence for the Aleutians, the Lesser Antilles, Japan, and the Cascades province, the extrusion rate varies by about a factor of 2 (from about 4 to 9 km $^3$  my $^{-1}$  arc km $^{-1}$ ), while the plate subduction rate varies by almost an order of magnitude (2 to 9 cm $^{-1}$  yr $^{-1}$ ) and there is no simple correlation observed between these two parameters.

### A. Volcanic Episodes in Arcs

Explosive volcanism in island arcs is recorded as tephra layers in the ocean basins, and this record forms an important archive of the temporal and regional variations in arc volcanism. The tephra layers are centimeters to tens of centimeters in thickness, and represent the fallout of airborne volcanic ash hundreds or even thousands of kilometers from the source. Their thickness indicates that they are derived from individual explosive eruptions involving hundreds to thousands of cubic kilometers of magma, of the type that occur only about once in 10,000 yr in the Holocene.

Global compilations of the distribution of thousands of tephra layers in deep-sea cores from drilling of the ocean basins during the Deep Sea Drilling Project and the Ocean Drilling Program shows that their occurrence is remarkably episodic in geologic time (Fig. 6). The

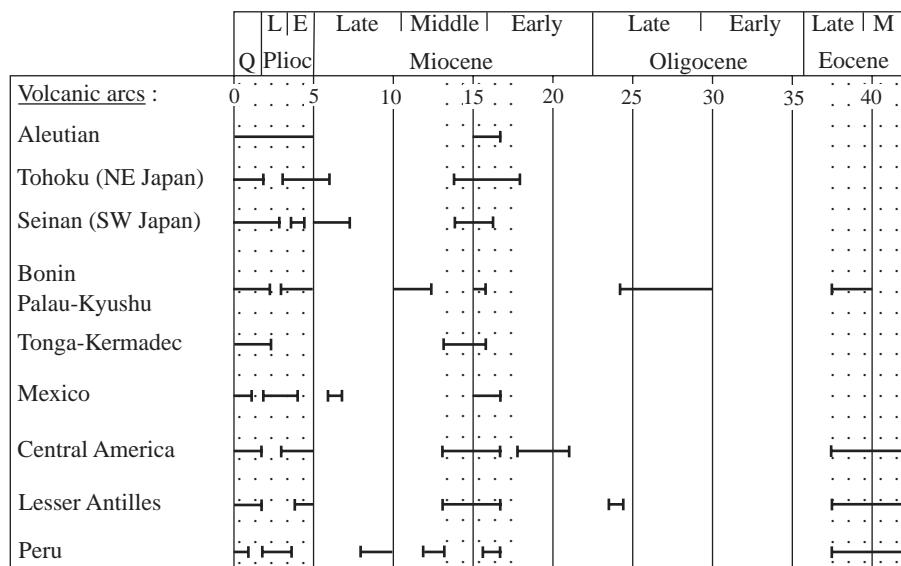

FIGURE 6 The occurrence of volcanic ash layers in deep-sea sediments near volcanic arcs is highly episodic. The horizontal bars show the periods of major tephra deposition for a number of circum-Pacific and Caribbean arcs, defining three principal global volcanic episodes (dotted regions) in the Pliocene to Quaternary (0–5 Ma), Miocene (13–17 Ma), and Eocene (37–42 Ma). (After Cambray and Cadet, 1996.)

frequency of volcanic ash layers shows a pronounced peak at all circum pacific sites in the Quaternary (0–5 Ma) and in the middle Miocene (ca. 13–17 Ma), and in addition, there is evidence for a volcanic episode in the Eocene (ca. 37–42 Ma). The results of recent drilling on ODP Leg 165 in the Caribbean region have reinforced the concept of volcanic episodes in island arcs, providing a more detailed record of volcanism throughout the Cenozoic with the recovery of more than 2000 tephra layers. The Caribbean tephra record, principally resulting from explosive ignimbrite-forming eruptions in the Central American arc, is compared in Fig. 7 with the global volcanic ash layer record. There is good agreement between the two in terms of a late Eocene to earliest Oligocene episode and the middle Miocene episode, whereas the Quaternary episode is poorly represented in the Caribbean record. While these marine tephra layers faithfully record the larger and typically silicic explosive eruptions, this archive does not normally contain a record of

the andesitic and basaltic volcanism that typically forms an important component of arc evolution.

The global volcanic ash record shows an interesting relationship to the foraminiferal oxygen isotope record of the Cenozoic ocean, as also shown in Fig. 7. The  $\delta^{18}\text{O}$  curve shows three abrupt steps, with major increase in  $\delta^{18}\text{O}$  coinciding with the volcanic episodes. These oxygen isotope events represent the major global climate cooling stages during the Cenozoic; their relationship to the volcanic episodes is a tantalizing idea, but a cause-and-effect relation remains speculative. One could hypothesize that during a single volcanic episode, the flux of sulfur dioxide gas from explosive eruptions to the atmosphere results in the buildup of a sustained sulfuric acid aerosol in the stratosphere, resulting in global cooling.

Regionally, such as in the Caribbean and Central America, the marine tephra record shows clear evidence of volcanic episodes. Such episodes could be attributed

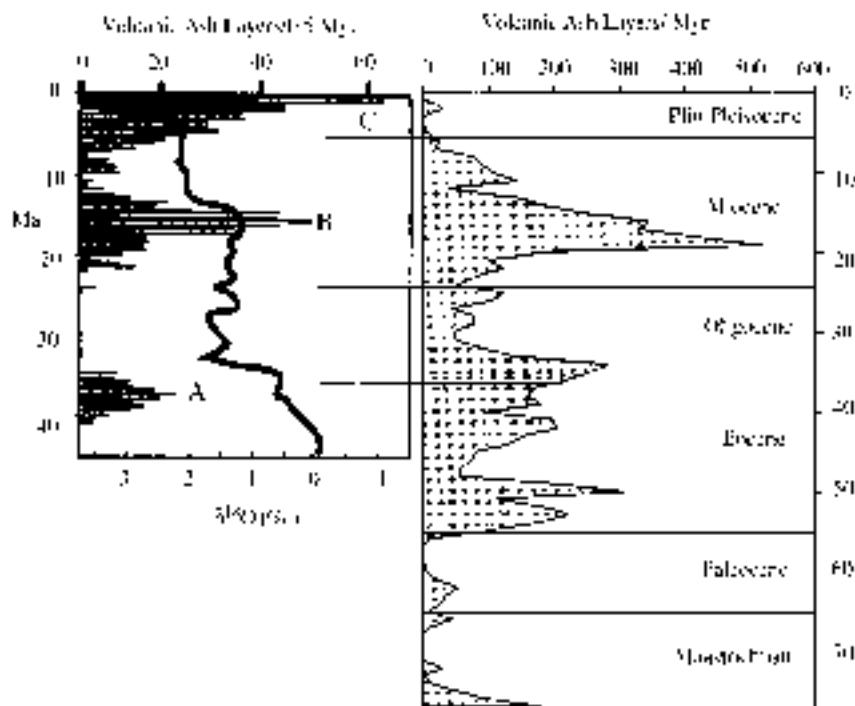

FIGURE 7 Comparison of global and Caribbean volcanic episodes, based on deep-sea tephra layer occurrence. The global compilation of marine tephra layers on the left (Herve Cambrey, personal communication, 1999) shows three episodes: (A) in late Eocene to earliest Oligocene, (B) middle Miocene, and (C) Plio-Pleistocene. The right-hand panel shows the tephra layer distribution in Caribbean sediments (ODP Leg 165). The early Eocene Caribbean episode is local, related to activity of the Cayman arc, while the late Eocene and middle Miocene episodes correspond to those of the global record. Also shown as a curve superimposed on the left-hand panel is the  $\delta^{18}\text{O}$  of benthic foraminifera in Atlantic sediments. Major steps in the oxygen isotope trend (increase) coincide with the volcanic episodes, and they mark the principal cooling steps in the climate history of the Cenozoic.

in turn to regional tectonic evolution of the subduction zone. Various ideas have been put forward to explain variations in the rate of volcanism. An accelerated rate of plate subduction could conceivably increase mantle upwelling in the mantle wedge below arcs, and enhance partial melting. Similarly, increased subduction of sediment may increase the flux of water and other volatiles that act as fluxing agents and lower the temperature of beginning of melting in the mantle and arc lithosphere. It is important to recognize, however, that the observed volcanic rate variations are almost entirely measured by the eruptions of high-silica magmas, whereas most of the plate tectonic and petrogenetic parameters relate to generation of primary basaltic melts.

While local or regional variations in rates may be accounted for, the indication of global episodes in explosive volcanism in arcs poses a major and unresolved problem for geologists. The concept of global synchronicity of explosive volcanism is particularly difficult to reconcile with the paradigm of plate tectonics. At any one time, the various subduction zones on Earth experience a spectrum of the parameters that may affect the rates of subduction zone volcanism, such as the rates and direction of plate motion and the age and composition of the subducting slab. No unifying mechanism is obvious that could lead to a simultaneous increase in global eruption rates. A possible exception to this may be the rate of sediment subduction. The high global rates of explosive volcanism in the Quaternary could possibly be related to increased availability of sediment for subduction, when the rate of sedimentation increased globally in response to accelerated continental erosion. In this scenario, the increased availability of sediment could result in greater rate of subduction of sediment and water, accelerating magma generation. Such a hypothesis does not account, however, for the Miocene and Eocene explosive volcanic episodes. Variations in the rate of volcanism may conversely be a response to climate-driven crustal dynamics, such as changes in sea level and glacier loading brought about by climate change.

# EFFUSIVE VOLCANISM

The term effusive volcanism refers to the nonexplosive extrusion of magma at the surface, and thus includes all eruptions of lava flows, coulees, and domes. Effusive volcanism exhibits a remarkable variety of eruptive styles, environments, and deposits. Ranging from sub-aerial eruptions to those occurring at great depths in the sea or under vast glaciers, effusive eruptions are ubiquitous on the Earth's surface, as well as on some of the terrestrial planets. Although effusive volcanism is by definition nonexplosive, it is clearly related to explosive activity in many instances.

The chapter Basaltic Volcanoes and Volcanic Systems introduces the different types of basaltic volcanoes whose eruptions produce mainly lava flows. These volcanoes should be more properly thought of as volcanic or magmatic systems, since beneath each volcano is a complex system of magma generation, transport, and storage. Monogenetic volcanoes erupt only once, whereas polygenetic volcanoes erupt repeatedly. Lava shields are low-angle volcanoes built by rapid effusions of basaltic lava and intrusions of magma at shallow depths. Stratovolcanoes are steeper edifices constructed of pyroclastic material as well as lavas; these volcanoes are normally associated with subduction zones, with magmas that tend to be rich in gas. Flood basalts are vast lava flow fields that are erupted rapidly from fissure systems located in areas of broad crustal extension. Central volcanoes comprise an outer zone, in part basaltic composition, and an inner zone with more silica-rich compositions; these volcanoes may have central calderas.

The different types of lava flows are treated in the chapter Lava Flows and Flow Fields. Interestingly, lava is the single most common feature on the surface of the terrestrial planets. Three main types of lava crusts are observed on Earth: pahoehoe, aa, and blocky. Pahoehoe is a smooth, continuous basaltic lava crust; aa is also basaltic but broken and irregular; and blocky lava

is fragmental but less irregular and more silica-rich than aa. Most lava flows do not travel very fast, but some are extremely rapid. The development of a lava flow depends on the effusion rate at its source, its physical properties, and its environment, such as the local topography, subaerial, submarine, and so forth. The potential lengths of lava flows depend on several factors, chief among which is the effusion rate.

When magmas become more silica-rich than basalt, lava domes may form instead of lava flows. The chapter Lava Domes and Coulees examines different types of lava domes and why they form. Sometimes a lava dome is transitional to a lava flow, in which case it is called a coulee. Since the outer skin of a lava dome may cool and form a crust, buildup of pressure may occur within the dome's interior, leading to explosive activity such as vulcanian eruptions, pyroclastic flows, and pyroclastic surges. Indeed, cyclic dome growth and destruction have been observed at various volcanoes. If a dome grows rapidly, it has an increased tendency to collapse, frequently resulting in pyroclastic flows.

Fire fountains and spatter-fed lavas are discussed in the next chapter, Lava Fountains and Their Products. Fire fountaining is generally characteristic of basaltic magma, which is both fluid and rich in dissolved gas; the reader will no doubt have a good image of the spectacular curtains of fragmental material thrown into the air by fire fountaining to many tens or even hundreds of meters. The fountains can occur along eruptive fissures or from central vents. The combination of rapid magma ascent and decompressive degassing and vesiculation forms the fountains. As the fragments fall to the ground, they may cool and remain in place, perhaps adhering to each other if they are still sufficiently hot and fluid. If the accumulation rate of particles is rapid, then the fragments may actually coalesce and flow as lava. This flow may not show any evidence of its initially fragmental origin.

The following chapter is Basaltic Volcanic Fields. Such fields are favored when the magma production rate is comparatively low and the crustal extension rate is high. The fields comprise a diverse variety of volcanic centers such as cones, maars, tuff rings, small shield volcanoes, and lava domes. The centers are frequently monogenetic, a good example being Parícutin in Mexico, which erupted in the 1940s. The various volcanic centers may show structural control such as linear alignments, suggesting control along fault systems and the presence of dikes beneath the vents. The volcanic centers also may show clustering; they are found frequently on the flanks of larger volcanoes, as well as inside and outside the margins of calderas.

The following chapter is Flood Basalt Provinces. In

contrast to basaltic fields where the magma production rate is low, flood basalt provinces are characterized by huge volumes of lava erupted rapidly over only one to two million years. Due to the high extrusion rates, basalt plateaus are formed instead of conical volcanic edifices. The magmas appear to come from great depths and are clearly associated with mantle plumes (hot spots), thinned lithosphere, and the breakup and separation of tectonic plates. Individual lava flows can be enormous in terms of their volume, area, and length, and the flows may be turbulent.

Submarine lava flows are the most abundant igneous rock type on the Earth's surface; the chapter Submarine Lavas and Hyaloclastite details the remarkable deposits found in this environment. At great depths in the ocean, exsolution of volatiles is hindered by the weight of the ocean mass, favoring lava flows at the expense of pyroclastic rocks. At shallower levels where the hydrostatic pressure is diminished, explosions are more feasible. The lavas are characterized by rapid cooling by seawater, resulting in pillow lavas, lobate lavas, and sheet flows, in order of increasing effusion rate. The rapid cooling also can thermally shock the lava, causing fragmentation and forming glassy fragments called hyaloclastite.

As submarine volcanoes evolve, they may progress to build seamounts or oceanic islands, the focus of the chapter Seamounts and Island Building. Seamounts may occur in clusters or chains, with the chains exhibiting a systematic age progression from one end to the other. The sizes of seamounts vary considerably; seamounts found in intraplate settings are generally much larger than those situated on or near mid-ocean ridges. Seamounts record a constructional stage that depends on the water depth, magma composition, eruption rate, and surrounding topography. As a seamount approaches the surface of the ocean, the observed proportion of fragmental rocks to lavas increases because explosive activity is facilitated at shallower depths. Seamounts also record valuable information on mantle upwelling, lithospheric subsidence, and sea level changes.

Subglacial Eruptions closes this section on effusive volcanism by looking at eruptions that occur beneath glaciers. The chapter provides a useful bridge to the next section on explosive volcanism, because subglacial eruptions can be both effusive and explosive in nature. Large volumes of water are generated rapidly by melting of ice by the eruption; these volumes are sometimes drained catastrophically, resulting in huge floods called jökulhlaups. The large volumes of water also result in magma–water interactions that influence eruptive activity, such as hydrovolcanic eruptions.

## GLOSSARY

**central volcano** A volcano that erupts magmas of various compositions, for example, basalt and rhyolite. These volcanoes frequently have calderas in their central parts.

**decollement** A detachment structure resulting in differential movement of rock above and below.

**lava shield volcano** A low-angle volcano constructed principally of basalt lava flows.

**monogenetic volcano** A volcano that erupts only once.

**polygenetic volcano** A volcano that erupts repeatedly, often in an episodic manner.

**stratovolcano** A volcano constructed of alternating layers of lava flows and pyroclastic rocks. Stratovolcanoes are steeper than shield volcanoes.

---

## I. INTRODUCTION

More than half of all volcanoes consist wholly or largely of basalt. Basaltic volcanoes are found in all tectonic settings. They follow both convergent (volcanic arc) and divergent (oceanic rift) plate boundaries, occur at hot spots and areas where crustal extension is taking place, and are developed on a vast scale on the ocean floors. This chapter describes their occurrences on land.

A basic relationship is that some volcanoes (called *polygenetic*) erupt repeatedly, whereas other volcanoes (called *monogenetic*) are born, erupt once only, and then die. Polygenetic volcanoes have a sufficiently large and persistent magma supply rate that an ascending magma batch will preferentially follow the still-hot pathway of the preceding batch. Conversely, a volcano is monogenetic if the magma supply is so small or episodic that any pathways have cooled down and are no longer favored routes for the next magma batch.

Polygenetic volcanoes are generally considered to possess a magma storage chamber at a neutral buoyancy level. Magma ascends into this chamber mainly because of its positive buoyancy (but sometimes aided by tectonic forces). Processes in the chamber, such as the exsolution of gases, modulate the output.

When describing volcanoes it is of great merit to recognize the existence of a larger entity, namely, the volcanic (or magmatic) system. A system may embrace the melting anomaly at the magma source, the conduits through which magma rises toward the surface, the magma chambers, intrusions, and geothermal zones, and the volcano itself.

A volcanic system may be crudely compared with a civilization system (a city), with the extensive infrastructure of transportation, water and power supply, waste disposal, and communications on which a city depends. Both systems are sustained by an input of energy (as hot magma and gases, or in the city system as fossil fuels, electric power, and food). Very roughly, a city of 1 million people requires about the same annual power input as an average-sized volcanic system having an annual magma input of 1 million cubic meters.

In this chapter a fivefold grouping of basaltic volcano systems is presented (Fig. 1). The two main parameters that control volcano type are the time-averaged magma supply rate and the frequency of incoming magma batches, as shown by Fig. 2.

## II. LAVA SHIELD VOLCANOES

Examples of lava shield volcanoes are Mauna Loa and Kilauea in Hawaii. They consist largely of thin lava flows, with minor pyroclastic layers. Their subaerial slopes are mostly 4–8 degrees (less on coastal lava deltas). They have steep-walled summit calderas (Fig. 1a) and also pit craters that are similar to calderas in form but smaller. Mauna Loa, at  $40,000 \text{ km}^3$  the largest volcano on Earth, stands 4169 m above sea level and 8 km above the ocean floor, plus an additional 4 km where the base of the volcano has sagged because of its huge mass. Mauna Loa and Kilauea are the most productive volcanoes on Earth, having a combined lava output of about  $8 \text{ km}^3$  per century.

The low-angle shield form results from the low lava viscosity, the commonly high effusion rates that drive lavas fast and far, the high proportion of lava that issues from flank vents and not from the summit, and the spreading (widening) and subsidence of the volcano that occurs in the summit area and rifts.

A point of confusion is that lava shields occur on two scales. The name is applied to mainly large polygenetic structures, but also to mainly small monogenetic structures. The latter may be termed shields of scutulum

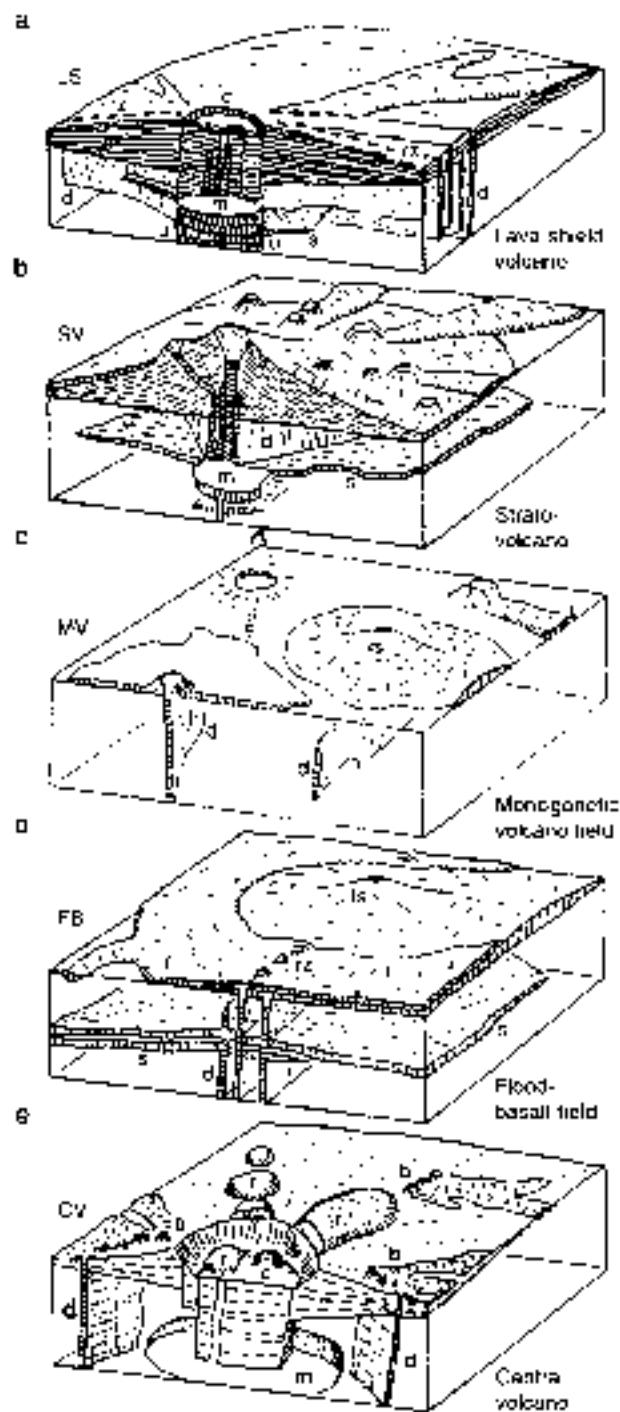

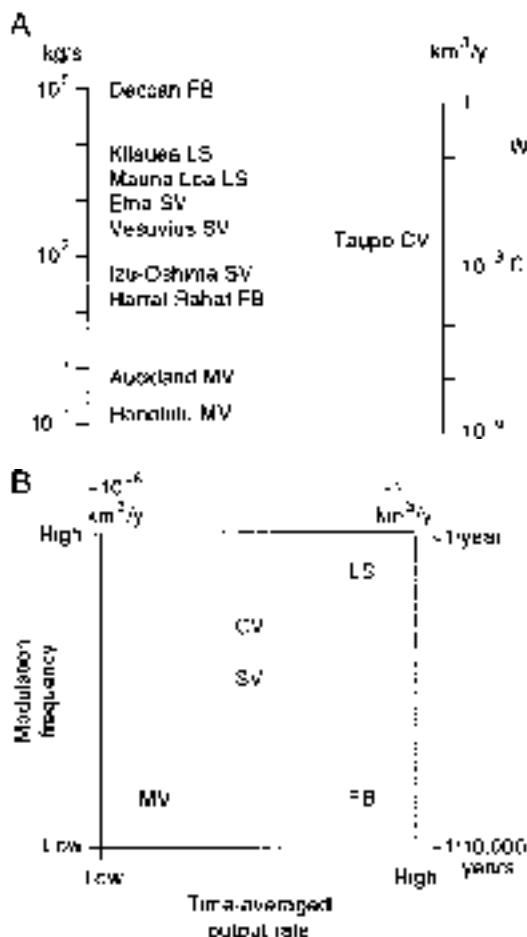

FIGURE 1 The five types of basaltic volcano systems illustrated schematically by block diagrams. Key: b, basaltic vents; c, caldera; d, dike; is, lava shield of scutulum type; m, magma chamber; rz, rift zone; r, rhyolitic lava dome; s, sill or intrusive sheet; u, plutonic, gabbroic, or ultramafic rocks. (1993, Geological Society of London.)

**FIGURE 2** (A) Time-averaged output rates of selected volcanic systems in kilograms per second and in cubic kilometers per year. Note that the greatest outputs are by flood basalt and lava shield systems, and the smallest by monogenetic volcano systems. Key: W, equivalent world energy consumption by mankind, excluding food; C, equivalent energy consumption, including food, by city having a population of 1 million. (B) Plot of the time-averaged output rate against modulation frequency (i.e., eruption frequency), the two main inferred controls on volcanic system types, showing the approximate average positions occupied by the five kinds of basaltic volcano systems. Semiquantitative scales are shown along the top and right-hand side. (1993, Geological Society of London.)

type (from Latin *scutulus*, the diminutive of *scutus*, meaning "shield").

Each large Hawaiian shield volcano has two narrow and well-defined colinear rift zones extending to as far as 250 km from the summit. Some volcanoes also have a third and less well defined rift. Eruptions are concentrated at the active rift zones. Vent edifices range from low ramparts consisting of highly expanded scoria and spatter formed when magma viscosity was least, to cin-

der cones up to 200 m high when viscosity was appreciably higher. Spheroidal and spindle bombs are common at cinder cones.

Two main morphologic types of lava flows occur. One, called *pahoehoe*, is smooth surfaced. The other, called *aa*, has a thick upper zone of loose clinkery or rubbly debris. Pahoehoe results when the volumetric flow rate of lava is low, and aa forms when it is high. Viscosity is indirectly involved, because aa still flows strongly after significant cooling, to the point where lava viscosity is too high for breaks in the surface crust to be healed.

Volcanic eruptions are mostly from fissures, and intense complexes of intrusive dikes (the subsurface manifestation of eruptive fissures) underlie the caldera and rift zones. A traverse across the Koolau volcano (Oahu, Hawaii) contains an estimated 7400 dikes, totaling in aggregate 4.5 km wide. It is inferred that coarse plutonic (gabbroic) rocks may underlie the dike complex.

Shouldering aside of the preexisting volcanic edifice by dikes is largely responsible for the seaward movement, by decimeters per year, of the southern flank of Kilauea. Movement is thought to occur on a decollement—a low-angle fracture zone on which lateral movement occurs—in slippery subvolcanic marine sediments. Major prehistoric volcano collapses, some involving as much as 1000 km<sup>3</sup> of rock, have occurred repeatedly in the history of some volcanoes. They include catastrophic rock avalanches that carried debris 200 km over the ocean floor. A surface limestone breccia reaching to 326 m above sea level on Lanai (Hawaii) is widely thought to be the deposit of a tsunami generated by a catastrophic collapse event.

Shield volcanoes elsewhere may deviate somewhat from the Hawaiian model. Some in the Galapagos Islands of Ecuador have radial dike swarms; also their shield culminates in a steep dome and deep summit caldera; a circumferential (annular) rift zone occurs around the caldera rim. Piton des Neiges (Reunion Island, Indian Ocean) is cut by swarms of flat-lying intrusive sheets in lieu of dikes. Maderia and Tahiti are dissected by profound erosional canyons.

A few shield volcanoes have persistent active lava lakes in their summit caldera. The most famous lava lake was that in Halemaumau pit crater (Kilauea), which persisted for more than a century until it drained into fissures in 1924. Drainout was accompanied by violent groundwater explosions. Others are found in Erta Ale (Afar, Ethiopia), Mount Erebus (Antarctica), and Nyiragongo (Congo). Lakes are sustained by strong magma convection in the conduit that joins them to their magma chamber.

The escape of a flood of highly fluid lava from Nyiragongo lava lake in 1977 gave rise to remarkably fast-moving (ca. 60 km/hour) lava flows that killed many people. Elephants were also overcome, and in a bizarre twist their carcasses were coated by a thin layer of lava.

Hawaiian lava shields at the peak of their activity erupt tholeiitic lava derived by a high degree of partial melting from mantle peridotite source rock. With declining activity, alkali basalts are erupted from scatters of flank vents as the summit magma chambers solidify and rift zones are no longer preferred pathways. Later, highly alkaline (e.g., nepheline) lava derived by a low degree of partial melting may erupt in a “rejuvenation stage” of volcanism that builds small fields of monogenetic volcanoes.

### III. STRATOVOLCANOES

Stratovolcanoes consist of explosively erupted cinders and ash interbedded with lava flows. They tend to a steeply conical form (Fig. 1b), and in their upper part stand at the repose angle of loose rock (about 35 degrees measured from the horizontal). Among the largest are Huzi (Fuji) in Japan and Klyuchevskoy in Kamchatka, which rise 3700 and 3000 m, respectively, above their surroundings and have estimated volumes exceeding 1000 km<sup>3</sup>.

The birth and growth of two stratovolcanoes has been observed. One, Izalco in El Salvador, was born in 1769 or 1770 and was almost continually active until 1966 by which time it had built to 650 m high. The other, Cerro Negra in Nicaragua, was born in 1850 and in the 17 eruptions since then grew to a similar height. Both began as cones of cinders and ash and became buttressed by lava flows.

A few volcanoes, notably Etna and Stromboli in Italy, display very persistent activity, and molten lava resides in their summit crater for decades or longer. Stromboli has many small explosions daily that throw up incandescent lava clots, and evidently it behaved similarly to at least as far back as ancient Roman times when it was referred to as the “Lighthouse of the Mediterranean.”

Some stratovolcanoes such as Oshima in Japan erupt at fairly regular intervals (their activity is time predictable), or the volumes of erupted lava are proportional to the lengths of the preceding repose periods (their activity is volume predictable). From a broader perspective, such volcanoes exhibit steady-state conditions, consistent with the notion that magma feeds steadily into

the magma chamber, but enough must be stored there before it can erupt.

Basalts in arc settings are tholeiitic or calc-alkaline and merge with increasing silica content to andesites. The prevalence of rather violent explosive activity, the occasional generation of pyroclastic flows as were observed on Lopevi (Vanuatu) in 1960 and Ulawun (Papua New Guinea) in 1978, and the prevalence of rough rubbly and blocky lava surfaces point to magma viscosities generally higher than those of shield tholeiites.

Many of the volcanic rocks of stratovolcanoes are porphyritic, that is, they contain macroscopic crystals (called phenocrysts) that grow in the cooling magma, likely in the magma chamber or conduit. Phenocryst minerals include plagioclase, olivine, and pyroxenes. Phenocrysts in the highly fluid shield tholeiites have commonly settled through the lava to produce striking local (decimeter-scale) concentrations. In contrast, the phenocrysts in stratovolcanoes are suspended in the lava and tend to be uniformly distributed through each lava flow. The phenocrysts are, thus, useful indicators of lava viscosity.

Many stratovolcanoes have cinder cones and craters of parasitic (adventive) vents on their flanks. Hundreds occur, for example, on Etna. Alignments of vents mark eruptive fissures. In some volcanoes these linear features have a radial distribution. In others they tend toward a parallel arrangement and delineate rift zones. Rift zones in arc volcanoes tend to be aligned parallel with the tectonic plate-convergence trajectory.

Many stratovolcano cones have been truncated by caldera collapse. Vesuvius in Italy is an example. The caldera in this case is asymmetric and is horseshoe-shaped in plan. The rim is called Monte Somma. Many stratovolcanoes have a lake in their crater. On the more active volcanoes the lake is steaming hot and muddy. It is also strongly acidic, due to the influx of hot acidic gases (SO<sub>2</sub>, HCl) from the magma chamber. When hydrothermal and phreatic explosions occur they eject mud and strongly weathered rocks. In the less active lakes the water often has brilliant blue or green colors, attributed to minute particles of sulfur in the water.

### IV. MONOGENETIC VOLCANO FIELDS

These are clusters or scatterings of small monogenetic volcanoes, each of which erupts once only. Many of the volcanoes comprise a cinder cone, commonly with

associated lava flows (Figs. 1c and 3). Some are small lava shields. Others are tuff rings or maars cored out by phreatomagmatic explosions (where lava exploded in contact with water) at vents on low-lying ground or under water. The shields are of the scutulum type, for example, Rangitoto Island in the Auckland field (New Zealand), which is 5.5 km in diameter, 140 m high, and 1.0 km<sup>3</sup> of it occurs above sea level.

A typical monogenetic field may contain 10–100 volcanoes of aggregate volume about 10 km<sup>3</sup>, and may span 50 ka to 5 Ma. The Michoacan-Guanajuato field in Mexico is much larger than average; it contains more than 1000 volcanoes, but merges into and partly consists of flood basalts. It had two historic eruptions. One saw the birth of El Jorullo in 1759–1774, a line of four or five cones along 3.4 km of fissure, and a lava field covering 12 km<sup>2</sup>. The main cone rises about 330 m above its base.

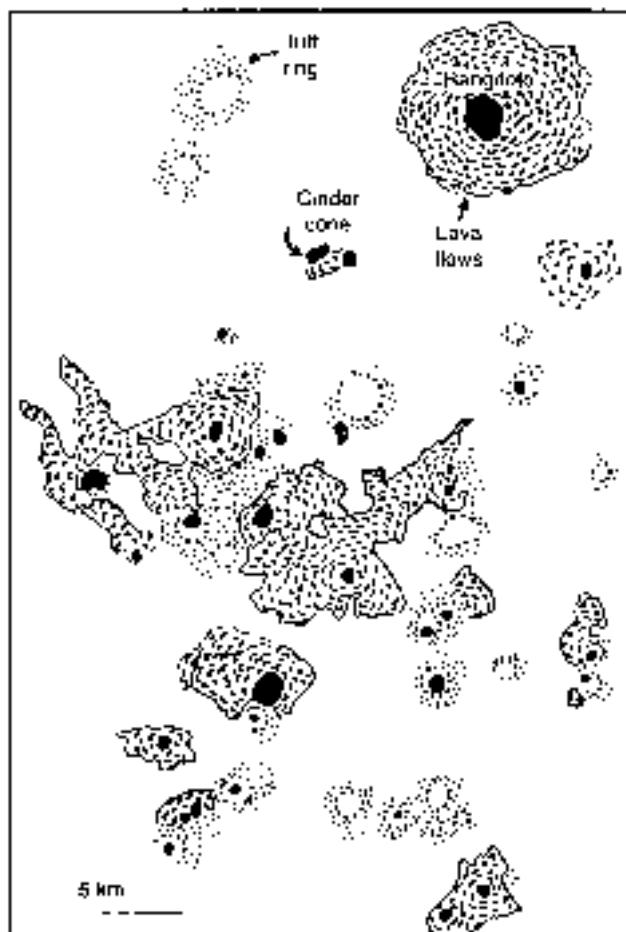

FIGURE 3 Sketch map of the Auckland, New Zealand, monogenetic field, simplified by deleting the coastline. (1993, Geological Society of London.)

The other eruption, that of Paricutin in 1943–1952, was andesitic.

Deeply eroded monogenetic fields are known in many places, for example, in East Fife (Scotland) where about 100 volcanic vents, the roots of monogenetic volcanoes, occur over an area 25 km across. Some vents are plugs of basalt. Others are diatremes, which are vertical pipes filled with explosively fragmented volcanic tuff and other debris. Dikes occur in other fields.

Monogenetic fields occur in volcanic arcs, where the basalt is associated with andesites, and they also occur in hot spot settings where the basalt is alkalic. A feature of the latter is that the basalt contains included fragments of mantle-derived ultramafic rock, often loosely referred to as olivine nodules. The presence of these inclusions indicates that the magma rose without pause from the mantle: if the magma had paused, the inclusions would have dropped out.

Rarely, the pipes in monogenetic fields contain diamonds. Diamonds form under very high pressures, equivalent to depths of 200 km or more. Their survival depends on being transported very rapidly from the mantle to the surface, otherwise they oxidize and are destroyed.

#### V. FLOOD BASALT FIELDS

These consist of voluminous and extensive spreads of lava flows erupted from scattered monogenetic fissure vents. They tend to flood the landscape and generate a new landscape of subdued relief (Figs. 1d and 4). They occur at hot spots where significant crustal spreading has occurred, for example, the Snake River Plain (Idaho), Iceland, and the fields in Arabia and Syria that parallel the Red Sea/Dead Sea rift system. Individual fields cover  $3 \times 10^3$  to  $5 \times 10^5$  km<sup>2</sup>. Outpourings of particularly large “giant” fields such as the Deccan in India have punctuated Earth’s history, and are approximately coincident with mass bioextinction events.

Many individual lava flows have volumes exceeding 10 km<sup>3</sup>. Youthful examples include the 1783 Laki lava in Iceland, which covers 565 km<sup>2</sup> and has a volume of 10–15 km<sup>3</sup>; and the Toomba flow in Queensland, Australia, which flowed 120 km down an average gradient of only 0.2 degrees. Giant fields such as the Columbia River Plateau in Washington state (USA) contain flows exceeding 1000 km<sup>3</sup> in individual volume. Vents are marked by crater rows of spatter, agglutinate, and cinders. Commonly, fissure vents evolved to point

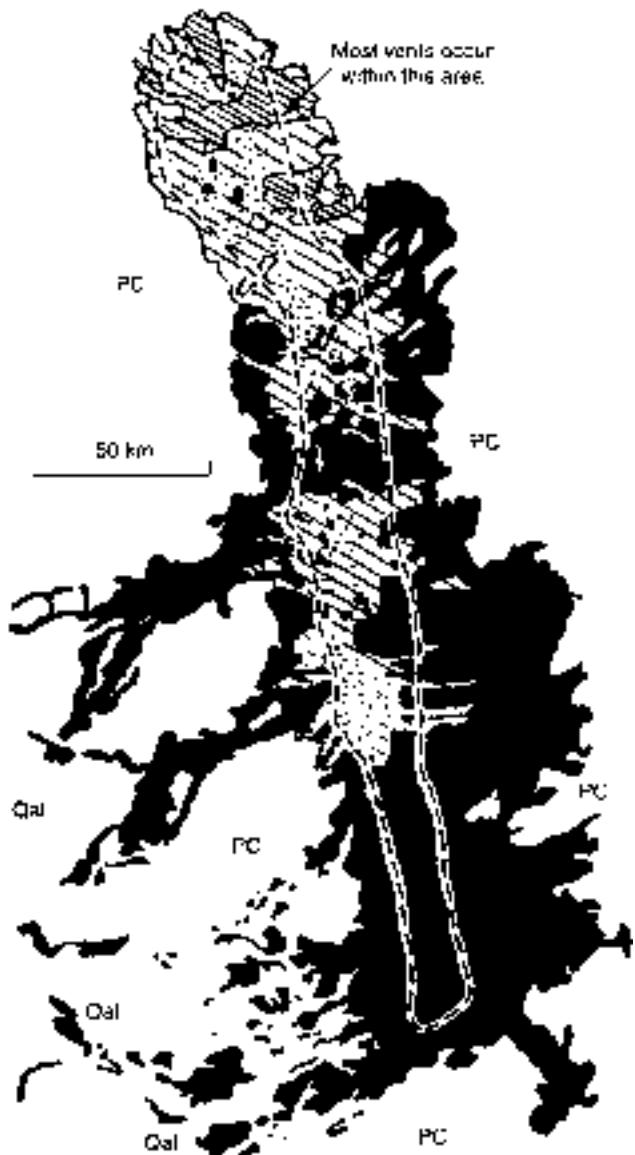

FIGURE 4 Sketch map of a moderate-sized flood basalt field: Harrat Rahat in Arabia. Solid black, lava 10–1.7 Ma; open diagonal shading, 1.7–0.6 Ma; dots, vents; closed diagonal shading, lavas under 0.6 Ma including those of historic eruptions in A.D. 641 and 1256; dashed line, approximate limit of vents; PC, Precambrian basement rocks; Qal, Quaternary sediments near Red Sea coast. (1993, Geological Society of London.)

sources where vent widening by localized wallrock erosion was concentrated.

Many lava flows are compound, meaning that they are divided into flow units, each unit having chilled margins against its neighbors. Great accumulations of pahoehoe flow units form shields of the scutulum type typically sloping at 1–7 degrees. A fine example from

Iceland is Skjaldbreid, 8 km in diameter and rising about 500 m above its base. Flood basalt fields in Iceland consist of many overlapping low-angle shields. Many of the compound lavas exhibit structures caused by endogenous growth as freshly erupted lava injected under and lifted up the surface crust, and lava tubes formed where lava drained out from under the crust.

Flow units are thickest where erupted on shallow slopes. They then commonly exceed 10 m thick. They exhibit distinctive pipe vesicles (elongate gas bubbles) and segregation bodies (vesicle cylinders and segregation veins). Lavas ponded in depressions may rest on lignite coal deposits (the fossilized contents of former marshes) and lake sediments. They show columnar jointing.

Eroded flood basalt fields are normally seen to have inwardly directed dips due to subsidence that are greatest where the lava pile is deepest. They are cut by linear dike swarms that locally comprise 5–20% of total rock. Good examples occur in the Hebridean Volcanic Province in Scotland. A typical swarm is 20 km wide by more than 100 km long, and in cross traverses dikes typically number hundreds and may aggregate up to 2 km wide. Dikes are narrowest and the swarm most intense where, locally, a flood basalt field is capped by a central volcano.

## VI. CENTRAL VOLCANOES

Central volcanoes are volcanoes that erupt silicic as well as mafic (basaltic) magmas. Commonly, the composition is bimodal, and silicic and mafic rocks may each be more voluminous than intermediate rocks. The broad central part of the volcano is mainly or exclusively made of rhyolitic rocks, and flanks consist of flood basalt. Newberry Volcano in Oregon, for example, has basaltic lower flanks 20 km wide, sloping at 1–3 degrees outward, and scattered with 400 cinder cones (Fig. 1e). The main cone and caldera occur in a central zone 12 km wide and consist mainly of rhyolitic rocks including pumice, ash, and obsidian flows. Some pumice and ash layers extend onto the flanks.

Typically, multiple rhyolitic vents occur. They tend to be monogenetic because intervals between rhyolitic eruptions are long (1–1000 ka). The zone in which they occur is crudely circular and typically about 10 km in diameter, embracing the caldera and caldera rim. This zone reflects the width of the inferred underlying silicic magma chamber from which the rhyolitic eruptions stem.

This central area is a shadow zone from which basaltic vents are excluded. This is because of the general inability of basaltic magma to pass up through a chamber that is at least partially molten and is less dense than basaltic magma.

It is envisaged that basaltic magma ascending beneath the shadow zone, being denser than silicic magma, is trapped at the base of the silicic chamber; being hotter it heats silicic magma and by reducing its viscosity and promoting gas exsolution, it mobilizes silicic magma and may trigger eruptive activity.

The coexistence of rhyolitic and basaltic magmas in central volcanoes is manifest as composite dikes (having basaltic rims and rhyolitic center), streaky mixed pumice, mixed lavas (having fluidal-shaped inclusions of basalt in rhyolite), and hybrid rocks.

Central volcanoes generally have one or more calderas, where subsidence of the magma chamber roof occurred as large silicic eruptions, caused partial evacuation of the chamber. Occasionally, rhyolitic vents occur along arcuate lines, for example, around Valles caldera in New Mexico.

Eroded central volcanoes commonly display granitic plutons (inferred to be solidified magma chambers). Ring intrusions and ring faults delineate cauldrons wherein piston-like subsidences of chamber roof occurred. These occurrences are called *ring complexes*. The type examples are found among the roots of a 400-Ma volcanic field in Scotland.

Many central volcanoes host ore deposits (of Ag, Au, Cu, Mo, Sn, W), including many of the porphyry copper type. The ore metals were transported and deposited by hot volcanic fluids. An unusual gold deposit occurs in the hot caldera floor of Lihir volcano, (Papua New Guinea). Ore deposits in central volcanoes are more closely associated with the silicic than with the mafic

volcanism, and likewise the spectacular geothermal manifestations (geysers, hot springs, and geothermal power plants) as seen in the Taupo Zone of New Zealand, the Yellowstone Park (Montana), and Iceland.

## GLOSSARY

**aa lava** Lava flows with extremely irregular surfaces, usually covered by fragments of broken crust that are typically decimeters thick. The thickness of the surface crust is controlled by cooling (compare blocky lavas).

**blocky lava** Lava flows with fractured surfaces, usually covered by debris up to meters across. The size of surface fragments is controlled by the rheology of the lava interior, rather than by the thinner surface crust (compare aa lavas).

**crust** The outer part of a lava flow that has solidified after losing heat to the exterior.

**flow** A discrete body of lava emplaced as a dynamically continuous unit.

**flow field** A collection of lava flows produced by the same effusion.

**lava** Molten or partially molten rock erupted at a planet's surface.

**pahoehoe lava** Lava flows with smooth, continuous surfaces.

**L**AVA FLOWS are the most common volcanic feature on Earth. They provide fine construction materials and are also an essential source of nutrients for future agricultural soils. They nevertheless remain a persistent threat to human activity. After describing the primary features of lava flows, this chapter will focus on how such features can be used to improve forecasts of how a lava will behave.

On Saturday, March 18, 1944, San Sebastiano was an unassuming Italian village in the foothills of Mount Vesuvius. On Tuesday, March 21, it ceased to exist. In less than 48 hours, lava streams from a new eruption had descended the volcano's flanks and crept through the village, slowly and inexorably eating their way from one building to the next. Today, five decades later, San Sebastiano is flourishing again as a popular residential area 10 km east of Naples. Yet the 1944 flows were the third set to have overwhelmed the settlement in less than 100 years. After both previous eruptions, in 1855 and 1872, the village and its neighboring villages were rebuilt around the very lavas that had caused their de-

struction. Not even the menace from Vesuvius could break the lure of the familiar.

The resilience, or perhaps stubbornness, that keeps populations returning to hazardous districts is the chief reason why lava flows are a common threat to human settlements, even though they are produced by one of the least powerful styles of eruption. Between 1973 and 1998, lava effusions worldwide caused property losses of hundreds of millions of U.S. dollars (equivalent 1998 prices). Although these losses are small compared to those due to major explosive eruptions, they have long-lasting repercussions on local economies and are a key force driving investigations into how lavas behave and how defensive techniques can be improved.

A second motive for studying lavas is that they are the single most common feature on the surfaces of the terrestrial planets. They cover 90% of Venus, 50% of Mars, at least 20% of the Moon, and some 70% of the Earth, where they are mostly hidden from view on the ocean floor. Understanding how lavas are emplaced is thus crucial to reconstructing the surface evolution of the inner planets and to investigating the conditions below the surface that favor effusive eruptions.

The main factors controlling how lava flows develop are the rate at which lava is effused from the ground, the lava's physical properties, and the local environment (such as ground slope, topography, and whether the eruption occurs on land or below water or ice). Each of these factors can vary greatly among eruptions, as well as during a single effusion, and it might be expected that lavas should show a wide range of behavior. In fact, the contrary holds and common lava types evolve along only a few, clearly defined trends, which link the morphology of lava surfaces to styles and rates of flow advance. Only by understanding why these natural evolutionary sequences occur will it be possible to improve strategies for mitigating lava hazard.

as far as general hazard studies are concerned. First applied at Vesuvius, the word "lava" is derived from the Italian *lavare* (to wash), which is ironic since the washing normally meant cleaning away the fruits of human labor.

Flows are distinguished from lava domes by their extreme elongation downslope. Historically, the volumes produced by single effusions of lava range from minor dribbles to outpourings of a few cubic kilometers (e.g., Etna, Sicily, 1614–1624; Lanzarote, Canary Islands, 1730–1736; Lakagigar, Iceland, 1783–1785). The resulting flow fields can extend tens of kilometers, spread kilometers across, and reach thicknesses of hundreds of meters, although most are more modest in size (Table I). The durations of single eruptions also cover a large range and, while some may reach decades, the majority lie between days and months. Rates of flow lengthening thus rarely exceed a brisk walking pace, so that it is usually possible for people to escape immediate danger. Exceptions occur during the start of effusions, when lavas can sometimes advance as fast as a galloping horse. In the saddest example, on Nyiragongo (Congo) at 10:15 in the morning of January 10, 1977, a fluid lava swept downslope at least 5 km in 20 minutes (15 km/hour), catching a small village unawares and roasting 70 people alive.

The Nyiragongo tragedy ghoulishly illustrates the need to prepare against lava invasion even before an eruption begins. To identify the most vulnerable districts, it is necessary to recognize probable locations of future eruptions and to forecast the likely travel distance of at least the initial lava flow. The first task is achieved by applying statistical analyses to the known distributions of vents at a volcano. The second requires a model that can link probable flow length to factors that can be measured before the next eruption begins, and it is here that the evolutionary sequences of lava flows assume a fundamental importance.

---

## I. WHAT ARE LAVA FLOWS?

Lava flows are outpourings of molten rock, or magma. On Earth, the overwhelming majority have silicate compositions, for which common melting temperatures are in the range 800–1200°C; lavas of sulphur (e.g., Siretoko-Iosan volcano in Japan, and Lastarria volcano in Chile) and of carbonate compositions (e.g., Ol Doinyo Lengai volcano in Tanzania) also occur at lower temperatures (about 150°C for sulphur and 600°C for carbonatite), but these are extremely rare and are not important

---

## II. EVOLUTIONARY SEQUENCES AMONG LAVA FLOWS

Most lavas are crystallizing on eruption, owing to chemical imbalances induced in magma as it approaches the surface from below. They continue to solidify during effusion, aided by loss of heat to the ground and to the atmosphere. As a result, flows begin to form channels or tubes (Fig. 1 and 2), which concentrate motion along only a small number of paths, so that subsequent lava

TABLE I Major Historic Lava Flows

Composition	Typical length (km)	Mean thickness (m)	Mean discharge rate ( $m^3 s^{-1}$ )	Flow (& flow field) volume ( $km^3$ )
$SiO_2 < 55$ wt% (basalts, basaltic andesites)				
<10 ( basalts to 50 )	3–20	10–100 ( basalts to 1000 )	0.01–0.1 ( <1–2 )	
For example, Kilauea & Mauna Loa, Hawaii; Etna & Vesuvius, Italy; Iceland; Piton de la Fournaise, Réunion Is; Lanzarote & Tenerife, Canary Is.; Arenal, Costa Rica; Parícutin, México.				
$SiO_2 > 55$ wt% (andesites, dacites, trachytes)				
<5 ( some to 15 )	20–300	1–10 ( andesites to 100 )	0.01–1.0 ( <10–20 )	
For example, Lonquimay, Chile; Nea Kameni, Santorini, Greece; Hibok-Hibok, Philippines; Trident, Alaska.				

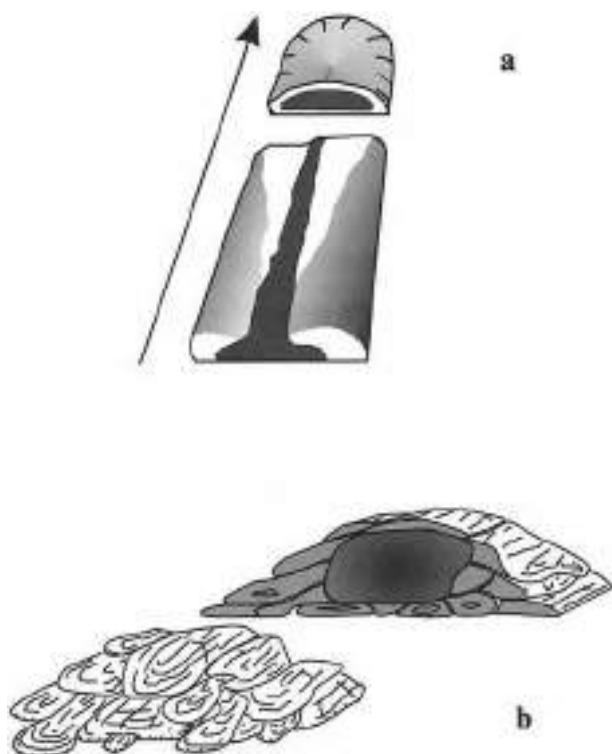

FIGURE 1 Major flow structures. (a) In aa and blocky flows, open channels (below) typically feed lava to simple fronts (above). Motion, in direction of arrow, is concentrated in the black zones. For major flows, the fronts are commonly ~100 m wide and tens of meters thick. In long-lived eruptions, the channels may evolve into tubes. [After Lipman and Banks, 1987.] (b) The fronts of pahoehoe flows are normally a complex of intermingling tongues and toes (up to meters across and tens of meters long) fed by lava from a tube system.

can be transported more efficiently from the vent to the front.

A flow initially forms a tube or a channel according to whether or not the lava surface can develop a continuous crust. When exposed to the atmosphere, a fresh lava surface chills to a strong, solid crust within minutes. At the same time, the new crust is pulled forward by more mobile lava. If the forward pull is large enough, the crust continually breaks into fragments and so, being unable to form a stable roof, the flow develops an open channel for containing the lava. If the forward pull is too small, a continuous crust can develop across the whole flow and this, anchored to the flow margins, gives birth to a tube.

A similar battle between crustal growth and disruption occurs at flow fronts. When disruption dominates, the front moves forward as a single unit, controlled by the properties of the frontal interior. When crust formation dominates, the front advances by oozing small tongues of lava through localized punctures in the crust. Whatever their style of motion, lava fronts are the slowest part of an advancing flow, in part because of crystallization, and in part because their areas of cross section are larger than the active areas along feeding channels or tubes.

From observation alone, it is clear that crustal structure can be linked directly to the early formation of lava channels and tubes, and to the style with which a flow front moves forward. The link with crustal structure is convenient since only the outer parts of an active flow are normally accessible to investigate, either by direct observation on the ground or by remote monitoring

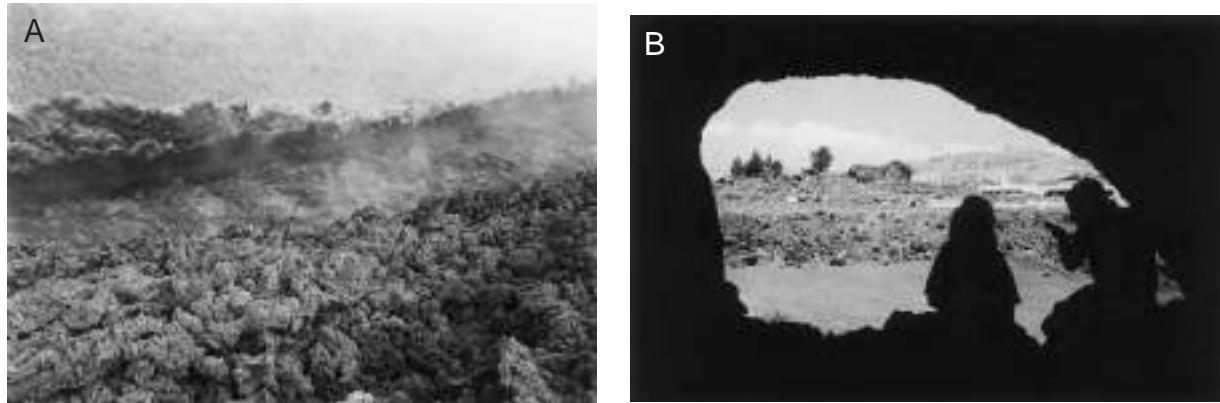

FIGURE 2 (A) A well-developed channel between static banks of aa lava. This example is a few meters wide, but channel widths may reach tens of meters in aa and hundreds of meters in blocky flows. Note the haze due to hot gases (mostly steam) escaping from the lava, moving from left to right [Photograph by C. R. J. Kilburn.] (B) Extensive lava tubes are essential features of pahoehoe flows and may also form in aa flow fields during long-lived eruptions. [Photograph by H. Pinkerton.]

using aircraft or satellites. Difficulties in studying the rest of a flow arise because lavas are hot and viscous. To measure the temperatures, velocities, and fluidities of flow *interiors*, it is necessary to stand close to poorly crusted lava, where it is easiest to insert monitoring equipment. The most active parts of flows have mean surface temperatures commonly between 475°C (when their color is a very dull red) and 1100°C (when they

are golden yellow), a range sufficient for radiant heat to cause serious burns even meters away. Protective clothing, although cumbersome, can normally overcome this difficulty. However, even at the start of eruption, the most fluid lavas are frequently a million times more viscous than water (Table II) and it is extremely difficult both to force a measuring device into a flow and, if successful, to retrieve it again.

TABLE II Physical Properties of Lava Flows

Composition	Eruption temperatures (°C)	Density at eruption temperatures (kg m <sup>-3</sup> ) (without vesicles)	Viscosities at eruption temperatures (Pa s) <sup>a</sup>
Basalt	1050–1200	ca. 2600–2800	10 <sup>2</sup> –10 <sup>3</sup>
Andesite	950–1170	ca. 2450	10 <sup>4</sup> –10 <sup>7</sup>
Rhyolite	700–900	ca. 2200	10 <sup>9</sup> –10 <sup>13</sup>
Komatiite	>1600?	ca. 2800	<1?
Water at Earth's surface	20	ca. 1000	10 <sup>-3</sup>
Temperature [°C (K)]		Color of lava surface	
1150 (>1423)		White	
1090 (1363)		Golden yellow	
900 (1173)		Orange	
700 (973)		Bright cherry red	
600 (873)		Dull red	
475 (748)		Lowest visible red	

<sup>a</sup> Newtonian approximation at low shear rate.

As a result, virtually no data are available from direct measurements of active lava interiors. Investigations must instead rely on theoretical studies or on indirect evidence from solidified lava interiors (exposed by natural collapse or by artificial excavations, such as road cuttings or quarries). In the first case, no theoretical model has yet been completely verified, precisely because the necessary field data are unavailable. In the second, the features preserved by solidified lava interiors (such as crystal size distributions, which depend on a lava's cooling history) may not reflect conditions that prevailed while the flow was still active, because these features (1) may have been dominated by changes (e.g., further crystallization) that occurred after the flow had come to rest, or (2) may have formed at different times during flow advance, and so cannot simply be related to the state of the active flow at any particular moment. Thus, until more reliable data are available for active flow interiors, the links between crustal structure and flow dynamics offer the best prospect for quantifying flow behavior.

duced in the late 19th century to describe the common lava types found on Mauna Loa and Kilauea, but they apply equally to other lavas with silica contents less than about 50–55 wt% (basalts and some basaltic andesites), as well as to the rare flows of sulphur and carbonatite. Blocky flows are common among lavas with silica contents greater than 55 wt% (basaltic andesites to rhyolites).

Diagnostic features are most evident when viewing a crust over distances of decimeters and meters (Table III and Fig. 3). At these distances, pahoehoe surfaces are smooth and, though occasionally broken, are normally continuous, whereas aa surfaces are extremely irregular, frequently fractured, and usually covered by rough, contorted fragments with typical dimensions of centimeters and decimeters. Blocky lavas, like aa, also have fractured surfaces and a covering of debris; they differ from aa flows in that their fragments are smooth and angular with common dimensions from decimeters to meters. From a distance, indeed, both aa and blocky surfaces look as exciting as piles of rubble on a building site.

### III. FIELD CLASSIFICATION OF LAVA FLOWS

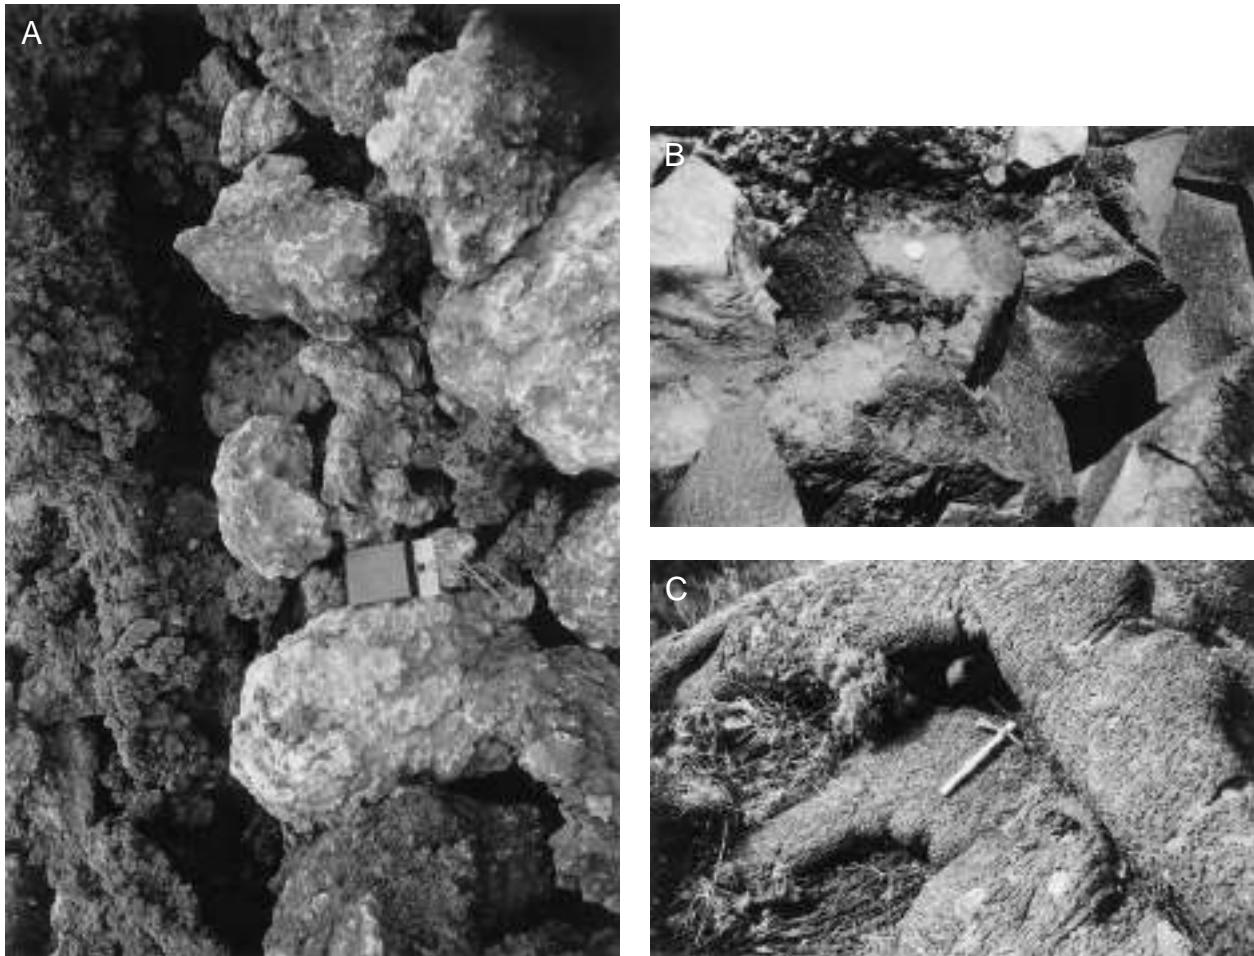

Crustal appearance provides the basis for classifying lava flows on land into three major categories: *pahoehoe*, *aa*, and *blocky*. Pahoehoe and *aa* are Hawaiian terms intro-

#### A. Aa and Blocky Flows

*Aa* and blocky flows show simple evolutionary trends. As might be anticipated from their broken surfaces, their fronts tend to advance as single units, and it is rare for one part of a front to move far ahead of neighboring sections. Blocky fronts crumble to produce a snout of

TABLE III Common Features of Flow Surfaces

Feature	Description
1. Aa lava	Surface is covered by a jumble of irregular crustal fragments.
Cauliflower	Crust twists upward as cauliflower-like protrusions. These break to give fragments up to decimeters across. Surfaces are gray-black, often glassy, and rough and spinose at the millimeter scale.
Rubbly	Crust fractures downward to yield rounded rubble up to meters across, often with an ochre-black granular surface, millimeters deep.
2. Blocky lava	Surface is covered by broken lava, containing fragments up to meters across with smooth, planar, and angular surfaces.
3. Pahoehoe lava	Surface is smooth and continuous, often with a millimeter-scale texture of interwoven lava threads or filaments.
Entrain	Dribbles of lava yield convoluted surfaces reminiscent of entrails.
Ropy (or corded)	Flexible crusts ruck into tight folds before chilling. Surface resembles segment of coiled rope. Each "rope" can be centimeters thick.
Shelly	Highly vesicular, fragile crusts. Often associated with skins, centimeters thick, over hollow lava blisters. The skins break underfoot, giving the impression of walking on egg shells.
Slabby (sometimes slab aa)	Slabs of broken crust, up to meters across and centimeters thick.
4. Toothpaste lava	Protrusions of viscous lava squeezed through gaps in flow crust. They may be tens of meters long and their cross sections often mimic the shape of the source gap, like toothpaste emerging from its container.

**FIGURE 3** The surfaces of aa and blocky flows are covered by broken surface fragments. (A) Aa fragments (Mt. Etna, Sicily) are contorted and initially appear black and spinose (left) but, during later stages of advance, the surface breaks to yield rounded and abraded rubble (right). (B) Blocky fragments (Nea Kameni, Santorini, Greece) are angular and have planar faces. (C) Pahoehoe surfaces (Vesuvius, Italy) are smooth and often billowy over distances of meters. [Photographs A and B by C. R. J. Kilburn; photograph C by S. Black.]

debris from the early stages of emplacement. Aa fronts show a greater range of behavior, often starting as fluid sheets, but finishing as near-solid masses that fragment throughout their thickness to maintain advance; between these limits, they move by various combinations of fracture and flow.

Fronts thicken while advancing, often growing to more than 10 times their initial thickness. Final thicknesses are typically about 20 m or less for aa fronts, but several tens of meters for blocky flows; their maximum lengths are measured in tens of kilometers and in kilometers, respectively. Major flows can achieve volumes of 1–100 million cubic meters, and tend to be emplaced within days when they are aa but within months when they are blocky.

Both flow types initially develop channels to feed lava

to their fronts. Channels form when a flow stops widening and concentrates motion downhill. The fronts themselves grow during advance because they decelerate as they solidify and allow faster lava to accumulate from upstream. For example, during the opening stage of emplacement (when they are fastest), major aa fronts may advance a few kilometers a day (occasionally 10–30 km in the first 24 hours), although the velocity of lava near the vent may be at least 10 times greater.

At one extreme, advance and thickening continue until a flow stops being fed by new lava, whereupon the front slows to a halt as remaining lava drains from the feeding channel. At the other extreme, effusion continues into the flow even though the front has come to rest. Lava begins to pile up within the channel, starting at the front and working its way backward. As it thickens,

the channel lava exerts an increasing pressure on its margins, and these may eventually breach to form an outlet through which the channel lava can escape. If the breach is too small, it may be able to heal itself through cooling or by being plugged with crustal debris. Otherwise, the breach may become a permanent outlet from which a major new flow can develop. The new flow, in turn, may halt and thicken until the cycle is repeated. In such a way, a *flow field*, the final product of one effusive eruption, may evolve with time from a single flow to a collection of interconnected flows (Fig. 4).

Breaching is more common among aa than blocky lavas. Apart from high channel pressures, the propagation of new flows by breaching requires channel lava that is much more fluid than its lateral margins. Only in this case can the channel lava easily escape through a breach; if, instead, the channel lava is almost as solid as the margins, breaching simply allows channel lava to spread into the breach and heal it. By virtue of its chemical composition, channel lava in aa flows tends to be more fluid than its blocky equivalent, so that conditions are more favorable in aa lavas for the propagation of new flows.

Although breaching may occur anywhere along a flow, it most commonly occurs somewhere along the upstream half of a flow's length. Newly propagated flows may extend downslope beyond an earlier stream, but rarely do they increase the length of a whole flow field by more than half the length of the initial flow. A result of such behavior is that the propagation of flows tends to widen, rather than to lengthen, the area covered by new lava (Figs. 4 and 5). It also means that, when addressing the hazard from aa and blocky flows, the first

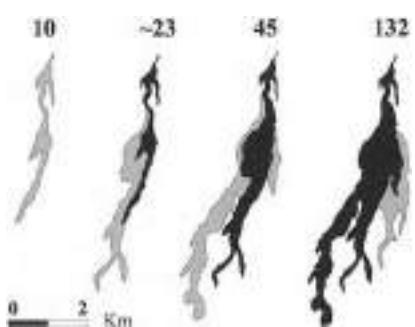

FIGURE 4 Aa flow fields grow as a sequence of flows, with new flows (shaded area) propagating from the sides of earlier streams (black). This example shows the evolution of Etna's 1983 flow field at 10, 23, 45, and 132 days after the start of effusion. Note how the final length of the flow field on day 132 is only about 30% greater than the length of the initial flow on day 10. [Data from Frazetta and Romano, 1984.]

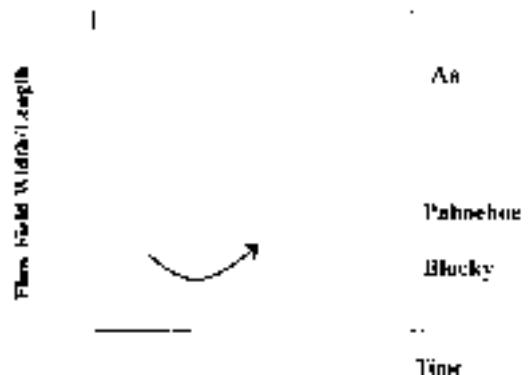

FIGURE 5 All flows initially lengthen so that their ratio of width to length decreases with time. This trend normally continues throughout eruption for pahoehoe and blocky flows. After the first flow is emplaced (arrow), aa flow fields tend instead to become wider. The initial aa flows rarely lengthen for more than 10–15 days. For all lava types, major flow fields are normally emplaced within months to years, although some historical effusions (especially of pahoehoe lava) have continued intermittently for a decade or more (e.g., Etna, 1614–1624; Pu'u O'o, Kilauea, continuing since 1983).

goal is to estimate the probable maximum length of the *initial* flow.

As well as promoting flow breaching, flow thickening can trigger the overflow of fluid channel lava across its lateral margins. The margins can thus build themselves up as a series of superposed overflows that, under favourable conditions, develop an inward overhang across the channel surface. As the exposed channel surface narrows, it becomes easier for adjacent segments of crust to congeal and to form a continuous roof over the flow. In this way, a lava channel can evolve with time into a tube, better insulating the lava beneath and allowing it to travel further before solidification sets in.

Tubes form in aa and blocky flows only after a channel has become well established, and may require several weeks to develop. When they occur, therefore, tubes are found along those parts of flows that remained active for long periods, typically behaving as feeders to sites of breaching downstream. As a result, tubes normally form after most major flows have been emplaced, and so rarely contribute in a significant way to extending a flow field (in complete contrast with pahoehoe flows, discussed later). As with the propagation of flows by breaching, the growth of lava tubes is favored by a large contrast between the fluidity of internal lava and its external margins. Accordingly, tubes are more common in aa than in blocky flows. Should lava drain from a tube toward the end of effusion, it may leave behind a tunnel perhaps kilometers long that is large enough at

least to crawl through. Among aa lavas, excellent examples can be found on Sicily's Mt. Etna, including the 1971 and 1991–1993 flow fields.

### B. Pahoehoe Flows

Pahoehoe flows have dimensions similar to aa flows, but normally advance at least 10 times more slowly. Because they spread slowly, their cooling surfaces resist extensive tearing and, though feeding channels can develop, it is not unusual for continuous crusts to form across a whole flow from the start of emplacement (unlike the weeks necessary in the case of aa lavas). The crust remains continuous around flow margins and fronts, whose initial thicknesses are usually only a few decimeters. Because early flows are thin, they are easily retarded by the crust and spreading occurs by a combination of lava leaking out as small tongues through breaks in the crust, and by allowing new lava from upstream to burrow beneath the tongues and to slowly lift the front upward. The front thus appears as a collection of intermingling tongues, each much narrower (by 10–1000 times) than the width of the whole flow (Fig. 1).

Pahoehoe tongues may extend by some 100 m, and even start to develop, feeding channels, before crusting over and extruding small lava toes, typically a few meters or less in length (analogous to the lava pillows among submarine flows). As a result, pahoehoe fronts and margins soon develop as a complex of budding tongues and toes, all of which are gently uplifted by newly arriving lava. The surfaces of pahoehoe flows thus evolve a curious hummocky form, involving swells that extend distances from decimeters to hundreds of meters. The largest of these seem almost flat to the casual gaze; the smallest appear curiously grotesque and intestinal (Table III).

Lava from the vent continually raises the surface and, within weeks, a flow field may have thickened to several meters, while thin lava tongues continue to emerge from around its edges and from occasional surface ruptures. Although many tongues and toes stagnate after halting, others remain connected beneath the crust to form a network of distributary tubes, casually resembling an underground river system. Compared with the open channels in aa and blocky flows, lava tubes reduce the rate of lava cooling, especially when they are partly drained so that hot gases can collect beneath the tube roof and keep the flowing lava surface at temperatures close to its initial value. Thus, although pahoehoe flows advance more slowly than their aa counterparts, their

interiors remain fluid for much longer periods. The greater lengthening time often dominates the slower velocity, so that pahoehoe flow fields can achieve lengths greater than aa flow fields of similar volume.

Historical pahoehoe flow fields have extended several tens of kilometers, the best examples being found on the Big Island of Hawaii. Some prehistoric flow fields, however, have been traced for more than 100 km, notably those in Queensland, Australia. Recently, it has been proposed that ancient flood basalts (such as the Columbia River Basalts in the United States), which have lengths of several hundreds of kilometers, are in fact enormous pahoehoe lavas, and not extreme aa flow fields as previously thought. The drained tube systems in such flows are truly impressive, reaching tens of meters across, up to 10–20 m high, and extending for several kilometers at least (the prehistoric Australian flow fields contain a tube system about 100 km long).

### IV. THE LAVA SPECTRUM

In the simplest of cases, a flow maintains the same type of surface morphology throughout emplacement. Frequently, though, a flow surface evolves through more than one type with distance downstream. Among basaltic lavas, downstream transitions occur from pahoehoe to aa morphologies, while the change from aa to blocky is found among some basaltic andesites; both transitions are unidirectional, so that blocky surfaces do not become aa, and aa surfaces do not become pahoehoe (although, as discussed later, special field conditions may give the false impression that reverse transitions can occur). The pahoehoe, aa, and blocky morphologies are thus not independent entities, but parts of a continuous spectrum of lava types. The association of the two transitions with different lava chemistry shows that composition is one underlying control. However, because each transition occurs between lavas of similar composition, other non-chemical factors must also be involved.

Both pahoehoe and aa surfaces are created during the formation of surface crust. At the start of eruption, the lavas are often too fluid to break before cooling, so that the degree of rupture must be controlled by the solidifying surface layers. To break a surface before it has chilled to its maximum strength, the rate of energy supplied predominantly by gravity to a unit volume of crust must be greater than a critical value. The critical value depends on how quickly a crack can be healed by chilling the newly exposed lava beneath. If the critical

value is exceeded, a flow breaks its crust more quickly than existing cracks can be healed and so evolves a fragmented aa surface; otherwise, a flow cannot tear its crust quickly enough and develops a continuous pahoehoe surface.

The rate of energy supply is measured by the product of the stress applied to the crust and the rate at which the crust deforms (Fig. 6). Two consequences are that the larger the pull, or applied stress, the smaller the deformation rate at which critical conditions are reached; and to cross the pahoehoe–aa transition, the rate of energy supplied (per unit volume) to the crust must also increase. The change from pahoehoe to aa occurs because, as lava advances downstream, a greater proportion of the gravitational energy flux for moving the whole flow is used in deforming a thickening crust. Eventually, the energy flux exceeds the critical value, after which the surface must break persistently as aa if the flow is to advance.

Blocky surfaces are associated with stronger and more viscous lavas that break before cooling is significant. In this regard, they can be considered magmatic glaciers, slowly moving sheets that flow near their bases but break at their surfaces. The aa–blocky transition thus occurs

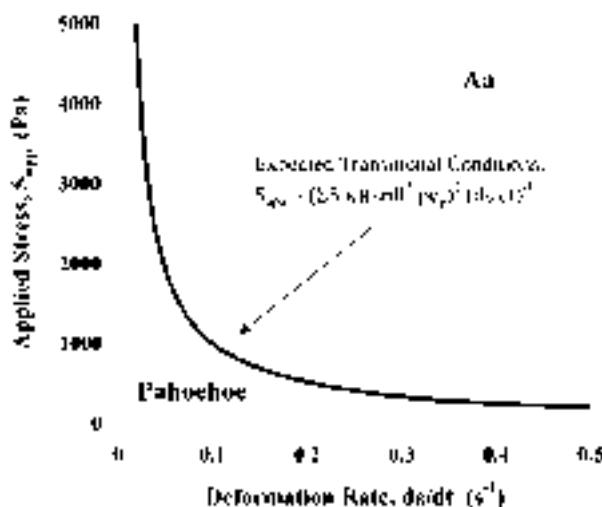

FIGURE 6 The evolution of pahoehoe and aa surfaces depends on the rate at which energy is supplied to deform cooling crust. The rate of energy supply per unit volume is given by the product of applied stress and deformation rate ( $S_{app} \cdot d\epsilon/dt$ ). Below a critical energy flux ( $\sim 100 \text{ J m}^{-3}$ ) controlled by the cooling and strengthening of lava exposed between cracks, the surface chills as a continuous crust to form pahoehoe. When this flux is exceeded, the surface breaks persistently to form aa. Blocky lavas are not shown on this diagram, because they are strong before eruption and, as if magmatic glaciers, they must break their surfaces to advance, independent of cooling effects.

when the lava interior becomes too crystalline to move forward only by flowing, so that surface fracturing is no longer controlled by crustal cooling. Indeed, the same reasoning explains why pahoehoe and blocky lavas have different surface morphologies, even though both advance much more slowly than aa flows: Blocky flows are slow because of their high viscosity and break because of their large associated strength; pahoehoe flows are slow because they advance as thin sheets or tongues whose fluid interiors are easily restrained by surface crust.

The transitions between surface morphologies are irreversible; highly fragmented surfaces cannot recombine to form continuous crust (hence aa surfaces do not evolve into pahoehoe), while subcrustal lava does not become less solid with time (hence, blocky surfaces do not evolve into aa). On occasion, however, it might appear that a reverse transition has taken place, especially between pahoehoe and aa types. The deception occurs under two main sets of conditions. The first corresponds to changing conditions of effusion from the vent. As an eruption decays to its close, so also decreases the rate of effusion. While early, fast lava may produce an aa surface, later lava may emerge slowly enough to form a continuous pahoehoe crust (good examples can be found on Mauna Loa, Hawaii). This change, though, does not represent a transition from aa to pahoehoe, because the later pahoehoe crust formed across an independent flow and did not evolve from lava already erupted with an aa surface. The second condition involves the escape from aa channels of hot internal lava, the result either of a channel overflow or of a margin being breached. In this case, the escaping lava may be less crystallized and, if advancing much more slowly than the parent flow, may form a pahoehoe crust. Once again, such a situation does not correspond to an evolution of the crust from aa to pahoehoe, because the escaping lava comes from deep within the parent flow and has had a crystallization history independent from that of the near-surface lava layers that formed the earlier crust.

## V. LAVA DYNAMICS AND INTERNAL SOLIDIFICATION

Because of its high viscosity, lava can rapidly reduce accelerations in a flow. As a result, flows tend to settle into a steady dynamic state. A simple example is shown by the preference of flow fronts to advance at nearly

constant velocities for extended periods of time (Fig. 7). Because inertia is not important, flow growth is controlled by how a lava's rheological resistance is overcome by gravity (pulling lava downslope) and by pressure differences due to local variations in flow thickness (notably at the flow periphery).

Another consequence of low inertia is that lava strives to maintain laminar flow, whereby adjacent packets of lava tend to flow past each other, rather than intermingling, as would occur if motion were turbulent (although turbulence may be important in some exotic lavas, discussed later). Without intermingling, a lava interior can diffuse heat only by conduction (i.e., interactions between neighbouring molecules), so that cooling effects tend to migrate inward from the flow exterior, itself maintained at a low temperature by radiation to the atmosphere, by cooling wind, and by precipitation. Lava, however, is a very poor conductor. The time needed for cooling to penetrate a depth  $D$  into a flow is given approximately by  $D^2/4\kappa$ , where the thermal diffusivity ( $\kappa$ ) of lava is between  $10^{-7}$  and  $10^{-6} \text{ m}^2 \text{ s}^{-1}$ . Thus it takes minutes to chill a layer centimeters deep, but weeks for this layer to thicken to meters.

To give an example of a lava flow 10 km long, the time for lava to travel from the vent to the front may be only hours for pahoehoe and aa flows, and days for blocky flows. (Recall that this travel time is less than the interval since effusion began: The former is given by [flow length]/[mean velocity along a flow]; the latter is [flow length]/[mean velocity of the flow front].) The corresponding mean flow thicknesses will be measured

in meters or tens of meters, implying conductive cooling times of weeks or longer. It might thus be expected that the interiors of pahoehoe and aa flow fronts will contain lava almost as fluid as it was near the vent. This condition is typical among pahoehoe flows, but not so for aa flows, which can develop solidified fronts within days.

Precisely why the interiors of aa flows can solidify so quickly is still not fully understood. One possibility is that, compared with other lava types, aa lavas are initially richer in volatiles. All magmas contain some volatiles, mostly water, that remain dissolved at depth, where the high pressure from surrounding rock prevents them from forming bubbles. As the magma ascends, the imposed pressure decreases and, eventually, bubbles can develop, just as they appear in a bottle of soda water when pressure is released as the bottle is opened. The loss of volatiles upsets the chemical balance in the liquid and can trigger crystallization at a rate that increases with the proportion of gases originally dissolved in the magma, but decreases with increases in liquid viscosity. Thus, compared with aa lavas, pahoehoe interiors may crystallize more slowly due to smaller amounts of initial gas, while crystallization in blocky interiors is retarded by high lava viscosity.

Another explanation appeals to crustal entrainment. Pieces of cold crust are dragged back into the lava interior, accelerating solidification by forcing internal lava to intermingle. Importantly, the intermingling in aa is a result of crustal entrainment and not of natural turbulence; when possible, the flow again seeks a simple laminar motion. This mechanism is less common in pa-

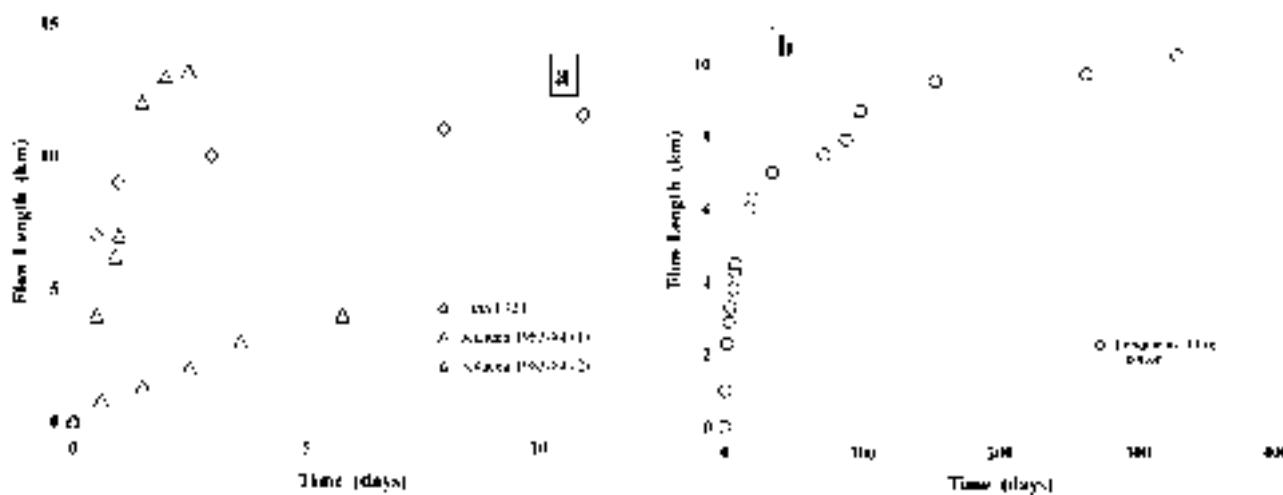

FIGURE 7 Most flow lengthening occurs during the early stages of effusion and at nearly constant rates of advance. This may be followed by a rapid drop in advance rate that, though continuing for a long time, does not extend a flow significantly. [Data for part (a) Ponte, 1923, and Wolfe et al., 1984; for part (b) Naranjo et al., 1992.]

hoehoe flows, since they form continuous crusts, and also in blocky flows, because their very large viscosity impedes incorporation of surface debris.

---

## VI. SHAPES OF LAVA FLOW MARGINS

As they negotiate topographic irregularities and adjust to local variations in physical condition, lava flows are rarely able to spread evenly over the ground and so usually develop margins with irregular outlines. The degree of margin irregularity varies with flow type and, because all types can evolve over similar topography, such variation must reflect differences in style of advance and, hence, also in the governing force balance.

Spreading as collections of tongues and toes, pahoehoe flows develop lobate margins having a degree of unevenness (measuring fluctuations about a smoothed, average outline) that happens to be similar for averaged outlines at least 1–100 m in length. Such a scale-independent (fractal) unevenness suggests that pahoehoe spreading is governed by the *ratio* (scale independent by definition) of imposed forces, and that these forces are of the same type at each scale. Because crustal restraint is essential to the pahoehoe style of advance, the obvious inference is that, whatever their size, tongues and toes propagate when, given sufficiently fluid internal lava, the forces driving lava spreading exceed crustal resistance by only a critical amount; otherwise spreading would cease (driving forces too small) or the crust would fragment and have no significant resistance (driving forces too large).

In contrast, aa and blocky flows spread mostly under conditions for which the driving forces are far greater than crustal resistance. Thus, although locally influenced by crustal debris, the bulk shape of their margins is more dependent on the rheological resistance of internal lava. As a result, the margins appear highly irregular over distances covering a few crustal fragments (notionally 10 m or less), but tend to show only subdued undulations over 100 m or more. Hence the shape of the flow outline is not scale independent, but becomes less uneven as the measuring distance becomes larger, coinciding with a change in the chief shape-controlling factor from the geometry of crustal fragments to bulk lava rheology.

The connection between flow type and margin geometry opens the possibility of using geometric measurements to infer styles of lava emplacement, especially important for investigating inaccessible volcanoes with

aerial and spaceborne techniques. However, apart from initial measurements on predominantly basaltic lavas, few data are available on the fractal dimensions (degrees of unevenness) of lava flow margins, and so the full promise of this approach must await future studies.

---

## VII. FORECASTING THE BEHAVIOR OF AA FLOWS

The three main types of lava surface are associated with distinct styles of flow growth. Because lava surfaces are easily monitored in the field, it would be convenient if the conditions for producing a specific surface type could also provide limits on the likely distance and velocity a given flow might travel. Such a state of affairs does exist for aa flows, a happy circumstance since aa flows are the lava type that has most frequently threatened human activity, and they are also intermediate between pahoehoe and blocky flows. Understanding the limits to aa behavior thus provides clues to the limiting behavior of the other flow types.

The aa surface criterion can be used to estimate the advance velocity needed to keep breaking lava crust. The time for which a lava flow can continue to advance is controlled either by the duration of eruption (for short-lived aa flows) or, during long eruptions, by the time needed for the flow to acquire a solid front. Combining the requirement for a lava front to solidify (which gives the longest time for advance) with the aa surface criterion, it is possible to link the *maximum* potential length ( $L_m$ ) of an aa flow to lava properties, mean underlying slope (angle  $\beta$ ), and mean rate of discharge ( $Q$ ). These expressions are:

$$L_m \approx [(1.5 \varepsilon S / \rho g)^2 (\Sigma \sigma \Theta^3) / (\kappa \rho c_p)] / \sin^2 \beta \quad (1)$$

$$\approx [3 \varepsilon S / \rho g \kappa]^{1/2} Q^{1/2}, \quad (2)$$

where the remaining symbols are defined in Table IV.

In both expressions, the terms in square brackets describe the physical properties of the lava crust and are approximately constant for a given lava composition. Thus the maximum potential length is expected to increase as the mean underlying slope decreases [Eq. (1)] and as the discharge rate increases [Eq. (2)], two trends that agree well with observation (Fig. 8).

The length-slope trend is counterintuitive. Other factors being equal, it might be supposed that steeper slopes would favor longer flows. The inverse trend arises because, to keep breaking their surfaces, aa flows must

TABLE IV Parameters in Flow Equations

Symbol	Meaning	Units	Nominal value for basalt
$\beta$	Slope angle	°	
$c_p$	Specific heat capacity	J kg <sup>-1</sup> K <sup>-1</sup>	1150 (during crystallization)
$D$	Thickness	m	
$\varepsilon$	Extension before failure	—	Min. 10 <sup>-3</sup> (for chilled crust)
$\varepsilon S$	Energy per unit volume for failure	J m <sup>-3</sup> (or Pa)	2 × 10 <sup>4</sup> (during crystallization)
$g$	Gravitational acceleration	m s <sup>-2</sup>	9.81
$\kappa$	Thermal diffusivity	m <sup>2</sup> s <sup>-1</sup>	4.2 × 10 <sup>-7</sup>
$L_m$	Maximum potential length of flow	m	
$Q$	Mean discharge rate along flow	m <sup>3</sup> s <sup>-1</sup>	
$\Theta$	Eruption temperature (absolute)	K	1350–1400
$\rho$	Density of lava crust (not whole flow)	kg m <sup>-3</sup>	2200 (~20% vol. vesicles)
$S$	Tensile strength	Pa	Max. 10 <sup>7</sup> (for chilled crust)
$\Sigma$	Surface emissivity	—	1
$\sigma$	Stefan-Boltzmann constant	J m <sup>-2</sup> s <sup>-1</sup> K <sup>-4</sup>	5.67 × 10 <sup>-8</sup>
$t$	Time	s	

maintain greater thicknesses on shallower slopes. Thicker flows need longer times for their fronts to solidify. As a result, the maximum *potential* length increases with decreasing slope. In practice (Fig. 8), such lengths are usually not achieved (especially on slopes with angles smaller than 6 degrees) because the eruption finishes or breaching occurs in the meantime. Nevertheless, the length–slope trend is important for hazard analyses because it provides realistic estimates of potential flow length when only the mean slope is known. Accordingly, it is well suited for preparing hazard maps before an eruption occurs.

The length–discharge rate trend may also have predictive value in some special circumstances. At several mature effusive volcanoes, the mean rate of lava effusion generally decreases with increasing altitude of the vent. Equation (2) can therefore be modified to link maximum potential flow length to vent altitude, shorter maxima being associated with higher elevations. Pre-eruptive maps of lava hazard can thus be prepared on the basis of vent elevation, and these provide a useful check on evaluations determined from mean slopes.

Equation (2) may also be used for short-term forecasts while an eruption is in progress. During the 1991–1993 effusion on Etna, for example, secondary aa flows began to overtop an artificial barrier and descend toward Zafferana, a town almost 3 km further downslope. Initial observations suggested that it was unlikely for the mean

discharge rate to exceed 1 m<sup>3</sup>s<sup>-1</sup> along any flow. From Eq. (2), a maximum flow length of about 2 km was anticipated, indicating that the immediate threat to Zafferana was small. A forecast was issued to that effect and, in the event, the longest secondary flow traveled only 1.8 km beyond the barrier.

The success of Eqs. (1) and (2) is remarkable not only for the simplicity of their underlying assumptions, but also because they use mean values of slope and discharge rate to determine length. In reality, surface slopes are uneven, while discharge rate changes with time and position along a flow. The agreement between theory and observation thus suggests that local variations normally have a secondary effect on maximum potential flow length, so that mean values are sufficient for most purposes. Extreme variations, such as flow over a cliff or through a very narrow ravine, may induce significant changes from the model results and, until more sophisticated analyses are available, these rare cases must be evaluated individually.

The expressions for maximum length assume that an aa flow travels until its front has solidified. The maximum time  $t$  required is

$$t \approx [(\varepsilon S / \rho g)(\rho c_p / \Sigma \sigma \Theta^3)] / \sin \beta. \quad (3)$$

As before, the combination of physical properties (Table IV) in the square brackets is roughly constant for a particular lava composition and, for typical angles of

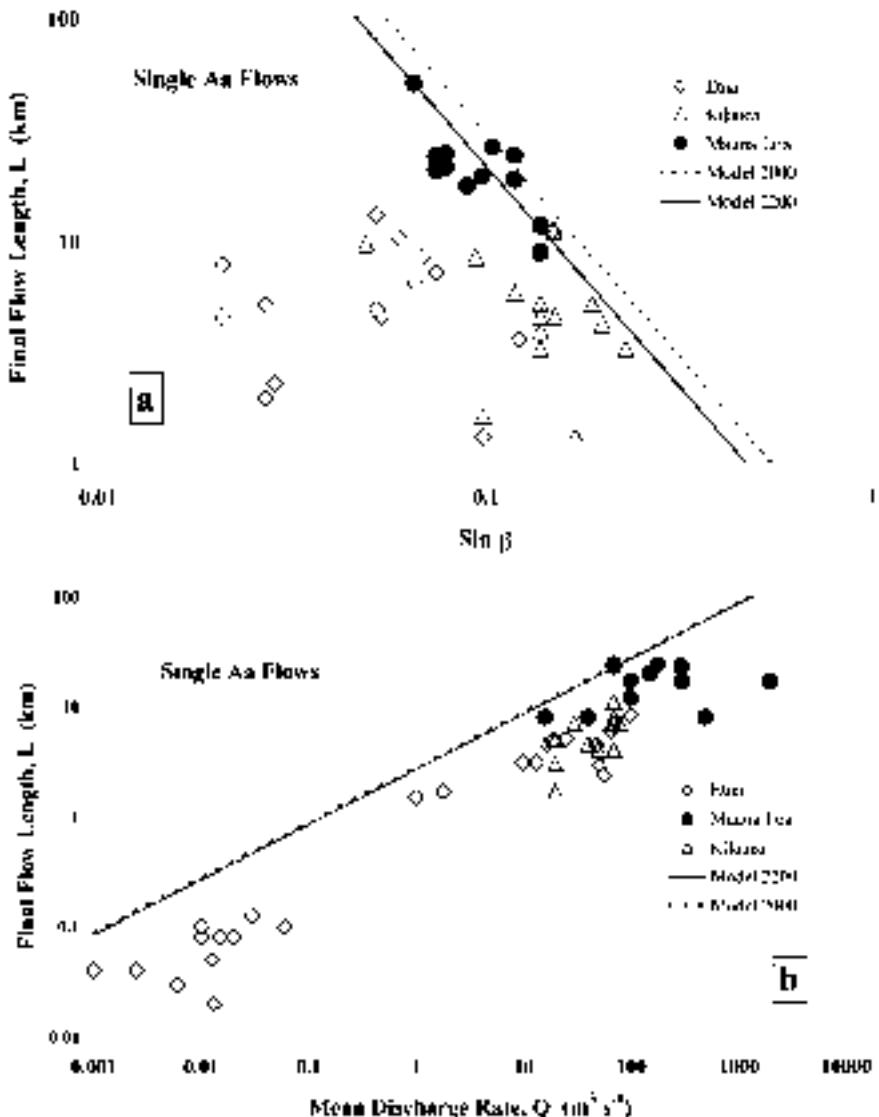

FIGURE 8 The conditions that (1) aa surfaces must break before they cool to their maximum strength and (2) flow fronts advance until solidified yield criteria for relating the maximum potential length of a single aa flow to (a) underlying slope ( $\sin\beta$ ) and (b) rate of discharge ( $Q$ ). These criteria [Eqs. (1) and (2)], shown by the solid and dashed trends, agree well with observations from Etna and Hawaii. The solid and dashed lines refer to respective mean crustal densities of  $2200$  and  $2000 \text{ kg m}^{-3}$ .

2–10 degrees for the slopes of basaltic volcanoes, yields lengthening times of about 1–10 days (the longer times corresponding to smaller slopes). During a long-lived eruption, therefore, major breaching and the propagation of new flows is most likely to commence within days following the start of effusion. Because new flows rarely extend a flow field by more than half the length of the first major flow, another forecasting problem is to assess the final width of a flow field, which may stretch to several kilometers.

An aa flow field can widen until halted by topography or by the end of effusion. The topographic control depends on local conditions and must be assessed on a case-by-case basis. The likely duration of an effusion can be estimated by comparison with previous eruptions, but even on well-studied volcanoes, such as Etna, Kilauea, and Mauna Loa, such estimates are rarely better than inspired guesswork. Improvements will follow when it becomes possible either to estimate (probably by geophysical monitoring) the quantity of magma be-

low ground that is available for eruption or to forecast the long-term decay in rate of effusion as an eruption proceeds.

---

### VIII. FORECASTING THE BEHAVIOR OF PAHOEHOE AND BLOCKY FLOWS

It is possible before an eruption to estimate the maximum length of an aa flow because the surface criterion provides a velocity and the solidification control yields a time. Such a combination is not available either to pahoehoe or to blocky flows and so forecasts of their growth are inherently more difficult.

For pahoehoe flows, the requirement to form a continuous crust can be used to constrain maximum rates of advance to about 1 km/day on slopes typical of basaltic volcanoes. Unfortunately, the burrowing mechanism, by which new lava intrudes into the front after traveling through insulated tubes, has so far defied realistic estimates of maximum cooling times. As it happens, observed pahoehoe flows (mostly from Hawaii) have frequently lengthened for the whole of an eruption, even when this has continued for several months (Fig. 5). In practice, therefore, pahoehoe emplacement is often limited by the available supply of magma, and so forecasting flow behavior is subject to the same problems encountered when estimating the final width of an aa flow field.

Among blocky lavas, surface fracturing appears to be controlled by the strength of lava beneath the chilled crust. As a result, fracturing is not required to be faster than the rate of surface chilling, and so no surface criterion is available for forecasting mean rates of advance. Velocity forecasts must therefore rely on knowing the rheologic state of a lava and the rate at which it is effused, factors that can be estimated by analogy with previous effusions from the same volcano.

Because the lava is viscous and slow moving, a blocky front is expected to solidify at a rate controlled by conductive heat transfer to the breaking surface. From standard conduction theory, a crude estimate of the solidification time for common final thicknesses of 10–30 m is from 6 months to more than 4 years, lengths of time that are greater than the usual durations for eruptions of blocky lava. Once again, the volume of magma available appears crucial for determining how far a lava can travel, and estimating this volume remains a fundamental obstacle to improving pre-eruptive forecasts of blocky flow growth.

---

### IX. TURBULENT LAVA FLOWS

Lava flows witnessed in historical time have had physical characteristics that favor laminar motion, and so it is this motion that has been assumed in developing quantitative models of lava behavior. However, some ancient lavas on Earth, erupted for the most part more than 2500 million years ago, may have been sufficiently fluid upon eruption for turbulent advance. Turbulent flow involves the spontaneous intermingling of neighboring packets of lava, so that internal lava cools and solidifies more quickly than would have been the case for simple laminar flow. The net result may well have been the persistent surface disruption of a lava undergoing wholesale internal solidification, analogous to conditions for aa lava flow emplacement (for which, as discussed earlier, internal solidification is induced by factors other than spontaneous turbulence).

Notable candidates for ancient turbulent flows are komatiite lavas (Table II), which, named after their discovery near the River Komati in South Africa, are found dotted across the world's oldest continents (Africa, Australia, and North and South America) and are often associated with economically important nickel deposits. Essentially basalts with unusually large amounts of magnesium, iron, and aluminum, these lavas since their eruption have been buried by younger material and grossly deformed by major changes at the Earth's surface. As a result, it has not been possible to investigate directly the influence of turbulent motion on lava flow morphology. This is unfortunate, because interest has been generated by speculation that komatiites could be among the types of lava flow observed on other planets. Only when direct chemical analyses are available for extraterrestrial flows will it be possible to gauge the potential significance of turbulent flow on volcanoes beyond Earth.

---

### X. LAVA FLOWS AND PLANETARY DEVELOPMENT

Lava flow fields are among the commonest surface features of the terrestrial planets. Quite apart from hazard analyses, therefore, an understanding of flow emplacement is essential for investigating the evolution of planetary surfaces. By virtue of their remote location, most information on extraterrestrial flows concerns their di-

mensions and geometry. Especially impressive is the fact that flows stretching hundreds of kilometers are commonplace on the Moon, Mars, and Venus, with some exceeding the size of ancient flood basalts on Earth. Primary goals of planetary studies are to use flow shape and size to deduce chemical composition and to infer conditions in the magmatic feeding systems, thereby probing also into the states of planetary crusts and mantles.

Despite their large size, the shapes of planetary flow fields resemble those of their smaller cousins on Earth. Because flow shape depends on the ratios of controlling factors, geometrical similarity suggests that these factors remain within the same range of proportions to each other as they occur on Earth. It is thus realistic to assume that, unless extraterrestrial lava flows have been emplaced exclusively under turbulent conditions, the range of controlling ratios (e.g., among the forces driving and resisting motion) found on Earth can be applied to the neighboring planets and, hence, that extraterrestrial flows will also belong to the pahoehoe–aa–blocky spectrum.

## XI. SUMMARY

Lava flows on land evolve along a small number of trends, each of which links surface structure to styles of advance and to modes of flow field growth. These trends correspond to particular combinations of the forces driving and resisting flow motion. Fortunately, one combination (corresponding to aa lavas) provides the possibility for forecasting flow growth before an eruption has started. Unfortunately, emplacement of the remaining flow types, pahoehoe and blocky, appears to need prior knowledge of the amount of lava available, a quantity that it is not yet possible to assess before an eruption has finished. Remedies are expected as geophysical methods for investigating the insides of volcanoes become more sophisticated, so that a complete forecasting potential may be available beyond the millennium.

## GLOSSARY

**coulee** An extrusion of lava that has aspects of both a lava dome and a lava flow. A lava dome that has experienced some flow away from the vent.

**cryptodome** An accumulation of molten material just beneath the surface. This material typically lifts the overlying rock and soil, forming a visible mound on the Earth's surface as the molten rock beneath gradually cools and hardens.

**endogenic dome growth** The enlargement of a lava dome as its exterior expands to accommodate an influx of new lava.

**endogenic explosions** Forceful ejection of volcanic material originating from the interior of an advancing lava flow or dome.

**exogenic dome growth** The enlargement of a lava dome as successive, discrete lobes of lava pile on one another.

**exogenic explosions** Forceful ejection of material from beneath a volcano through a vent on its surface.

**lava dome** Mounds of volcanic rock that form as lava flows onto the surface and amasses over a vent.

**vesicular** Texture of a volcanic rock characterized by an abundance of void spaces.

**rheology** The study of flowing materials.

## I. DEFINITION OF LAVA DOME

Lava domes are mounds of rock extruded from a volcanic vent (Fig. 1). They form as viscous magma cools relatively quickly after emerging onto a planetary surface. Although dome compositions may cover the full spectrum of silica contents, the majority have relatively high

**FIGURE 1** The Mount St. Helens composite lava dome in 1985. This dome formed as distinct lobes of lava extruded onto the surface between 1980 and 1986. The dome, which is approximately 1 km in diameter and 300 m high, enlarged primarily through endogenous growth during the late stages of formation.

silica contents. Dome diameters vary from a few meters to several kilometers, and their height varies from a few meters to greater than 1 km. They may be steep sided or tabular in cross section, circular, elliptical, or irregular in outline, and uniform or varied in color and texture. Some occur in isolation, whereas others form linear or arcuate chains up to 20 km long on Earth and more than 150 km long on Venus. They may have steady or episodic growth, with emplacement times ranging from a few hours to many decades. Effusion rates vary from less than 1 m<sup>3</sup>/s to more than 100 m<sup>3</sup>/s. Some of the larger lava domes exhibit some flow of lava away from the main vent, and are referred to as *coulees*. Generally, lava domes advance too slowly to threaten nearby populations with burial, or to make colorful footage for news broadcasts. Yet in recent years, lava dome emplacement has been among the most deadly types of volcanic eruptions with more than 100 fatalities recorded at active lava domes this decade, including 44 deaths at Mount Unzen (Japan) in 1991 and 66 at Mount Merapi (Indonesia) in 1994 (Table I).

The danger associated with lava domes comes less from their growth than from their collapse. Volcanologists have devoted much attention to understanding why some domes suddenly transform from passively expanding mounds of lava to violently explosive clouds of scalding rock and ash fragments. In this article, we consider the character of lava domes, the different ways geologists try to decipher their growth and hazards, and

the significance of their interior and exterior textures and structures.

## II. WHY STUDY LAVA DOMES?

Domes are of interest to geologists for several reasons: (1) Although some may grow unaccompanied by significant hazard, they more typically form part of an eruptive cycle that includes dangerous explosive phases. Understanding why eruptive violence waxes and wanes

**TABLE I** Partial List of Fatalities Associated with Dome Emplacement, Collapse, and Destruction this Century

Volcano	Date	Fatalities
Mt. Pelée (Martinique)	1902	29,025
Soufrière (St. Vincent)	1902	~1,600
Santiaguito (Guatemala)	1929	~1,000
Merapi (Indonesia)	1954	64
	1976	28
	1994	66
Mt. Unzen (Japan)	1991	44
Soufrière Hills (Montserrat)	1997	19

is one of the main goals of volcanology, because it is necessary for issuing accurate volcanic hazards. (2) In contrast to more widely dispersed explosive eruption products, many domes are well preserved in the geologic record because their mass is confined to the near-vent regions of the volcano. Consequently, their shapes and locations are indicators of conduit geometry, which in turn reflects the prevailing state of stress at the time of eruption. (3) Similarly, mixing or stratification that takes place hidden from view in the magma chamber may cause chemical variations observed in dome rocks. These geochemical signatures can provide volcanologists with evidence of processes occurring beneath the volcano. (4) Water and other volatile phases dissolved in viscous silicic lavas have difficulty escaping, so that the surface of a dome may preserve an assortment of vesicular textures that offer clues about the role of volatiles in eruptive processes. (5) The spreading of active lava domes can be mathematically modeled and simulated in the laboratory, providing rare insights into the rheologic behavior of real magma containing bubbles, crystals, and large temperature gradients. (6) Dome-like features are recognized on the surfaces of the Moon, Mars, Venus, and on some of the icy satellite of Jupiter. Establishing the conditions needed for dome formation on Earth allows for more accurate interpretation of the evolution of these extraterrestrial bodies.

### III. WAYS TO STUDY LAVA DOMES

Geologists use an arsenal of tools to learn about lava domes, depending on the questions they are trying to answer. Observations of dome morphology, structure, and texture come from remote sensing, surveying, and other field techniques. Repeated aerial photography or other remotely sensed data record changes in diameter, height, volume, and structure of active domes. Thermal infrared measurements are sensitive to the vesicularity and mineralogy of older dome surfaces, or temperature variations within active domes. Magnetic studies of active domes provide insights regarding cooling rates. Radar studies may describe the blockiness of a dome surface, or the grain-size distribution in pyroclastic deposits formed when lava domes collapse. Carefully constrained surface sampling combined with research drilling is necessary to unravel the geochemical character and degassing behavior of domes. Laboratory simulations help relate the surface structure of a dome to its eruption rate, cooling rate, and lava composition, and the spreading dynamics to magma rheology.

### IV. MAJOR HAZARDS ASSOCIATED WITH LAVA DOMES

Most hazards associated with domes originate when a part of a lava flow front collapses, giving rise to an avalanche of hot, fragmented material called a *pyroclastic flow* or *surge*. Pyroclastic phenomena formed from material previously erupted from a volcano are called *endogenic* explosive eruptions. They may occur with little warning and up to several months after a particular lobe began its growth (Figs. 2 and 3; see also color inserts). The cooled outer carapace of a dome can contribute to a buildup of pressure in the flow's interior, releasing a violent explosion when the dome front collapses. The destructive potential is roughly proportional to the volume and volatile content of the collapsing lava. Studies at Mount Unzen and Soufrière Hills (Montserrat) suggest that variations in dome extrusion rate also may correlate with the frequency of pyroclastic flow generation by gravitational collapse. The pyroclastic currents emitted from domes may travel tens of kilometers at very high speed. In the 1990s, such events killed more than 100 people at Unzen, Soufrière Hills, and Merapi. Similar activity at the Santiaguito dome complex on Santa María Volcano (Guatemala) produced pyroclastic flows that killed more than a thousand people in 1929.

In contrast to the endogenic pyroclastic events generated by dome collapse, the size and violence of *exogenic* explosive eruptions, those that eject new material from the volcanic conduit or magma chamber beneath a dome, may show little apparent relationship to the lava resting on the surface. These eruptions, which may partially or totally destroy an existing dome, can be easier to predict because they tend to be accompanied by precursory seismicity, deformation, or gas emissions that can be monitored remotely. A small dome preceded the major plinian eruption of Mount Pinatubo (Philippines) in June 1991. The devastating pyroclastic surge that destroyed the city of St. Pierre on the island of Martinique in 1902 is thought to have emerged from the base of a dome that had been visible on the distant skyline of Mount Pelée for several days. In the 5 months that followed the cataclysmic plinian eruption of Mount St. Helens (USA) in May 1980, a series of domes appeared and were then destroyed by explosive eruptions from the conduit. Similarly, the extrusion of 13 separate domes at Mount Redoubt in Alaska in 1991 alternated with explosions that pulverized them.

Because of their position high on a volcanic edifice, many domes pose dangers to the surrounding area even after they have fully cooled and solidified. For instance,

**FIGURE 2** Pyroclastic material from the Mount Unzen lava dome (background) has caused extensive property damage in Shimabara, Japan. The eruption on June 3, 1991, was responsible for 44 fatalities. (See also color insert.)

one of the Chaos Crags dacite domes on the shoulder of Mount Lassen (USA) collapsed several hundred years after its extrusion, possibly in response to an earthquake, forming the Chaos Jumbles rockfall avalanche that traveled more than 5 km away from its source. Parts of the dome at Mount Unzen are today perched precariously a few kilometers away from the city of Shimabara, and large-scale failures near the E1 Brujo vent of the Santiaquito dome occurred in 1992, nearly 15 years after extrusion ceased at this vent. Domes in wet climates are subject to hydrothermal alteration, which promotes increased rates of erosion, resulting in voluminous slurries of water, ash, and eroded volcanic rocks that can cause deadly flooding. Such events represent major ongoing hazards at both Santiaquito and Merapi.

#### V. TYPES OF LAVA DOMES

Volcanic features referred to as *lava domes* share many attributes; they are made of viscous lava, they tend to pile up over their vents, and their surfaces are generally blocky. However, a global inventory suggests that domes may be subdivided into different categories on the basis of morphology, surface texture, and eruptive style. The steepest sided, named Pelean or spiny domes, are circular in plan view and have relatively smooth upper sur-

faces punctuated by tall vertical spines. Examples include domes at Mount Pelée (both 1902 and 1932–1933) and Santiaquito (1922–present). Somewhat less steep domes are typically composed of a series of distinct lobes that emerge sequentially from a vent. These domes have some portions covered with small blocks and others displaying very smooth surfaces, smaller cross-sectional profiles, and more irregular plan forms (Fig. 4; see also color insert). They include domes that followed major plinian explosive eruptions at Mount St. Helens, Katmai, and Pinatubo, as well as the 13 domes that formed at Redoubt volcano in 1991. A third type, called *platy* or *endogenous domes*, has an even lower profile, blockier carapace, fewer and shallower fractures, and more numerous transverse surface ridges. Examples include the domes at Mount Merapi and Soufrière of St. Vincent (Fig. 5). Domes of the final type have nearly level upper surfaces, highly irregular plan outlines, and surfaces covered with variously colored small blocks and linearly extensive surface corrugations. These are referred to as *axisymmetric domes* because of their tendency to have shapes constrained by local topography. Holocene age axisymmetric rhyolite domes include Little Glass Mountain on Medicine Lake volcano in northern California and Big Obsidian Flow at Newberry volcano in Oregon.

The progression of dome categories just described—spiny, lobate, platy, and axisymmetric—corresponds to conditions of increasing eruption rates and decreasing cooling rates and yield strengths. Carefully scaled labo-

ratory simulations using analog materials allow the quantification of relationships between these dome types and eruption conditions. Slurries of polyethylene glycol wax mixed with kaolin powder can reproduce many of the most common attributes of these four dome types. Comparison with eight well-documented eruptions and their estimated effusion rates allowed the calculation of effective yield strengths of the active domes. Using a complementary approach, eruption rates of prehistoric and extraterrestrial domes were estimated, values that cannot be determined in any other way.

Cryptodomes are another variety of lava dome, and differ from the previous examples in that lava never reaches the surface of a volcano. Thus, it is an accumulation of molten material just beneath the surface. This material typically lifts the overlying rock and soil, forming a visible mound on the Earth's surface as the molten rock beneath gradually cools and hardens. Usu volcano in Japan produced a cryptodome in 1910, called Meiji Sin-zan. In 1943, new lava intruded through Meiji Sin-

**FIGURE 3** An explosion at the Santiaguito lava dome in 1988. These small explosions pose few hazards for local residents, although larger ones could destroy larger sections of the dome. (See also color insert.)

**FIGURE 4** Smooth area of the Mount Unzen dacite lava dome in 1995. The width of the field of view is approximately 75 m. (See also color insert.)

zan and reached the surface, forming the spiny Showa Sin-zan lava dome.

Cryptodomes may have significant implications for volcanic hazards. The deformation of the north flank of Mount St. Helens in 1980 was triggered by the formation of a cryptodome. The injection of lava beneath the surface of Mount St. Helens fractured and destabilized the preexisting rocks, eventually leading to the catastrophic debris avalanche and explosion of the cryptodome on May 18, 1980.

#### VI. LAVA DOME SURFACE TEXTURES AND STRUCTURES

Walking across a lava dome is not a particularly pleasant experience. In fact, terrestrial lava domes have some of the roughest of geologic surfaces when measured at decimeter to meter scales. Haphazard piles of loose,

FIGURE 5 Blocky, spiny surface of the Mount Merapi lava dome (foreground) in 1995, with Mt. Merbaru in the background.

sharp blocks separated by deep cracks and hollows conspire against easy walking. Only anomalously smooth areas, most commonly near vents, provide any respite. Aerial photographs reveal that on many domes, the seemingly chaotic mounds and depressions align into regularly spaced ridges and troughs that may extend continuously for hundreds of meters. The same photos show that smooth areas commonly occur in pairs, symmetrically distributed about a central fracture called a *crease structure*. In addition, explosion pits dot the surfaces of some of the larger rhyolitic extrusions. Hand samples collected from dome surfaces reveal a variety of glassy and vesicular textures, and detailed mapping can record their spatial distribution. During the past two decades, volcanologists have found that studies of block size distributions, lava textures, and surface structures each can provide unique information about the emplacement of silicic magmas. These lava textures and structures typically result from brittle deformation, at a variety of scales, of a cooled, rigid flow exterior during emplacement. This is in contrast to basalt lava flows, whose surface morphology is controlled largely by ductile deformation prior to solidification.

### A. Blocks

The most basic structural element on a lava dome surface is the block. Blocks on a particular portion of a

dome can vary greatly in size, ranging from more than 5 m in diameter to others small enough to sift through gaps between larger blocks to the flow interior. Although the placement of blocks on a lava dome may appear random, block size distributions actually reflect eruption dynamics. Average block sizes generally decrease outward from a vent area to the flow front (Fig. 6). Observations at the active Mount St. Helens and Mount Unzen lava domes showed that high extrusion rates lead to rapid fracturing of the flow surface and the production of small primary blocks. Low extrusion rates cause less intense fragmentation and the formation of large slabs in the vent area. This relationship has been confirmed in laboratory simulations using kaolin/wax slurries; lower eruption rates produce more extensive smooth surfaces.

Although most blocks initially form in the vent region, new ones may be generated downslope through fracturing associated with compressional folding, crease structure formation, and as rootless explosions toss blocks onto the flow surface. These primary blocks may fracture further through mechanical and thermal processes as they are carried downflow. Most silicic lava flows reach a “steady-state” in which the average block size at the surface remains in the 20- to 30-cm range despite increasing distance from the vent. Finer grained material (blocks <12 cm) does not typically accumulate on the flow surface because it falls into the interior. Therefore, long silicic lava flows are not expected to be covered by a blanket of fines along their entire lengths, an important

consideration for remote evaluation of extraterrestrial lava flow compositions.

### B. Vesicular Lava Textures

Besides varying in size, the blocks that cover lava dome surfaces also display a spectrum of glassy and vesicular textures that develop at different flow depths. Surface and flow-front mapping as well as drilling studies reveal a complex stratigraphy of these textures within many silicic lava domes. Rhyolitic extrusions typically consist of a surface layer of finely vesicular pumice (FVP) underlain by a zone of obsidian (OBS). Beneath this upper obsidian, a layer of coarsely vesicular pumic (CVP) forms where volatiles from the flow interior accumulate beneath the crust of obsidian and FVP. This CVP layer has a lower density than the overlying material and may rise to the surface as regularly spaced diapirs (Fig. 7). These features may then deform into folds and crease structures as the advancing flow surface compresses and stretches. Beneath the CVP zone, the lowermost portion of the flow consists of a combination of more obsidian and a central layer of partially crystallized rhyolite.

Two contrasting models have been proposed to explain the textures in rhyolitic lava domes. According to the first, most of the lava emerges from the vent as dense obsidian that then degasses and inflates during advance

to form surficial (FVP) and interior (CVP) vesicular zones. An alternative view, sometimes referred to as the *permeable foam model*, suggests that the entire flow is erupted as a highly inflated magmatic foam that compresses under its own weight to form obsidian zones. Both models assume that most of the originally high magmatic gas content (commonly greater than 5 wt %) is lost into the wallrocks and through the open vent as the magma works its way to the surface. The controversy concerns the texture of the magma as it comes out from the vent.

Dacitic lava domes, such as those at Mount St. Helens and Mount Unzen, exhibit simpler, though similar, textural stratigraphy as compared to the rhyolitic domes. Many of the flow lobes extruded at Mount St. Helens from 1980 to 1983 display a vesicular carapace underlain by a dense interior, analogous to the FVP and OBS layers in rhyolites. Observations of active dacite lobes show that the frothy carapace forms through vesiculation of originally dense lava during surface flow, and chemical analyses demonstrate that a significant amount of water may be liberated from the lava during this process. In contrast, most Mount St. Helens flow lobes formed between 1983 and 1986 have little or no vesicular material on their surfaces, suggesting that more substantial degassing occurred prior to emergence of this magma. One possible interpretation of this relationship is that later in its history, the taller dome with a thicker cooled crust more effectively inhibited magma extru-

FIGURE 6 Summit of the Mount Unzen dacite dome towering above Shimabara, Japan. Note the large blocks in the foreground with smaller blocks dominating the distal surfaces.

**FIGURE 7** The Little Glass Mountain rhyolite flow in northern California with Mount Shasta in the background. The dark, irregularly shaped surfaces in the foreground are outcrops of coarsely vesicular pumice that form as volatiles accumulate beneath a cooled flow surface. The CVP then rises diapirically to the surface.

sion, allowing more substantial degassing to take place beneath the surface.

### C. Explosion Pits

On some of the larger rhyolitic lava domes in the western United States, 10- to 15-m deep explosion pits disrupt the flow surface. These craters typically occur in the distal regions of a flow, far from the primary vent. They penetrate the upper FVP and OBS layers, suggesting that they originate in the interior CVP region. Analyses of the CVP zone show that it can have two to three times the water content of the OBS and FVP zones. These anomalously high water contents may develop when gases released by crystallization of the flow interior migrate upward through cracks to accumulate beneath the cooler and less permeable upper obsidian layer. These additional volatiles could provide the energy necessary to drive the explosions that disrupt dome surfaces and increase their hazard potential.

### D. Compressional Ridges

Surface ridges form in response to compression parallel to flow during advance of some silicic lavas. Folding

theory has been used widely to interpret regularly spaced tectonic structures, and also can be applied to corrugations on lava flows. The geometry of lava folds offers a means of estimating the bulk rheological properties of the magma. These estimates may differ significantly from those determined by laboratory measurements. Experimental procedures use relatively small, homogeneous samples, while natural lavas contain bubbles, crystals, and compositional and thermal gradients that are difficult to replicate in the laboratory. These viscosity estimates can be used to calculate flow velocities, which in turn are needed for hazard assessments.

The growth of surface folds on a viscous fluid requires a particular combination of stress and rheologic conditions. The upper surface of the flow must have a viscosity that is greater than that of the interior, and compression must be sufficiently high to overcome the tendency of gravity to minimize any large-scale topographic irregularities. If the viscosity contrast is too high, the top of the flow will not deform in a ductile manner but instead will fracture. If the contrast is too low, compression will cause the upper part of the flow to thicken rather than fold. Fold wavelengths are roughly proportional to the thickness of the flow's cooled upper carapace. The ratio of wavelength to carapace thickness depends on the flow composition, with more silicic compositions having larger wavelength-to-thickness ratios than more mafic

compositions. In some cases, the surface of a flow may undergo more than one folding episode. On photographs of the resulting “refolded” surface, the ratio of first- to second-generation wavelengths can be determined. This ratio, which ranges between 2 and 5, has also been shown to have composition dependence, since flows with more silicic chemistry have smaller ratios. This approach was used to determine that several lava flows on Mars had andesitic compositions.

### E. Crease Structures

Probably the best documented emplacement of a lava dome was that of Mount St. Helens between December 1980 and December 1986. The dome consisted of an assemblage of lobes that each required a few days to a few months to grow, separated by repose periods of a few weeks to a year. For many of these lobes, the first and last lava to appear at the surface emerged from a prominent crack on the flow surface called a crease structure. This fracturing process is cyclic, with small increments of crack growth alternating with brief periods of cooling. The result is a pair of fracture surfaces cut by striations that parallel the crack axis and form as the crack tip temporarily stops during inward propagation

(Fig. 8). Similar striae are found on the surfaces of cyclically fractured columnar joints.

Detailed studies of crease structure morphology and formation on active and recent silicic flows show that these features develop where lava is allowed to spread laterally, either as the flow advances across a relatively flat area, or along the crests of surface ridges perpendicular to the direction of maximum compression. Crease structures vary greatly in size, with their long axes measuring from less than 3 to more than 250 m. In fact, the entire surface of some lava domes, such as many along the Devils Hill chain on South Sister volcano (Oregon), consists of a single crease structure. Observations of several Mount St. Helens dome lobes that were emplaced as single, large creases provided estimates of strain rate during formation and allowed for modeling of the thermal and mechanical evolution of these structures. Estimated formation times generated from a one-dimensional conductive cooling model were used to calculate extrusion rates for several older rhyolitic domes emplaced as single crease structures. These emplacement rates varied from less than  $1.0 \text{ m}^3/\text{s}$  for domes in the Devils Hill chain, to more than  $100 \text{ m}^3/\text{s}$  at the Glass Creek dome in the Inyo Dome chain (California). These values compare favorably with those determined independently through analysis of overall dome morphology.

FIGURE 8 Crease structure on the Medicine Lake dacite flow in northern California. The parallel banding evident in the lower right side of the photograph results from a cyclic fracture process. The width of the crease structure visible in the lower part of the figure is approximately 5 m.

---

## VII. INTERNAL STRUCTURE OF LAVA DOMES: FLOW BANDS AND JOINTS

In addition to their textural stratigraphy, many lava domes display two types of internal structure, flow bands and joints, that provide clues about the state of stress in the flow interior. Flow bands are subparallel, planar concentrations of small crystals or bubbles that develop in response to friction along the conduit walls during magma ascent, and deform in response to velocity changes during flow advance. Some domes display a concentric “onion-skin” foliation pattern in which the earliest extruded magma forms the outermost layer, and later magma inflates this rind like a balloon. Other domes have a more fanlike pattern originating when lava emplaced vertically above the vent slowly spreads laterally, accompanied by continual fracturing at the flow’s upper surface. Domes with a complex emplacement history may produce flow banding that has no easily discernible pattern, although careful measurements of these foliations may uncover the direction in which the flow moved and the sequence in which different lobes were emplaced.

Older, dissected lava domes also may display a range of columnar, polygonal, or sheetlike joint patterns in their interiors that reflect stresses associated with flow advance and cooling. Columnar joints form in response to thermal stresses accumulated during cooling of a dome, and their diameters are proportional to the cooling rate. Because these joints propagate away from a cooling surface, their orientations can help locate original flow margins. Such relationships have been used in a number of Cascade Range domes to identify where the lava may have been in contact with glaciers that are no longer present. Subparallel, platy joints commonly occur in the interior portions of domes where basal shear dominates the state of stress.

mic caldera-forming eruption on June 15 provided volcanologists with a glimpse of the magma composition of the volcano and hinted that a relatively clear conduit was available for any subsequent eruptions. This information allowed for timely and accurate warnings that minimized casualties.

Transitions between early explosive activity and late effusive behavior were originally ascribed to volatile stratification in a magma chamber; the volatile-rich upper part of the chamber first erupts explosively and then the volatile-poor lower portions erupt effusively. However, mineralogic studies later showed that the “dry” magma that forms domes and the “wet” magma that forms pyroclasts both had similarly high water contents prior to eruption. This realization led to the suggestion that variations in eruptive style are caused by differing ability of the ascending magma to lose gas, rather than by differences in the primary volatile content. This gas loss in turn is controlled by the permeability of the conduit walls and the magma ascent rate.

Although this model did a good job of explaining transitions from pyroclastic to effusive eruptions, it was less able to account for detailed textural relations in silicic domes and lava flows. Its proponents argued that all domes emerge from a vent as uniformly frothy magma that then compresses to dense lava during surface flow. However, field mapping and observations of active domes showed that in many cases the opposite is true: dense lava first appears at the vent and then vesiculates to form different textural zones during advance. The two views can be reconciled through a three-part hybrid model. (1) Most gas loss occurs into the wallrocks and out the top of a conduit during magma ascent. (2) Foam collapse takes place in the vent prior to the emergence of lava at the surface. (3) The surface of the advancing dense lava flow can vesiculate, and small amounts of volatiles within the flow interior can become redistributed by migrating through small transient cracks. Resulting zones of unusually high water content are most likely to be the sources of explosive phenomena if exposed suddenly by flow-front collapse.

---

## VIII. TRANSITIONS BETWEEN EXPLOSIVE AND EFFUSIVE BEHAVIOR

Lava domes typically extrude as part of an eruption sequence that may involve both effusive and explosive phases. Understanding the processes that favor a particular style of volcanism is essential for assessing hazards. For example, the extrusion of a silicic lava dome at Mount Pinatubo on June 8, 1991, prior to the cataclysmic

---

## IX. LAVA DEGASSING MECHANISMS

As indicated in the previous sections, the rate of volatile escape as magma moves from the chamber toward the surface is a major factor determining eruptive style. Stable isotope characterization of the small amounts of water remaining in dome lavas allows discrimination of

different degassing processes. *Closed-system degassing* is an equilibrium process that takes place in the chamber, where exsolved gases remain in contact with the magma. *Open-system degassing* occurs in the conduit, where gases released from the magma can escape to the atmosphere or into the host rocks, causing more rapid changes in isotopic signature. *Kinetic degassing* is only observed in extruded lavas whose low water content and high viscosities inhibit isotopic exchange between exsolved and residual gases within bubbles.

At Obsidian Dome (California) glassy rhyolite samples were collected both from the lava flow and from an underlying pyroclastic deposit whose emplacement immediately preceded dome extrusion. Obsidian from the pyroclastic layer had higher water and deuterium contents than obsidian from the dome surface. The data suggested that most of the gas loss accompanying formation of the dome obsidian had been an open-system process, presumably in the conduit. In contrast, the isotopic signatures of lava samples from the Mount St. Helens dacite dome could best be explained by a combination of closed-system, open-system, and kinetic degassing, requiring a more complicated interpretation of the timing of gas loss during the 6-year, episodic extrusion of the dome.

---

#### X. GEOPHYSICAL AND GEODETIC STUDIES OF LAVA DOMES

The Mount St. Helens eruption gave volcanologists an unprecedented opportunity to monitor geophysically the growth of an active dome. Seismic, magnetic, geodetic, tilt, and other data were collected during the dome's 6-year emplacement. The cyclic nature of dome growth combined with its proximity to a major urban area and adequate funding provided ideal conditions for acquiring repeated measurements throughout the entire growth sequence. For example, repeated magnetic surveys across the dome's surface before, during, and after several episodes of lobe extrusion showed that the dome contained a hot, nonmagnetized core surrounded by a cool, magnetized carapace and talus apron. The magnetized carapace thickened at an average rate of 0.03–0.01 m/day from 1984 to 1986. Snowmelt, rainfall, and large-scale fracturing all enhanced the rate of cooling. This work enabled volcanologists to predict that the dome would completely solidify within 18–36 yr of the last eruption (1986). Detailed seismic studies gave a view of the plumbing system that fed the dome. These data

showed that the conduit was less than 50 m wide, only 2–3% of the final dome diameter. They also suggested that the rising magma passed through two reservoirs at depths of 3 and 6 km beneath the summit.

The repeated data acquired by the U.S. Geological Survey at Mount St. Helens also provided the framework for a number of new models of dome emplacement. Geodetic studies showed that dome growth events were volume predictable; the volume of lava erupted during a single episode was proportional to the preceding period of repose. These extrusions can be explained if overpressurization in the magma chamber occurs at a constant rate. The 1980–1986 eruption also provided the first complete series of detailed topographic data collected during growth of a lava dome. After each of the nearly 20 lobes was extruded, the U.S. Geological Survey took high-resolution aerial photographs of the entire dome and then made digital topographic maps with 2-m contours. These data allowed volcanologists to study the detailed intrusive and extrusive growth patterns of a lava dome.

The overall patterns and rates of dome deformation suggested that the size, shape, and behavior of a lava dome are primarily controlled by the interplay between the strength of the cooled carapace and the magnitude of pressurization in the dome's interior. Furthermore, as a dome grows larger, it can accommodate a greater volume of endogenous (intrusive) growth before the brittle carapace ruptures. This idea explains the progressive increase in endogenous growth that is observed with each successive episode of dome extrusion.

#### XI. DOMES AS INDICATORS OF TECTONIC STRESS ORIENTATIONS

Dikes feed many silicic domes. These domes tend to occur in groups that are arranged either in linear or en echelon arrays. Many of the individual domes are asymmetrical and elongate parallel to the overall trend of the dome group. Near-vent fractures on the dome surfaces also are aligned preferentially to the orientation of the group of domes. Paired ground cracks, which form above and parallel to a rising dike, are commonly found near domes. Where inferred dike trends pass under topographic highs, the spacings of these pairs of fractures tend to increase, suggesting that the distance between the ground surface and the dike top is increasing. These types of structural evidence have been mapped in the vicinity of several Holocene dome groups,

allowing the orientation of the feeding dikes to be inferred. These dike trends can then be related to stress directions determined by other means to evaluate the relative influence of magmatic and tectonic forces. For instance, structures mapped along the trend of the Inyo domes near Long Valley Caldera, California, suggest that the domes were fed by a dike that rose obliquely to the north from an area beneath Mammoth Mountain. Domes on the southeastern slope of South Sister volcano reflect an echelon series of dikes or dike segments that rotated slightly as they approached the surface. Rhyolite domes in the Coso Range of eastern California trace paths that suggest the underlying dikes have predominantly north-south orientations (consistent with tectonic influences) but bend inward to a more radial attitude as they approach an inferred central magma body.

## XII. SUMMARY

The hazards associated with the recent, deadly eruptions at Mt. Unzen, Soufriere Hills, and Merapi demonstrate the need to better understand the formation and behavior of lava domes. Past studies of the Mount St. Helens dome form the foundation for current investigations of these more recent extrusive events, and enable volcanologists to better mitigate the hazards associated with these underappreciated volcanic features.

## GLOSSARY

- agglutination** Instantaneous flattening of hot, soft pyroclasts upon landing. The resultant deposit is an agglutinate or spatter pile; particle outline is in part retained.
- ash** Pyroclasts smaller than 2 mm in diameter.
- basaltic** Magma composition with high iron and magnesium content, but low silica content, having highest temperatures and lowest viscosities of common magmas.
- bombs** Pyroclasts larger than 64 mm in diameter.
- clastogenic lava** A lava flow formed by the rheomorphic flow of coalesced and agglutinated hot pyroclasts, typically fed by a lava fountain. Lava may contain obvious spatter fragments.
- coalescence** The process by which hot fluidal pyroclasts form a homogeneous liquid in which the particle outlines are obliterated.
- explosive eruption** Any eruption in which the magma is torn into fragments by gas pressure as it leaves the vent.
- fissure** A linear volcanic vent.
- Hawaiian** A relatively gentle type of explosive eruption in-

volving lava fountains and minor ash and scoria production.

**lapilli** Pyroclasts between 2 and 64 mm in diameter.

**lava fountain** An upushing jet of incandescent pyroclasts that falls to the ground near the vent.

**pyroclast** A fragment of magma.

**scoria** A pyroclast containing bubbles that are typically several millimeters in diameter.

**spatter** Synonymous with agglutinate.

**strombolian** Slightly more violent than hawaiian activity, strombolian eruptions produce copious amounts of scoria and ash, piled up around the vent to form a cone. The eruption plume typically pulsates with a period of several seconds.

**welding** Postdepositional compaction of a hot pyroclastic deposit under its own weight. Note that agglutination, coalescence, and postdepositional welding are part of a process continuum.

**yield stress** A mechanical property of many substances; the stress that must be exceeded for the substance to flow. True (Newtonian) liquids have zero yield stress. Also known as *yield strength*.

---

## I. INTRODUCTION

Explosive volcanic eruptions occur when magma in an open conduit or vent is torn apart by expanding gas,

and the fragments are ejected into the atmosphere. If the fragments are still hot, fluid blobs when they fall to the ground, they may agglutinate or coalesce. This process—lava fountaining and fallback—commonly feeds basaltic lava flows in Hawaii, Iceland, Reunion, Japan, and other active volcanic areas. Lava fountains probably fed most of the ancient basaltic lavas that are so common in the geologic record. Many basaltic lavas are thus pyroclastic in origin, although, due to complete clast coalescence, the final lava may yield few clues to a fragmental origin unless one has had the luck to observe the eruption.

Because the hot fragments must be able to coalesce to form a lava after their flight, specific conditions must be met if a fountain-fed lava is to form. These are low magma viscosity and low gas content. The effect of low viscosity is easy to see; the effect of gas content—explored later in the chapter—is complex. Low viscosity is favored by low magmatic silica content and high temperature. These conditions are commonly met by basaltic magmas and occasionally by other compositions, even (rarely) silica-rich compositions such as rhyolite. Where they are not fully met, the process is incomplete, and piles of spatter, or agglutinated, partly coalesced and flattened fragments that did not collapse to form a lava, are preserved around the vent. These spatter piles are very valuable for exploration and to research geologists working in extinct volcanic terranes, because they mark the site of volcanic vents that may otherwise be extremely difficult to identify.

as a rigid fragment that cannot agglutinate to form spatter or feed a lava. Too low a gas content and the magma may not be fragmented at all.

The most important magmatic volatiles in terrestrial magmas are  $H_2O$ ,  $CO_2$ , and sulfur species, with relatively minor amounts of others such as  $HCl$  and  $HF$ . The initial volatile content of magmas is hard to quantify, because these species are partially lost before one can sample and analyze the material. Rough estimates can be obtained from experimental petrology and thermodynamic modeling aimed at finding combinations of temperature, total pressure, and volatile fugacities that result in a duplication of the phase assemblages and compositions found in natural samples. However, the most reliable estimates come from direct analysis of samples that escaped degassing. Samples are of two types: (1) glass inclusions trapped in phenocrysts, representing tiny volumes of pre-eruptive melt, and (2) submarine lavas. Application of inclusion data to bulk magmatic volatile contents assumes that the enclosing phenocryst has acted as a perfectly sealed “bottle” since entrapment, and that the inclusions are fully representative of the liquid enclosing the phenocrysts. Submarine lavas retain volatiles if the water depth is great enough to prevent vapor saturation on eruption, or if vesicular magma is quenched prior to loss of bubbles from the lavas.

Available data for oceanic tholeiitic basalts indicate typical total dissolved volatile contents of 1–2%, with either subequal amounts of  $H_2O$  and  $CO_2$  or dominant  $CO_2$ . Alkaline basalts may be much richer in volatiles, with up to 7%  $H_2O + CO_2$  in the case of lavas of the 4-km-deep submarine North Arch volcanic field near Hawaii. This probably covers the range of volatile contents for subaerial oceanic basalts and continental flood basalts. It is unclear, however, whether basalts with such a high volatile content as the North Arch lavas ever erupt from subaerial volcanoes;  $CO_2$  especially is prone to open-system degassing between source and surface (see later discussion). Subduction-related mafic magmas also have high, but variable,  $H_2O$  contents, perhaps as high as 6% in some cases.  $H_2O$  contents of intermediate and felsic magmas achieve similar values. In these magmas,  $CO_2$  is probably subordinate.

Because different volatile species have different solubilities, it is necessary to consider all of them simultaneously in order to understand the mechanics of magma degassing. This has been done for  $H_2O-CO_2$  mixtures. Due to its low solubility, the effect of even a small amount of  $CO_2$  on the degassing behavior of hydrous magmas is profound: 500 ppm  $CO_2$  raises the volatile saturation pressure of a magma with 0.5 wt% water from a few megapascals to more than 100 Mpa, with almost

## II. FOUNTAIN PRODUCTION

### A. Magmatic Volatile Contents, Vapor Saturation, and Degassing

A *magmatic volatile* is any chemical substance, soluble in magma under pressure, that is gaseous at magmatic temperature and atmospheric pressure. Dissolved volatiles come out of solution to form bubbles that expand by decompression as magma approaches the surface, and provide the driving force for pyroclastic eruptions. The final stages are explosive, and tear the magma into blobs that are entrained into the expanding gas and ejected from the vent. Blob velocity is largely a function of initial gas content; too much magmatic gas results in adiabatic cooling and, much more importantly, a high ejecta velocity and consequent long flight path during which the clast loses heat to the atmosphere, and lands

all of the CO<sub>2</sub> partitioning into the vapor phase. The practical result of the partitioning behavior in H<sub>2</sub>O–CO<sub>2</sub> mixtures is a strong contrast between open- and closed-system degassing. In open-system degassing, where vapor is instantaneously removed after each degassing increment (essentially Rayleigh fractionation), CO<sub>2</sub> is rapidly preferentially removed and the system can be closely described by the pure water vapor case regardless of initial CO<sub>2</sub> content.

During closed-system degassing, however, a substantial fraction of original CO<sub>2</sub> remains in the melt. Because the timescale for bubble flotation in fluid basaltic magma is short (hours to days), vapor-saturated magma stored in a shallow subvolcanic chamber over a significantly longer period will experience something close to open-system degassing, while vesiculation occurring during uprise of magma into a vent system during eruption, which occurs over seconds to minutes, will, prior to the moment of magma disruption, closely approach the closed-system case. Pre-eruptive shallow storage occurs in Hawaii, Iceland, and many other basaltic volcanic areas where lava fountains are common eruption mechanisms, and in these cases we can expect that the exsolving gas has little CO<sub>2</sub>. In contrast, magmas that rise steadily to the vent from great depth may feed CO<sub>2</sub>-rich eruptions.

Two other factors should be mentioned. First, volatile solubility depends on magma composition, particularly for CO<sub>2</sub>, which is several times more soluble in nephelineitic than in olivine basaltic liquids. Second, nonequilibrium degassing, such as could occur during rapid exsolution at low pressures, would tend to enhance concentrations of water in the vapor over CO<sub>2</sub>, due to its higher diffusivity.

In summary, the volatile content of erupting magma is largely determined by its prior history of crustal transport and degassing. In eruptions fed from shallow chambers, water is the dominant species in the exsolved vapor and may account for up to 2% by mass of the eruption mixture. Eruptions of deep-seated magma, especially of silica-poor compositions, may be CO<sub>2</sub> rich.

## B. Bubble Growth and Magma Fragmentation

Theoretical modeling of the ascent of vesiculating magma, mainly carried out by Lionel Wilson and co-workers, has given us a first-order understanding of the generation of lava fountains. As magma approaches the Earth's surface, volatile exsolution results in bubble

growth. For the typical volatile contents noted earlier, most of this growth takes place within a few hundred meters of the surface. Nucleation of new bubbles requires that the magma be sufficiently supersaturated to overcome surface tension pressure of incipient bubbles. Little is known about the surface tension of magma-vapor interfaces under the conditions of interest, but it is likely that nucleation is enhanced by the presence of phenocrysts and by shearing of the liquid. Once formed, bubbles are fed by diffusive transport of volatiles through the liquid and grow as spheres until they begin to crowd each other. Left to itself, a magmatic foam might evolve to become locally permeable and form a network of glassy filaments outlining the edges of polyhedral bubbles with open faces. Excellent examples of a rock called *reticulite*, with porosities up to 99%, are a minor product of hawaiian eruptions and seem to represent such a foam frozen to rock. Usually, however, because the magma is rising toward the surface, individual bubbles become overpressured and explode before bulk permeability develops. Overpressures are a function of conduit-vent geometry and mass fraction of exsolved gas, and are typically of the order of a few bars to tens of bars. Theoretical models for exploding magma have assumed that explosive disruption occurs when the fraction of bubbles reaches 75%, although in reality it probably occurs over a range of porosities centered on this value. The explosively decompressing mixture of gas and magma blobs forms a spreading jet as it emerges from the vent; this is the rising part of the lava fountain. The vertical height reached is chiefly a function of exsolved gas content. In radially symmetrical, vertical fountains, fallback from the top of the spreading jet forms a skirt of descending fragments around the jet. More often, the jet is slightly angled from the vertical, or the falling skirt is affected by wind, causing preferential deposition on one side of the vent.

Lava fountaining is closely associated with strombolian activity, in which individual closely spaced explosions feed the rising jet. The degree of magma disruption is usually greater than in a lava fountain, producing finer ejecta that cool more readily to form scoria and spatter. Lava fountain eruptions usually include at least some strombolian-style activity. The two eruption styles may be closely linked: Observations of strombolian vents have revealed that the individual pulses are related to the explosion of giant bubbles at the magma surface, and they typically have lower mass eruption rates than hawaiian-style fountains. Basaltic magma is fluid enough that bubbles can rise through the magma column as it ascends. If the net bubble velocity is a significant fraction of the upward magma velocity, bubbles

will tend to collect toward the upper surface of the magma in the conduit. Large bubbles will collide and coalesce with smaller ones, producing still larger bubbles with greater upward velocities. A snowball effect may result, in which very large bubbles occupy a significant fraction of the conduit width and intermittently arrive at the magma surface. Thus, the difference between hawaiian-style fountaining and strombolian cone-building activity can be explained simply by different magma rise velocities. For basaltic magmas, the critical rise speed may be about  $0.5\text{--}1 \text{ m s}^{-1}$ ; much less than this and bubbles segregate (strombolian); much more and a lava fountain results.

### C. Fountain Structure

Although hawaiian-style eruptions often initiate along fissures to produce an early “curtain of fire,” continued flow of magma usually becomes localized at points along the fissure to produce a series of central vents, such as was observed during the 1973 Eldfell eruption at Heimay, Iceland. This discussion will refer to central vents only; the qualitative structure of fountains is the same in both cases.

The structure of lava fountains, and the deposits that result from them, depends mainly on two parameters: magma gas content and effusion rate. High gas content produces a high, spreading fountain and smaller clasts (magma blobs). High mass effusion rates favor collimated fountains and high accumulation rates of fragments on the ground around the vent. Models predict that the gas contents noted above for subaerial oceanic and continental flood basalts should easily allow fountains of 1 km high to develop. In fact, this is greater than typical observed heights for terrestrial eruptions perhaps because magmas partly degas at very shallow levels prior to eruption. In Hawaii and Iceland, sustained fountains are rarely higher than 500 m. An exception is the 1986 eruption of Izu-Oshima, described in more detail below, in which the fountain height reached 1,600 m. Lava fountaining from a single vent site is commonly most vigorous at the start of an eruption and wanes thereafter although lava production continues unabated. This pattern of activity (which may be modified where the eruption migrates along a fissure, opening new vents) may be caused by the establishment of a degassing lava pond in the vent, so that newly arriving magma mixes with the partly degassed pond liquid, resulting in a lower effective magma gas content and reduced fountain height.

Observations, especially of the long-lived Pu’u O’o eruption on Hawaii, allow fountains to be divided into an inner, hot, yellow to orange incandescent portion and an outer, dull red to brown or nonincandescent portion (Fig. 1). Wind may strip, and rapidly chill, fine particles from the outer portion of the fountain. High mass eruption rates produce fountains in which most of the ejected mass is in the hottest, inner portion, while high gas content favors the cooler, outer part. Hot, inner fountain material has little opportunity for cooling and may fall so close to the fountain base that it is recycled into the vent system, leading to a steady increase in the mass of fluid lava in the vent, forming a pond or, if it can move away from the vent, feeding a flow. Outer fountain clasts may be too cool to completely re-coalesce and build up a cone around the vent, while dispersed fines form a downwind ash deposit. We now turn to a consideration of processes occurring when clasts of different temperatures and, hence, rheologies are deposited.

### D. Agglutination and Welding

Welding is the process by which a pyroclastic deposit becomes compacted into a coherent rock through load-pressure deformation of hot, plastic magmatic fragments. Because it occurs after deposition (although it may begin before the entire thickness has been deposited), it helps to visualize welding as being distinct from syndepositional agglutination (see later discussion), although in reality the two processes form a continuum. One of the main parameters influencing welding is clast accumulation rate; it is favored if a clast at the surface of the accumulating deposit is buried before it can cool significantly, and if the number density of falling hot clasts above the surface is great enough that radiative heat loss, both from the surface and the falling clasts, is minimized. Agglutination refers to the adhesion and deformation of clasts on deposition. It differs from welding in that it is almost instantaneous, and that the energy required for deformation is the kinetic energy of the falling clast. Both welding and agglutination involve porosity loss, although equal-volume spreading or splashing (cow-dung effect) is additionally involved in agglutination. Agglutination requires lower magmatic viscosities than simple welding. Hence, for clasts of identical composition, agglutination requires higher temperatures than welding.

Modeling of the agglutination process indicates that 1-cm or larger clasts with viscosities of 1000 Pa s or less

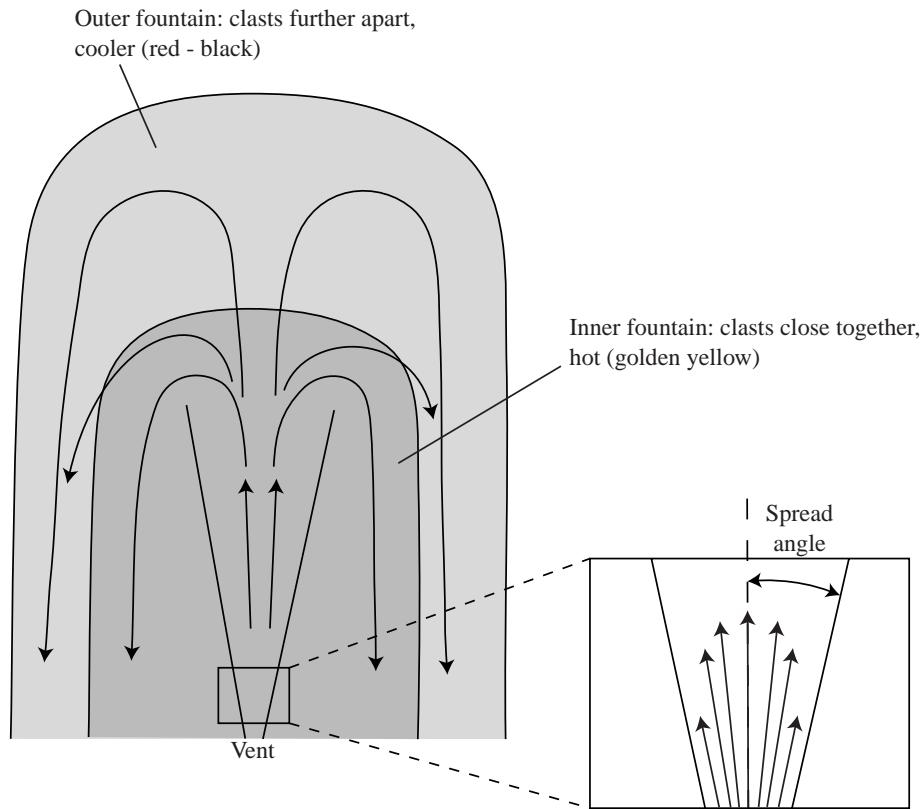

FIGURE 1 Sketch of the basic elements of lava fountain dynamic structure. The fountain actually consists of many thousands of clasts following the general paths indicated by arrows. Relative widths of inner and outer fountains may vary. Lengths of arrows in inset indicate velocity profile. Note that fountain asymmetry may result in more inner fountain material being deposited on one side, leading to deposit relationships like those sketched in Fig. 5. Based on the observations of Head and Wilson (1989).

will agglutinate (Fig. 2). This is a good description of most of the mass in the inner part of a fountain for basaltic magma compositions. As clast viscosity increases with falling temperature, only large fragments experience deformation upon landing, although smaller clasts may still compact during postdepositional welding. At up to 10,000 Pa s, complete welding is accomplished in a matter of seconds. Also, large clasts with chilled rinds may burst on landing and their fluid cores can still coalesce. At these viscosities, the agglutinated and welded mass begins to flow immediately, forming a clastogenic lava. A more important measure of the rheology of cooling basaltic magma may be the development of yield stress due to progressive groundmass crystallization. Yield strength is necessary for the preservation of agglutinate piles (Fig. 3) that do not collapse to form lava flows; the common occurrence of small drips, liquid segregations, and postflattening gas inflation structures in spatter piles indicates that the material did not immediately solidify upon landing, contained low-viscosity

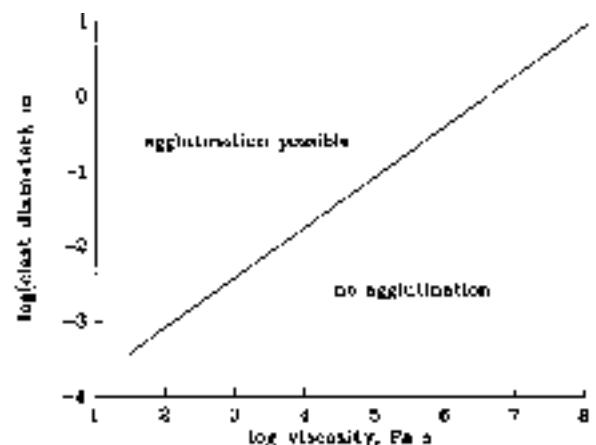

FIGURE 2 Plot of  $\log_{10}(\text{clast viscosity})$  versus  $\log_{10}(\text{clast diameter})$  to show limits of conditions under which syndepositional agglutination of falling tephra, exclusive of later welding, is possible. Model assumes that clasts reach terminal velocity before landing, hence, the boundary of the "no agglutination" field is conservative.

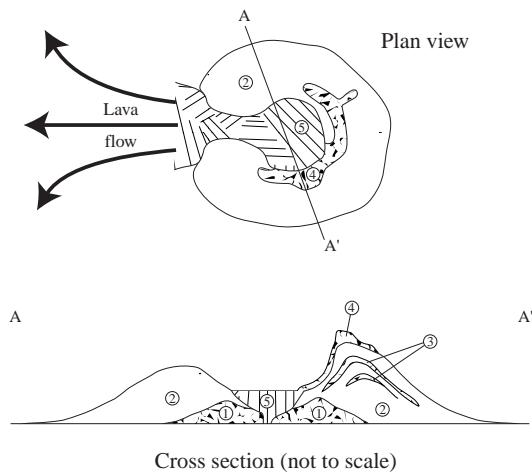

**FIGURE 3** Spatter (agglutinate) pile at the Sprout vent, San Francisco volcanic field, Arizona. Each layer is an individual flattened spatter bomb. Note bombs draping a small intraformational high in center of photograph.

residual liquid, yet did not flow en masse. A lava may still form if the combination of thickness and ground slope causes the yield strength of the spatter pile to be exceeded at the base, which occurs for most cases where the yield strength is  $10^4$  Pa or less. Yield strengths 2 to 3 orders of magnitude greater are required to completely resist agglutination, hence there is a range of values around  $10^5$  Pa favoring the formation and preservation of spatter piles. Preservation is most likely for thin agglutinate layers.

### III. FOUNTAIN-FED LAVAS AND ASSOCIATED ERUPTION PRODUCTS

We are now in a position to link fountain structure to final products (Fig. 4), although these processes have yet to be quantitatively modeled in detail. The inner part of the fountain experiences little heat loss and essentially remains at magmatic temperatures, with viscosities around 1000 Pa s and negligible yield strength. If the accumulation rate (chiefly a function of magma production rate) is high enough, a lava flow will be fed from the point where the magma fragments land. It is worth noting that, at the start of an eruption at a new vent, the environment is cold and cooling rates may be sufficient to form an early spatter pile. The outer parts of the fountain will yield clasts that experience sufficient in-flight cooling to develop either a yield strength due to groundmass crystallization and/or a viscoelastic skin. Small clasts may be completely cooled to a brittle glass.

Because of the annular fountain structure, the pile that results from outerfountain deposition forms a collar, growing to a cone, around the vent, and its contents are quite sensitive to changes in accumulation rate, fountain width, and wind speed. Low accumulation rates will favor spatter layers and brittle scoria, which are very commonly seen to be interbedded in old, eroded vent cones. The extreme sensitivity of spatter preservation to eruption conditions is shown by thin, vertical walls of spatter such as are seen around vents for the prehistoric Devil's Garden flow, Oregon. Agglutinate accumulations on the cone may collapse to form small, spatter-fed lava flows down the cone flanks. The growing cone acts as a funnel to confine the inner fountain-fed lava to a vent pool, which may breach or overtop the cone. Alternatively, if lava has been flowing from the start of the eruption, the cone will be open on one side as falling scoria fragments are carried away by the lava. Coherent pieces of spatter or welded scoria from the cone may be carried away on the surface of the lava, especially

**FIGURE 4** Plan view and cross-section sketches of the deposits resulting from an asymmetric lava fountain. Deposition rate is higher on the righthand side of the cross section than on the left. The fountain itself has been omitted for clarity, but compare this diagram with the fountain dynamic structure in Fig. 1. Key: 1, early-formed spatter ring; 2, scoria cone; 3, layers of spatter and small clastogenic lavas, formed by agglutination, interbedded within the scoria cone; 4, actively forming spatter layer, depicted as slumping down the crater wall to form a small clastogenic lava that is feeding the central lava pond; 5, central lava pond, fed mainly by direct fallback from inner fountain, and also from layer 4. In the plan view, the central lava pond is shown breaching the left-hand side of the cone to feed the main lava flow. The sketches are based on the observations of Head and Wilson (1989).

during a breaching episode, when large sectors of the vent cone may be rafted out on the flowing lava.

Vents may undergo morphologic evolution to complex structures that outwardly bear little resemblance to this simple picture, and eventually cease lava fountaining altogether. Cones may be modified by repeated breaching and healing; shifts in vent location or simultaneous activity at nearby vents on a fissure may produce overlapping cones; the lava may roof over to emerge as an incandescent stream some distance away, spatter walls may develop to form overhangs and restrict central vents; and temporary cessation may allow the vent lava pool to roof over and suffer subsequent partial drainage.

---

#### IV. AGGLUTINATION IN OTHER COMPOSITIONS AND ERUPTIVE STYLES

Agglutination and coalescence of fluid tephra, sometimes to the degree of nonparticulate secondary flow as a reconstituted coherent lava, are not restricted to Hawaiian-style eruptions of basaltic magma. The deposits from violent plinian and ignimbrite eruptions may include agglutinated material, and a fountain-fed origin has been deduced for some prehistoric rhyolitic lavas. In nearly all cases, the magma compositions and/or temperatures are such that ejecta viscosities are significantly less than those of typical rhyolites ("typical," or calcalkine, rhyolites are the most viscous magmas known, with depositional viscosities frequently greater than  $10^8$  Pa s).

Agglutinated andesitic pyroclastic flow deposits occur in arc settings such as Santorini and the New Hebrides, and alkali-rich ignimbrites (pantellerites and phonolites) in the Canary Islands and Italy. The distinctive feature of these "spatter flows" or "high-grade" ignimbrites is an imbricated texture consisting of large flattened clasts that were sheared by flow during deposition and consequently have a consistent upflow dip. This structure may be preserved at the base of the sheet, or where the fine matrix is nonwelded. In some cases, clast coalescence has continued until most of the thickness of the sheet is reconstituted and undergoes nonparticulate or lava-like flow. Extended nonparticulate flow may largely destroy evidence for a particulate origin.

Spatter-fed alkaline felsic lavas have been described for Mayor Island (New Zealand), the Canary Islands, and Italy. The inferred formation mechanism is similar to that of typical Hawaiian lava fountains. None of these

eruptions was observed, and the interpretations are based in part on preserved spatter-like structures in the final rocks. Caution is necessary here, because similar structures occur in true lavas, where marginal rubble becomes partly recoalesced.

---

#### V. RECENT DEVELOPMENTS

Mechanisms of agglutination, clast deformation, coalescence, and the transition to clastogenic lava have received relatively little attention from volcanologists. In fact, unusual occurrences such as those noted in the previous section have been studied in greater detail than the common process of lava generation from Hawaiian lava fountains. In part, this is because the slightly higher viscosities (and probably yield strengths) of intermediate and alkaline felsic ejecta favor preservation of agglutinate piles, whereas almost all of the agglutinating mass in a Hawaiian eruption rapidly coalesces to lava. Nonetheless there is a clear need for more field data on the near-vent products of fountain activity.

A recent, well documented and observed mafic to intermediate composition fissure eruption generating fountain-fed lavas, spatter deposits, and a scoria cone occurred in November 1986 at Izu-Oshima volcano in eastern Japan. The B phase of the eruption lasted for about 8 hours on November 21, producing unusually high fountains reaching a maximum of 1600 m. Examination of eruption products in the light of eyewitness reports of the timing of lava flows (both syn- and postdepositional) has shown that lavas were generated by three distinct mechanisms. The first was reconstitution of fountain-generated spatter around the vent by syndepositional agglutination, commonly assumed to be the only mechanism involved in lava production from fountains. The second mechanism was syneruptive collapse of a rapidly built scoria spatter cone by a slumplike process of rotational slip and extensional sliding (Fig. 5A), consequent on failure of the cone along a completely coalesced basal spatter layer, which thus acted as a lubricating layer. The third mechanism involved generation of a similar basal coalesced layer, which then extruded through the side of the cone to form a lava without wholesale cone collapse (Fig. 5B). Within each lava there is a range of textures from nonwelded through welded scoria and agglutinate to homogeneous, holocrystalline lava. Future studies should indicate whether the latter two mechanisms, and perhaps others not hitherto recognized, are common.

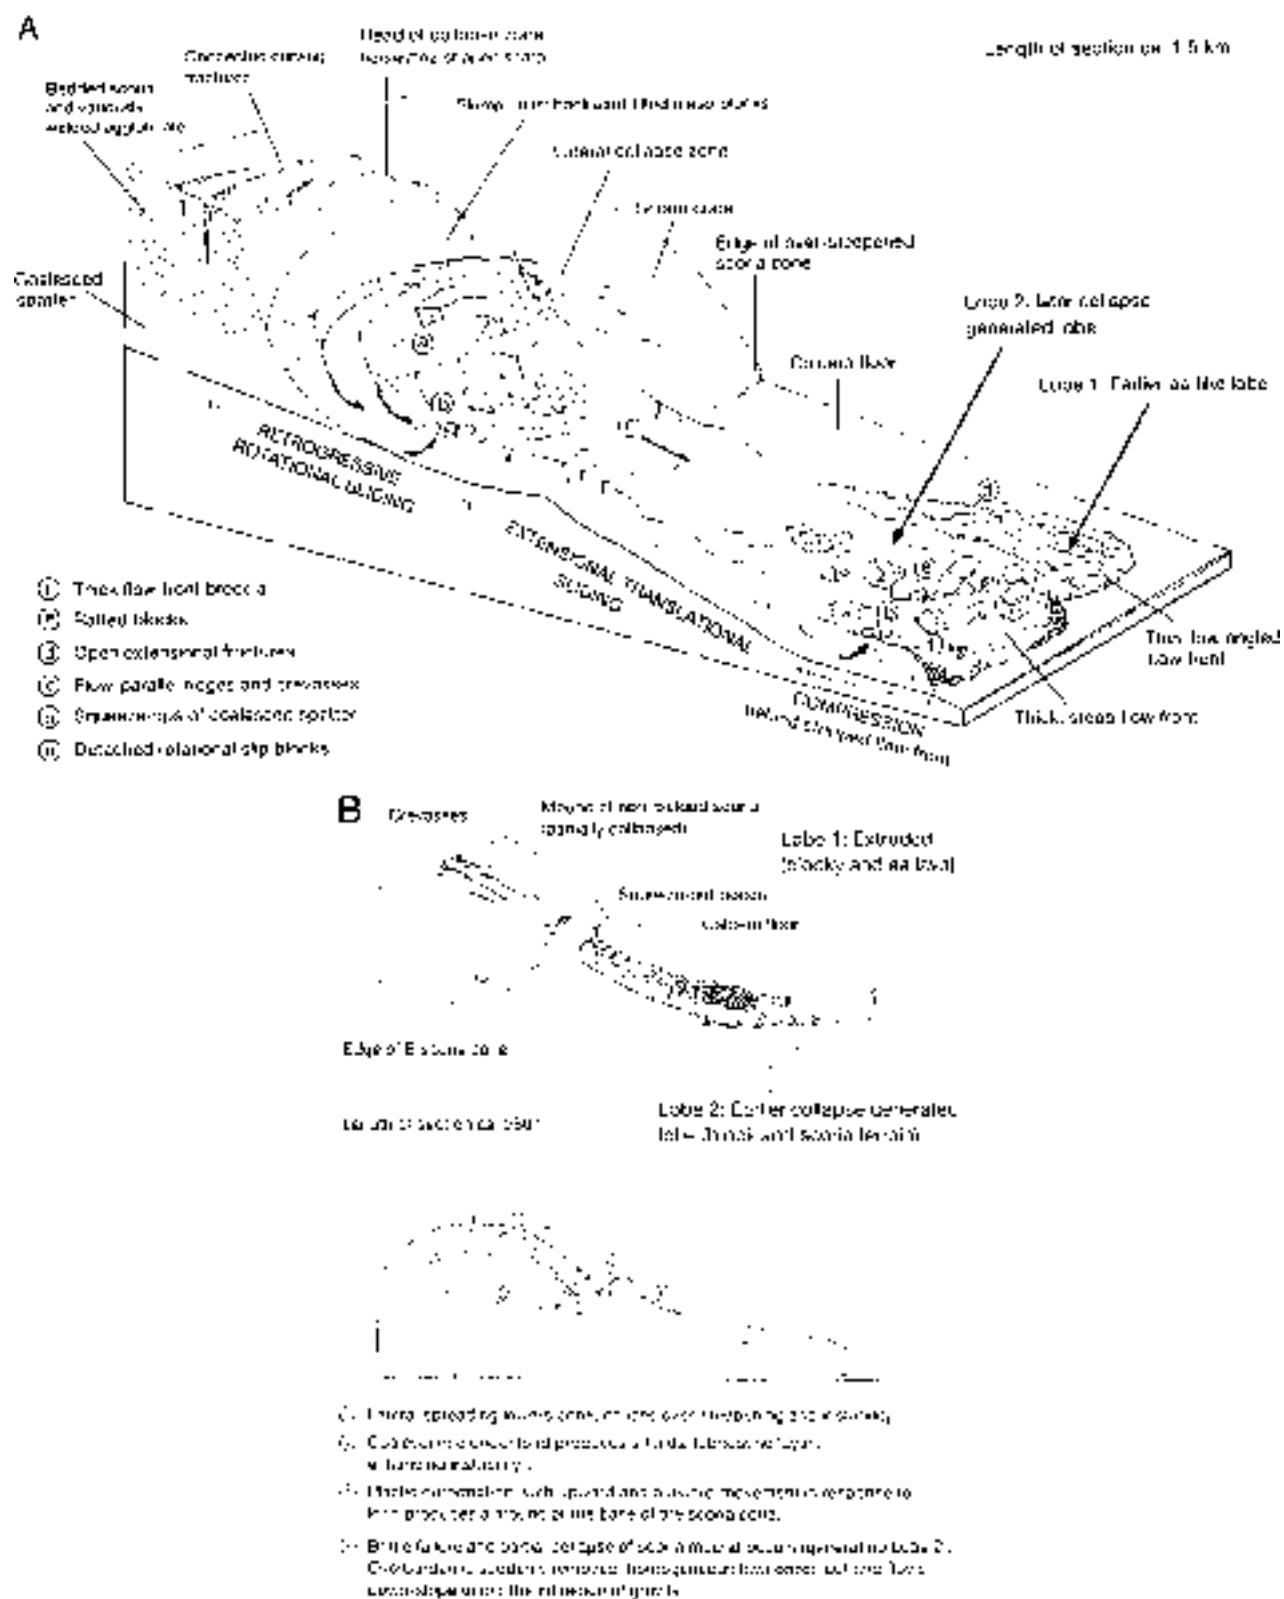

FIGURE 5 Lava generation mechanisms during the 1986 Izu-Oshima eruption, Japan. (From Sumner, © 1988 Springer-Verlag.) (A) Block diagram showing the main features and processes involved in lava production by syneruptive, slumplike collapse of rapidly built scoria cone. An aa-like lobe, formed by earlier nonparticulate flow of vent agglutinated spatter, is shown for comparison. (B) Diagrams showing the production of lava through basal coalescence and lateral extrusion from scoria cone. Upper panel: summary diagram showing main morphological features; lower panel: interpreted sequence of events.

---

VI. SUMMARY

1. The character of explosive eruptions is largely a function of magma volatile content, which for mafic magmas is in turn controlled by crustal residence history.
  2. Sustained lava fountains develop where the magma rise speed is sufficient to prevent bubble accumulation near the surface of the erupting magma; otherwise pulsing strombolian activity, less likely to produce lava, results.
  3. Sustained fountains consist of a hot inner and a cooler outer portion. Deposits from the inner part rapidly coalesce to feed lava flows and/or vent pools, whereas deposits of the outer zone may produce spatter and scoria that builds up to form a collar around the vent.
  4. Processes of clast agglutination, coalescence, welding, and lava generation depend critically on the rheologic properties of the ejecta during, and up to hours after, deposition. Preservation of spatter piles that do not collapse into lava requires a finite yield strength.
  5. Andesitic eruptions, and other compositions of similar rheology such as phonolites and pantellerites, may produce a wide range of deposits, including ignimbrites, that undergo agglutination during deposition.
  6. A range of mechanisms may be involved in the transformation of agglutinating ejecta to lava, but the subject has, as yet, received little attention.

## I. INTRODUCTION

Often, volcanic activity results in the formation of volcanic fields rather than single large volcanic edifices. Volcanic fields comprise small volcanoes (usually with volumes less than  $1 \text{ km}^3$ ), such as cinder cones, maars, tuff cones, tuff rings, small shield volcanoes, and lava domes. These volcanoes are dominantly basaltic in composition and each is produced by a single episode of volcanic activity that can last from several days to a few years or, in rare cases, decades. Volcanoes formed during single episodes of volcanic activity, without subsequent eruptions, are referred to as *monogenetic*. Monogenetic volcanoes are commonly clustered within volcanic fields or may constitute linear chains that follow tectonic structures, such as faults. Volcanic fields also form on the flanks of composite or large shield volcanoes and within calderas, where they are often distributed along rift

zones. Over periods of hundreds of thousands to millions of years, monogenetic volcanic activity can result in a really extensive volcanic fields consisting of hundreds to thousands of individual volcanoes and cumulative volumes approaching those of individual composite volcanoes.

Studies of volcanic fields are among the earliest works in volcanology. Desmarest mapped the cinder cones of Auvergne, France, around 1766, in the process making one of the first geographically accurate geologic maps and employing what Lyell (1830, p. 59) referred to as "minute accuracy and admirable graphic power." One of Desmarest's major contributions was the relative dating of cinder cones in Auvergne using the geomorphology of the cinder cones and superposition of lava flows that he carefully correlated to vents where possible. Desmarest's techniques have subsequently been emulated by virtually all volcanologists mapping in volcanic fields. The 1759–1774 eruption of Jorullo volcano, Mexico, in the Michoacán-Guanajuato volcanic field focused additional attention on volcanic fields. Geologists such as von Humboldt, Scrope, and Lyell noted the tremendous number of cones around Jorullo and realized that these cones formed during episodes of activity evinced by the Jorullo eruption. The 1943–1952 eruptions of Parícutin volcano, also in the Michoacán-Guanajuato volcanic field, led to more systematic mapping in this area. In his seminal work on volcanoes of the Parícutin region, Williams (1950) conducted petrologic investiga-

tions, mapping, and relative dating of volcanoes in this region, resulting in the first comprehensive, modern treatment of basaltic volcanic fields.

Recent studies of volcanic fields have employed advancing geochronological, geophysical, and geochemical techniques to describe the rates of activity, longevity, and tectonic settings of volcanic fields. Many of these studies have focused on the distribution and timing of volcanism to better understand the processes that govern magma supply and magma ascent. Numerous studies have considered the development of volcanic fields in terms of their regional neotectonic setting, and the influence of

geologic structures, such as faults, on vent distribution. Others have focused on the petrologic evolution of volcanic fields through time, attempting to relate changes in petrogenesis to changes in patterns and rates in eruptive activity. Cumulatively, these studies provide substantial insight into the volcanology of basaltic volcanic fields. Increasingly, these insights are used to evaluate the long-term hazards associated with volcanic fields located near cities or sensitive facilities such as nuclear power plants and port facilities. Such long-term hazard issues drive the need to improve models of the timing and distribution of eruptions within basaltic volcanic fields.

TABLE I Physical Characteristics of Selected Basaltic Volcanic Fields

Volcanic field	Basaltic vents	Silicic vents and vent complexes	Area (km <sup>2</sup> )	Age range (Ma)	$\lambda_t$ (vents/yr)	Data sources
Eifel Volcanic Field, Germany	323	7 phonolite centers	1,000	0.7–0.01	$5 \times 10^{-4}$	Schminke <i>et al.</i> , 1983

## II. PHYSICAL CHARACTERISTICS OF VOLCANIC FIELDS

Fundamental physical characteristics of basaltic volcanic fields include the number of individual vents, the timing and recurrence rates of volcanic eruptions, the distribution of vents, and their relationship to tectonic features, such as basins, faults, and rift zones. Table I summarizes the number of vents in some basaltic volcanic fields, their areas, and the age ranges of activity. It is evident that basaltic volcanic fields encompass a wide range of areas, volumes, and longevities. Small basaltic volcanic fields typically contain <50 vents distributed over <1000 km<sup>2</sup>. Large volcanic fields contain >100 vents distributed over >1000 km<sup>2</sup>. No apparent correlation exists between the number of vents in a volcanic field and its longevity (Table I). For example, the Springerville volcanic field (Fig. 1) contains approximately 400 vents formed within 2 million years (Ma). In contrast, the

Yucca Mountain volcanic field (Fig. 2) has approximately 30 vents formed over 4 Ma. In these two volcanic fields, as in many others, Plio-Quaternary volcanic activity followed earlier episodes of volcanism in the Miocene and Early Pliocene. Rates of volcanism typically wax and wane over long time periods (>1 Ma) in basaltic volcanic fields.

### A. Temporal Recurrence Rates

Determination of the timing of volcanism has been a central issue in the study of volcanic fields. Age determinations for individual volcanic vents are used to estimate temporal recurrence rates of volcanism, sometimes referred to as the intensity of volcanic activity, and to correlate rates of volcanic activity with other factors, such as plate motion, rates of crustal extension, and changes in petrology. Age dating techniques applied to basaltic volcanic fields include relative dating of lava

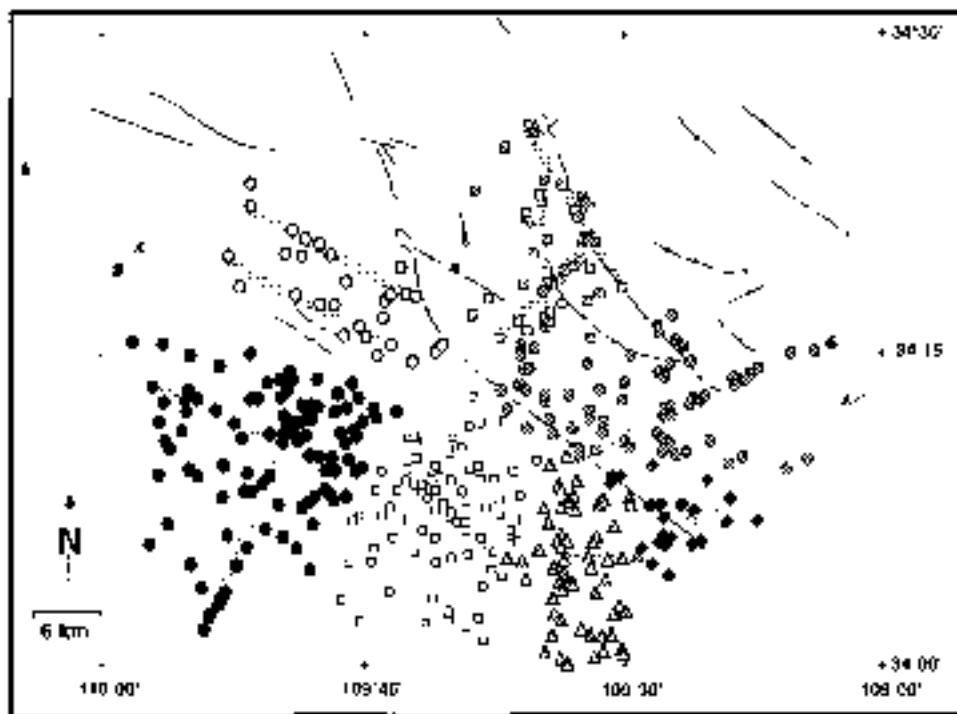

FIGURE 1 With over 400 vents, the Springerville volcanic field in Arizona is a typical large volcanic field located on the margins of the Colorado Plateau in the western United States. Most of the mapped vents formed between 2.1 and 0.3 Ma during volumetrically steady-state volcanism. Coupled studies of vent distribution and timing of volcanism have shown that rates of activity varied from cluster to cluster, suggesting that individual source regions for magma were localized and short lived compared to the entire volcanic field; this idea is supported by geochemical trends. Vents indicated by symbols correspond to clusters; thick shading shows vent alignments; thin lines show faults.

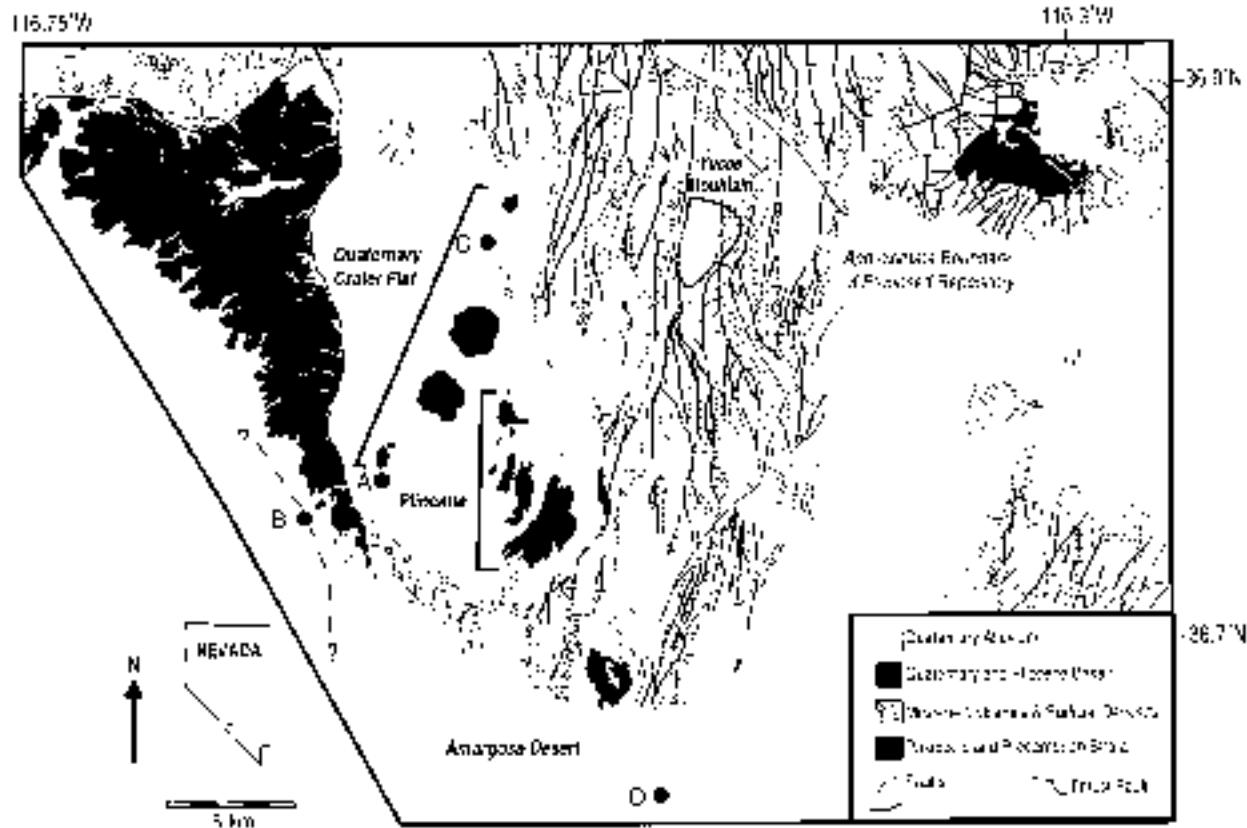

FIGURE 2 The Yucca Mountain volcanic field in Nevada is a small volcanic field active since large-volume, caldera-forming silicic eruptions ceased about 8 Ma. As in larger volcanic fields, Plio-Quaternary volcanism occurs in spatial clusters. Thus the volcanic eruptions leading to the formation of the northeast-trending Quaternary Crater Flat alignment (Northern Cone—Little Cones) were preceded by volcanism at nearby Pliocene vents. Magnetic anomalies (A–D) are buried volcanoes in this area, which has high sedimentation rates. Delineating the volcanic history of this region and the relationship between volcanism, faulting, and episodes of extension is a key element of geologic hazards investigations for the proposed high-level radioactive waste repository at Yucca Mountain.

flows using stratigraphy, paleomagnetic age dating, cinder cone geomorphology, and detailed radiometric age determinations of individual vents (Fig. 3). Often a variety of dating techniques need to be implemented and linked to geologic mapping in order to delineate the chronology of eruptions within a basaltic volcanic field (Fig. 4).

Even where excellent age determinations are available, confusion can arise over the definition of the volcanic events used to estimate recurrence rates. Ideally, volcanic events would correspond to volcanic eruptions. However, subsequent volcanic eruptions often obliterate or obscure evidence of previous activity. A more easily implemented definition is based on morphology: An individual cinder cone, maar, or similar edifice represents a volcanic event. Alternatively, volcanic events can be defined as mappable eruptive units, each unit being an

assemblage of volcanic products indicating a cogenetic origin from a common vent. This definition can become complicated by the formation of multiple vents during a single episode of activity. For example, three closely spaced vents formed during 1975 eruptions in the Klyuchevskoy Group, Kamchatka, forming the New Tolbachik cinder cones. This alignment of three cinder cones might be considered to represent a single volcanic event. These cones extended an alignment formed by three older Holocene cones, creating an alignment that is about 5 km long. In the geologic record, it would be quite difficult to determine if these cones represent one, two, or six volcanic events. Similar alignments are found in many basaltic volcanic fields.

In older, eroded volcanic systems, evidence for the occurrence of vents such as vent buds and breccia zones may constitute volcanic events. In these eroded systems

it is clear that the number of dikes reaching the shallow crust can far exceed the number of vents formed at the surface. For example, in the San Rafael volcanic field in Utah more than 1700 dike segments are mapped in an area with approximately 60 breccia pipes and buds that are interpreted as vents. Even where detailed mapping is available, grouping dikes and vents in such areas into volcanic events or episodes is problematic.

A straightforward method of estimating average recurrence rates of volcanic activity is given by:

$$\lambda_r = \frac{N - 1}{t_o - t_y},$$

where  $N$  is the total number of volcanic eruptions or vents,  $t_o$  is the age of the oldest event, and  $t_y$  is the age of the youngest event. Long-term average recurrence

rates in volcanic fields are typically on the order of  $10^{-4}$ – $10^{-5}$  volcanic events per year (v/yr) (Table I). These average rates are very low compared to the frequencies of eruptions at individual composite cones. Long-term averages smooth out significant variation in recurrence rates that may span comparatively short periods of time (<100 kyr). For example, in the Michoacán-Guanajuato volcanic field in Mexico, average recurrence rates since 40 ka are on the order of  $2 \times 10^{-3}$  v/yr, higher than the long-term average. In the Springerville, Arizona, volcanic field, recurrence rates reached a maximum of  $3\text{--}4 \times 10^{-4}$  v/yr during peak activity in the field about 1 Ma. In contrast, average recurrence rates of vent formation in the Yucca Mountain, Nevada, volcanic field are on the order of  $8 \times 10^{-6}$  v/yr during the last 1 Ma. Episodic behavior can produce orders-of-

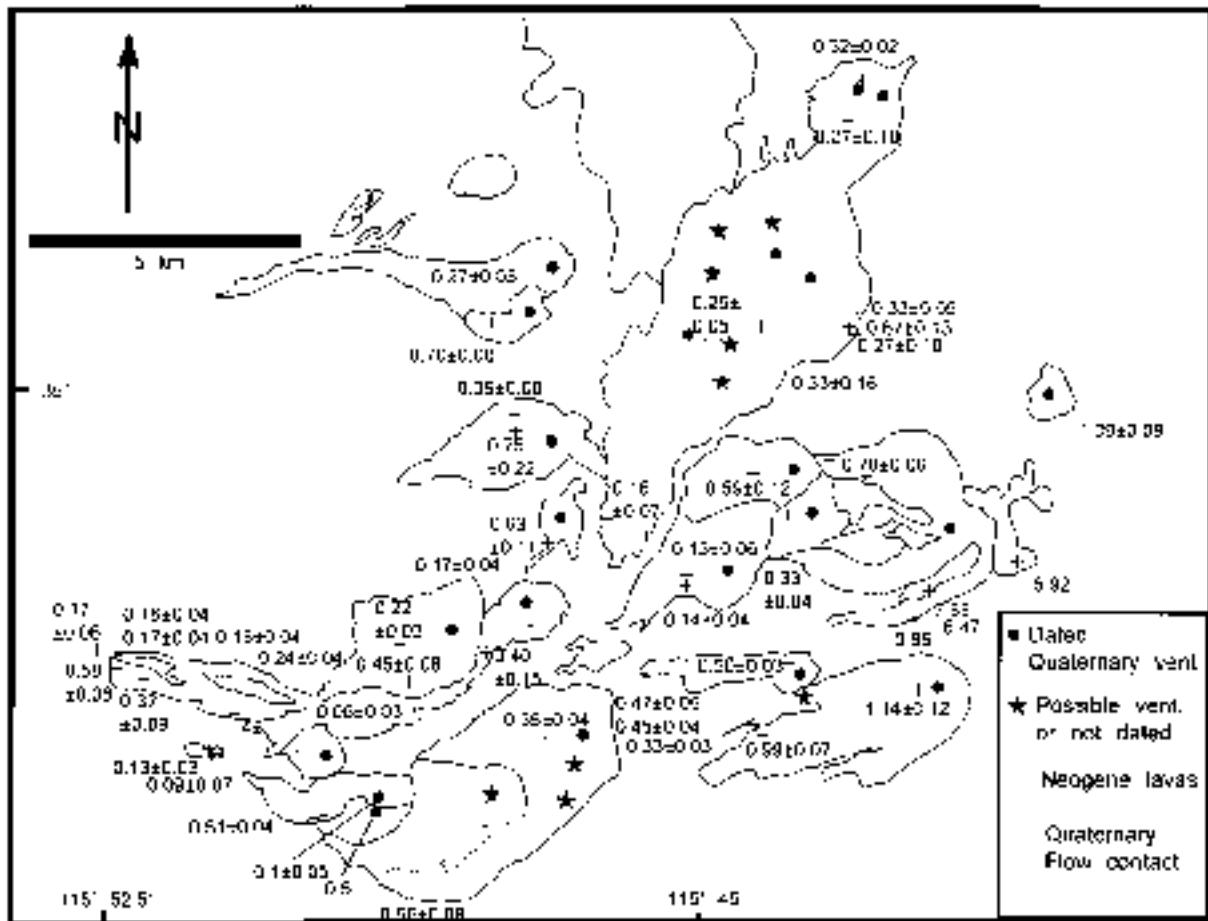

FIGURE 3 The southern part of the Cima volcanic field in California provides an excellent example of how detailed mapping and age determinations are essential for understanding the evolution of volcanic fields. This cluster of approximately 30 vents formed largely during the last 0.7 Ma. This pulse of activity accompanied a significant shift in the locus of volcanic activity in the field—older vents are located north of this cluster.

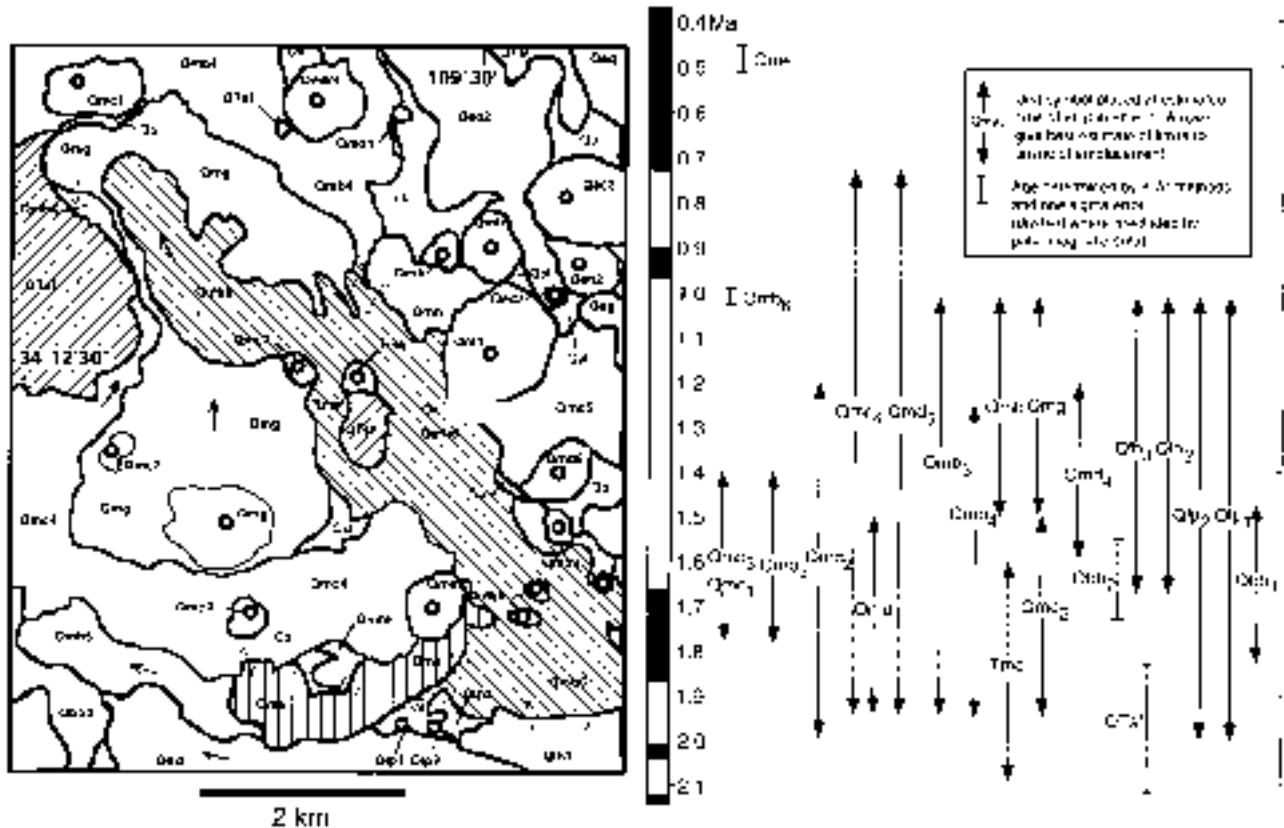

FIGURE 4. A combination of stratigraphic relationships, radiometric age determinations, and paleomagnetic dating is used to delineate the volcanic history of the Springerville, Arizona, volcanic field (see Fig. 1). Here, a geologic map of a small part of the volcanic field illustrates how stratigraphic relationships are used to constrain the age of each eruptive unit. The age range chart illustrates the uncertainty in each age estimate. Stippled pattern shows near-vent facies, lined pattern shows radiometrically dated lavas, arrows indicate lava flow directions, o and y indicate older and younger units where relative ages of adjacent units can be determined.

magnitude variation in eruption recurrence rates compared to long-term averages. Currently, a significant challenge is to better delineate the timescales of such episodes.

Average recurrence rates of volcanic events are a simple measure of the relative activity in volcanic fields, but more detailed analyses have revealed time trends relating eruption volumes and rates of activity. For example, the cumulative erupted volumes of both basalts and rhyolites in the Coso volcanic field of California are remarkably linear in time. Hence, successive eruptions occur at time intervals that depend on the volumes of the previous eruptions. This linear relationship has been used to forecast the timing of future eruptions. A similar pattern of activity has been identified in the Springerville volcanic field, where the areas of individual lava flows rather than volumes were used to estimate magma output rates,

primarily because the highly variable thickness of lava flows makes the volume estimates difficult. In the Springerville volcanic field, the rates of volcanic eruptions waxed, then waned during the last 2 Ma but the cumulative area impacted by eruptions remained constant during much of the time prior to 0.3 Ma, despite major changes in the geochemistry of the basalts (Fig. 5).

## B. Spatial Patterns

The episodic character of small-volume basaltic volcanism is further revealed by spatial patterns in vent distributions common to nearly all basaltic volcanic fields. Studies of spatial patterns of vent distribution in volcanic

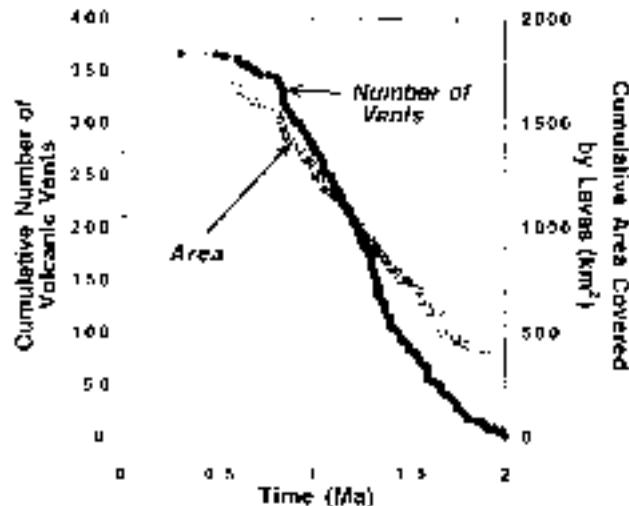

FIGURE 5 Temporal trends in volcanic activity can be represented by the cumulative number of volcanic vents and cumulative volume of volcanic events through time. Here, volume is represented as area covered by lava flows, which is more easily and accurately determined from maps than lava flow volumes. The cumulative area covered by lavas was remarkably steady in the Springerville volcanic field (see Fig. 1) between 1.75 and 0.75 Ma. Such steady-state volume-time relationships have been observed in several volcanic fields. In contrast, the recurrence rate of volcanic events waxes then wanes during this period.

fields have revealed the following: (1) Shifts in the locus of cinder cone volcanism are a common phenomenon in volcanic fields; (2) cinder cones cluster within these fields, often on several scales; and (3) vent alignments are ubiquitous, including short local alignments of several vents and more regional alignments that are usually more than 20 km in length and consist of numerous vents. These spatial patterns exist because recurrence rate is often not uniform across a volcanic field even if volumetric output in the field as a whole is steady state. Various density estimation techniques are used to delineate and characterize spatial patterns in basaltic volcanic fields.

Large-scale shifts in the locus of volcanism have been observed in numerous volcanic fields. For example, Plio-Quaternary volcanism in the Pancake, Nevada, volcanic field (Fig. 6) has shifted from southwest to northeast through time, creating an elongate volcanic field that parallels many local Basin and Range structures. This trend in the Pancake field extends Miocene–Early Pliocene volcanic activity in the Reveille Range southwest of Pancake, now preserved as dikes and eroded vents. Similar shifts in activity through time have been ob-

served in the San Francisco, Springerville, Coso, Cima, and Camargo volcanic fields. In some of these volcanic fields, shifts can be related to regional tectonic processes such as plate motion. In other areas, however, shifts in the locus of volcanism seem independent of regional tectonic processes.

Vent clustering is a widely recognized phenomenon in volcanic fields. Vent clusters occur on several scales. In the Michoacán-Guanajuato and the Springerville volcanic fields (Fig. 1), vent clusters consist of 10–100 individual vents and have diameters up to 50 km. In smaller volcanic fields, statistical methods can delineate clusters of 1–10 vents. In some volcanic fields, volcanic activity within clusters waxes and wanes on short timescales compared to the volcanic field as a whole. In other areas, recurrent volcanism occurs within individual clusters over most of the history of the volcanic field.

A simple explanation for vent clustering is that magma supply varies across volcanic fields. Mantle rocks beneath vent clusters are close to their solidus and produce melts more readily in response to small changes in the thermophysical or geochemical state of the mantle. Magma in these areas can be generated repeatedly in response to episodic extension or heating as long as the fraction of partial melting is sufficiently small that the source region of the magma is not depleted substantially as a result of repeated melt generation. The scale and longevity of vent clusters, therefore, may reflect the scale of geochemical, temperature, and pressure variations in the mantle source region. An alternative explanation is that crustal structures are somehow responsible for the development of clusters. However, the distribution of clusters in most volcanic fields does not directly correlate with the distribution of faults or other features that may ease magma transport through the crust. Although vent alignments and individual vents within clusters often occur near or on faults, fault densities are rarely high within vent clusters compared to nearby areas.

### C. Probability of Future Eruptions

Spatial patterns and temporal recurrence rates may be combined to estimate probabilities of future volcanic activity within volcanic fields. The probability of future volcanic eruptions within some small area within a volcanic field,  $\Delta x, \Delta y$ , during some time interval,  $\Delta T$ , can be estimated as follows:

$$P[\text{volcanic eruptions within } \Delta x, \Delta y, \Delta T] = 1 - \exp[-\lambda_r \lambda_t \Delta T \Delta x \Delta y],$$

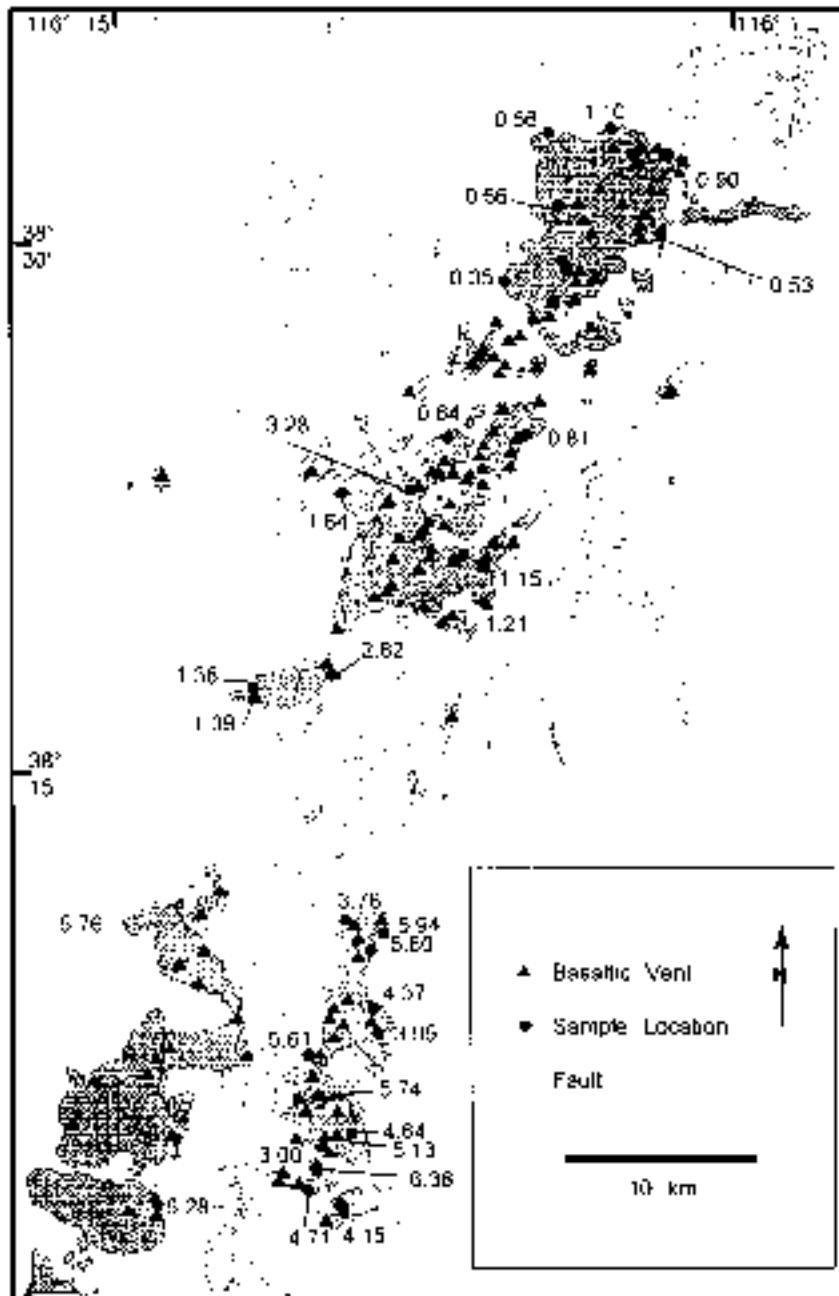

FIGURE 6 Vent distribution in the Pancake-Reveille range, Nevada, shows a clear northeast shift in volcanic activity through time, creating an elongate volcanic field that parallels local faults and regional neotectonic patterns.

where  $\lambda_t$  is the temporal recurrence rate and  $\lambda_r$  is a spatial weighting factor. Both  $\lambda_t$  and  $\lambda_r$  are usually estimated from past patterns of volcanic activity. This equation can be integrated over some larger area than  $\Delta x$ ,  $\Delta y$  to estimate the probabilities of volcanic eruptions

within all or part of the volcanic field while still capturing smaller scale variations in recurrence rate, or integrated over some long period of time. Alternatively, probability of volcanic eruptions may be contoured across the volcanic field.

### III. GEOLOGIC STRUCTURE OF VOLCANIC FIELDS

Alignments of basaltic vents are common in volcanic fields, on shield volcanoes, and in calderas. These alignments and their related structures are used to infer the presence and orientation of subsurface dikes and dike sets, as indicators of crustal stress orientation, and to infer mechanisms of shallow dike injection in active volcanic areas (Fig. 7). In active Holocene volcanic

fields, such as Craters of the Moon, Idaho, the Laki fissures, Iceland, and the south flank of Tolbachik, Kamchatka, a strong correlation has been recognized between structural trends (faults and fractures) and volcanic alignments consisting of contemporaneous cinder cones associated with single episodes of dike injection. Development of volcano alignments has also been increasingly important in the assessment of long-term volcanic hazards because of the comparatively large map extent of these features.

Distinguishing alignments in basaltic volcanic fields comprising hundreds of vents is problematic, however,

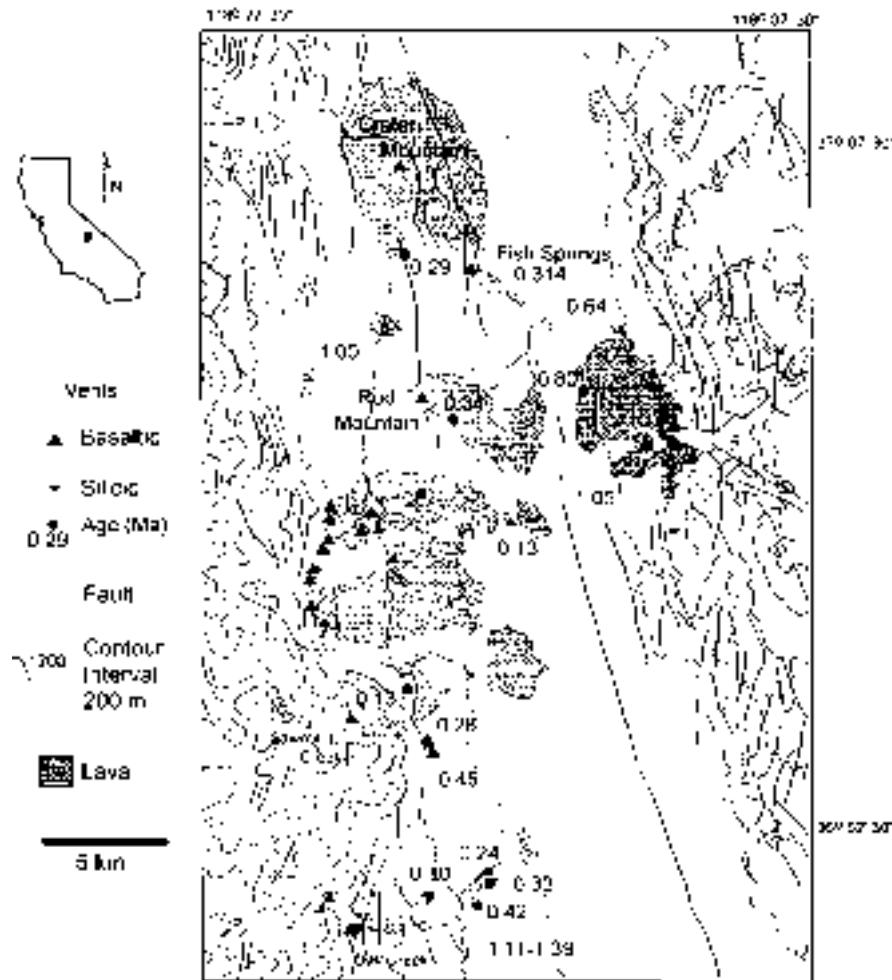

FIGURE 7 The Big Pine volcanic field in California illustrates the relationship between regional faults and vents in basaltic volcanic fields. Three young vents and their lava flows (Crater Mountain, Fish Springs, and Red Mountain) are cut by fault splays of the Owen's Valley fault. A vent alignment on the west side of the valley appears to have formed during a single episode of activity and is fault controlled. Near Fish Springs and Oak Creek, some Quaternary basalt lavas cannot be traced back to vents, an indication of the high rates with which volcanoes are covered by alluvium and displaced by faulting in this rapidly subsiding basin. Water wells reveal that much of the subsurface in this area consists of intercalated basalt flows and alluvium.

because aligned vents are often interspersed among a greater number of unaligned cones. Recently, statistical methods have been used to identify vent alignments and improve the ability to discriminate these features objectively (Fig. 1). Vent alignments delineated by statistical methods typically parallel regional and local structures, which suggests that vent alignments can form because ascending magmas exploit preexisting structures repeatedly during separate episodes of activity (Fig. 6–8).

One explanation for the occurrence of volcanic vents along faults is that during ascent a dike may abandon its course perpendicular to the least principal stress in favor of a more energy-efficient path along a preexisting joint or fault. This effect can be modeled in two dimensions, treating the country rock as a uniform, linear-elastic, brittle rock that fractures at some tensile stress level,  $\sigma_o$ . The stress needed to create an open vertical fracture in the undeformed rock is

$$\sigma_v = \sigma_o + \sigma_3 + \sigma_d,$$

where  $\sigma_3$  is the least principal *in situ* stress and  $\sigma_d$  is the additional stress needed to deform the fractured host rock to create an aperture. Where a preexisting fracture exists, dipping at angle  $\theta$ , the stress required to dilate this preexisting fracture is

$$\sigma_f = \sigma_3 \sin^2 \theta + \sigma_1 \cos^2 \theta + \sigma_d,$$

where  $\sigma_1$  is the greatest *in situ* principal stress. A dike will exploit the preexisting fracture when  $\sigma_f < \sigma_v$ . Using a range of appropriate bounding values, the minimum fracture dip a dike is likely to follow at a depth of 10 km is between 75° and 86°. The minimum exploitable dip decreases at shallower depths. Stress effects near the Earth surface may cause a dike to break out of a fault zone at shallow depths. Such near-surface effects become important at a depth of about 500 times the dike width.

In three dimensions, the orientation of a fault relative to  $\sigma_3$  plays an essential role in determining whether a fault zone is likely to dilate in response to dike injection. Faults oriented roughly perpendicular to  $\sigma_3$  are termed *high-dilation tendency faults* and are more likely to provide low-energy pathways to the surface than faults of other orientations. Considering these factors together, vent alignments may form in response to a variety of fault geometries (Fig. 9).

Faults and dikes are further interrelated because faulting and dike injection play a similar role in accommodating crustal stress, by slip in the case of faults and in-

creased total crustal volume in the case of dikes. In some areas, topography related to faults is suppressed near volcanic fields and individual vent alignments because stress is accommodated by dilation of the crust during dike injection rather than by fault slip. This relationship can explain much of the variation in structure of volcanic fields. For example, cinder cone alignments are common in low-volume, low-density volcanic fields (e.g., Fig. 2 and 7). In larger volume basaltic volcanic fields, like the Springerville volcanic field (Fig. 1), mapped faults are rare and cinder cone alignments, though present, are less pervasive. In the former case, rates of dike injection are not sufficient to fully accommodate crustal stress. As a result, fault systems continue to experience slip and dikes tend to parallel or inject into these fault systems. In the latter case, rates of dike injection are sufficient to completely accommodate regional tectonic stresses within the volcanic field. This equalizes, or nearly equalizes, the magnitudes of principal horizontal stresses, and their orientations may vary substantially across the volcanic field and over time. Thus, vent alignments are less common in volcanic fields with comparatively high rates of volcanic activity.

The linear or nearly linear behavior of total eruptive volume through time (e.g., Fig. 5) has suggested a link between crustal strain rate and volcanic activity. If crustal strain rates are relatively uniform over a long

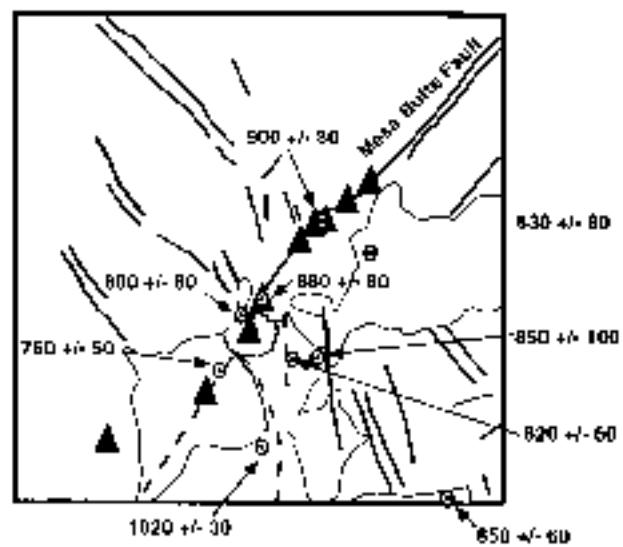

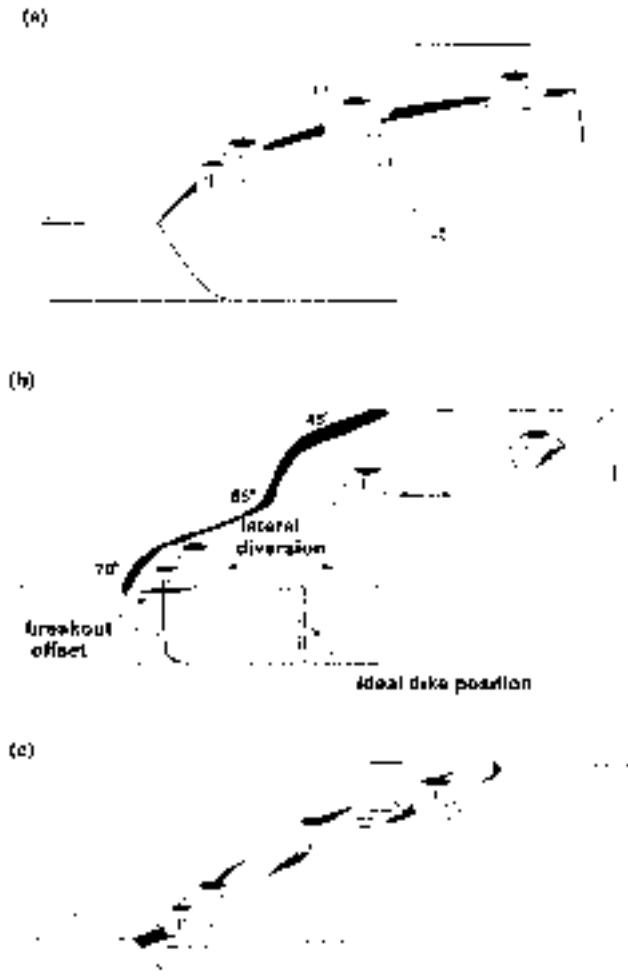

FIGURE 8 Cinder cone alignments can form as a result of several episodes of volcanic activity when ascending magmas are captured by faults. Such an alignment is shown on a geologic map of the Mesa Butte fault zone in the northcentral part of the San Francisco volcanic field in Arizona.

**FIGURE 9** Cinder cone alignments can form along faults in a variety of geometries. (a) Cones can be aligned along the fault trace or at the intersections of two faults. (b) Cones can be offset laterally from the fault as a function of fault dip, which controls the distance from the fault trace at which the ascending dike will break out of the fault zone. (c) Cones can form an en echelon array along the fault trace.

period of time and melts are produced by decompression in response to extension, then a direct relationship between crustal strain rate and volume eruption rate should exist. Conversely, changes in the strain rate may result in changes in the rate of volcanic activity. If such a relationship between crustal strain and volcanism recurrence rates proves correct, estimates of volcanic hazards associated with basaltic volcanic fields might be substantially improved by accurate measurements of variation in crustal strain.

#### IV. PETROGENESIS OF BASALT VOLCANIC FIELDS

Basaltic volcanic fields are volumetrically dominated by basaltic ( $\leq 52$  wt% silica) and basaltic andesite lavas (52–56 wt%). The importance (i.e., volume) of more evolved andesitic to rhyolitic lavas varies considerably from field to field. For example, the San Francisco volcanic field has erupted substantial volumes of evolved lavas that crop out in seven large silicic domes (dacite through rhyolite composition) and the voluminous ( $=100 \text{ km}^3$ ), andesitic San Francisco Peaks composite volcano. In sharp contrast, the Springerville volcanic field, which lies just south of the San Francisco field, erupted few intermediate lavas.

Basaltic lavas in volcanic fields display a broad range of petrographic features, with every possible gradation from vesicular to nonvesicular, aphyric to porphyritic, and wholly crystalline to glass-rich lavas. In most cases, phenocryst phases of mafic lavas comprise, in widely variable proportions, olivine, plagioclase, clinopyroxene, and less commonly orthopyroxene and magnetite. The groundmass of most basalts is typically dominated by the same phases accompanied by titaniferous magnetite, apatite, sparse ilmenite and spinel, and frequently basaltic glass.

Basalt magmas originate from partial melting of a lithospheric mantle or asthenospheric source material; the most frequently named parent materials are peridotite and eclogite. Regardless of the source composition, basaltic magmas erupted onto continents are required to rise through substantial thickness (approximately 20–45 km) of continental crust before erupting. The compositional variability in basaltic volcanic fields can be explained by some combination of the following:

1. Variable degrees of partial melting of various garnet-bearing upper mantle sources
2. Mixing of at least two components in the source region of the mantle
3. Fractional crystallization in the deep crust
4. Assimilation of crustal material with concomitant fractional crystallization

Geochemical analyses confirm that the short-lived, monogenetic nature of cinder cones precludes the involvement of long-lived shallow basaltic magma reservoirs beneath basaltic volcanic fields.

The variety of mafic rocks erupted in basaltic volcanic fields is exemplified by the San Francisco volcanic field. This field comprises a broad spectrum of mafic lavas,

including basanite, alkali olivine and tholeiitic basalts, and basaltic andesites. Chemically, lavas range from strongly nepheline-normative to quartz-normative basalts. While the locus of basaltic volcanism in the San Francisco volcanic field migrated, broadly, from east to west, extensive sampling and geochemical analyses (including 1000 major and 200+ trace element analyses) do not show any evidence of a corresponding systematic spatial or temporal change in basalt lava composition. Remarkably, a single cinder cone cluster, SP cluster which comprises just 60 Early Pleistocene through Holocene basaltic vents, shows a breadth of mafic geochemistry comparable to that of the entire field.

Overall, field-wide geochemical trends have been identified in some volcanic fields (e.g., Eifel, Big Pine, Springerville) that can be related to changing source conditions. Elsewhere (e.g., Michoacán-Guanajuato and Cima volcanic fields) temporal and spatial trends in geochemistry are indistinct. Rather, the geochemistry of basalts from these fields appears to reflect the natural variability in steady-state, low-volume, basaltic magmatic systems.

## V. ORIGINS OF VOLCANIC FIELDS

Early ideas on the formation of volcanic fields often involved widespread partial melting with ascending magmas relying on structures to serve as low-energy pathways to the surface. In such a model, rates of volcanic activity would be governed directly by crustal processes, rather than rates of melt generation. The origin of this idea is easy to understand—in many volcanic fields the crust appears to have leaked basalt from every conceivable fault and fracture. However, this idea is not consistent with the petrogenesis of basaltic volcanic fields, which almost always involves low rates of partial melting and melt production from a variety of levels in the lithosphere, asthenosphere, or both. These melts do not have long residence times in the crust or upper mantle, waiting for tectonic processes to ease their ascent and ultimate eruption. Instead, current evidence indicates that distributed basaltic volcanism is a natural consequence of ongoing low rates of magma production. Nonetheless, rates of extension or subduction are involved, because these rates can play a critical role in rates of partial melting.

A thermophysical model has been developed for distributed clustered volcanic fields based on observations in the Klyuchevskoy Group. Central volcanoes such as

composite cones develop when magma supply is sufficient to maintain a thermal anomaly about a central conduit. This conduit provides a low-energy pathway to the surface as long as the thermal anomaly persists. In volcanic fields, magma supply rates are so low that such a conduit is not maintained between volcanic eruptions; new ascending magma batches find their own path to the surface, with no opportunity to accumulate in shallow crustal magma chambers. Thus, low rates of heat transfer due to low rates of magma production lead to distributed volcanic fields. This model has been augmented by suggesting that rates of extension also play a role. Numerical and physical analog experiments indicate that crack and dike coalescence is more likely within lithosphere that is experiencing low rates of extension compared to lithosphere experiencing high rates of extension. Therefore, distributed volcanoes are more likely to occur in areas of high strain rate due to the decreased opportunity for dike interaction and coalescence of magmas in crustal magma chambers. Thus, bimodal volcanism can develop in volcanic fields in response to changes in rates of magma production, extension, or both. Cumulatively, this work provides a mechanistic basis for the observation that low rates of magma production and high rates of extension result in formation of volcanic fields rather than central volcanoes.

## VI. SUMMARY

Basaltic volcanic fields vary in size, total volume, longevity, and rates of eruptive activity. Commonality among volcanic fields is found in their low rates of magma production, clustered vent distributions, and petrogenesis dominated by mantle, rather than crustal, processes. Delineation of the timing of volcanism, petrologic evolution, and neotectonic setting of volcanic fields involves detailed investigation, a formidable undertaking given the large number of vents in most basaltic volcanic fields. The interplay between magma production and the neotectonics of the brittle crust exerts a strong control on development of volcanic fields, indicating that such comprehensive study is necessary. Although volcanic fields are characterized by low average rates of magma production, current data indicate that most volcanic fields experience dramatic changes in rates of vent formation and vent distribution over periods of 100 ka or less. As geophysical and geochronological techniques develop, it should become possible to delineate episodes of activity in volcanic fields with greater resolution and

to relate such episodes to regional tectonics. This degree of resolution will enable volcanologists to move toward a more deterministic understanding of the processes governing the evolution of volcanic fields.

## GLOSSARY

- asthenosphere** The relatively plastic low (seismic) velocity zone in the Earth's upper mantle that underlies the more rigid lithosphere that forms tectonic plates.
- basalt** A volcanic rock with high iron and magnesium and low silica content and composed mainly of small crystals of the minerals plagioclase and clinopyroxene, with Ti-Fe-Mg oxides and often olivine or orthopyroxene.
- eclogite** A rock of basalt chemical composition, but composed primarily of the minerals clinopyroxene and garnet, which are stable under mantle conditions of temperature and pressure.
- hot spot** An area in the Earth's upper mantle that is hotter than the ambient temperature.
- lithosphere** The brittle outer layer of the Earth, made up of the crust and uppermost part of the mantle, that

"floats" on the asthenosphere and constitutes the tectonic plates.

**magma** Mobile rock, created by the partial melting of rocks at high temperature.

**mantle** The largest part of the planet Earth, between the core and thin outer skin or crust.

**mantle plume** The hypothetical cause of a hot spot, originating in the deep mantle, with a large plume head and a much narrower plume tail.

**MORB** Mid-ocean ridge basalts, formed by the decompressional melting of mantle peridotite previously depleted by partial melting. MORB forms new oceanic crust.

**nephelinite** Strongly alkalic volcanic rock with low silica content.

**picrite** A volcanic rock with a large proportion of the magnesium-rich mineral olivine.

**syenite** An alkalic intrusive rock.

**tholeiite** A relatively siliceous and iron-rich basalt.

---

## I. INTRODUCTION

Flood basalt provinces are products of the largest volcanic events known on Earth. They are characterized by their prodigious volumes of homogeneous tholeiitic basalt erupted in a very short time span. These provinces form extensive plateaus on all continents and on all ocean floors (Fig. 1). The plateau surfaces result from

## Large Igneous Provinces

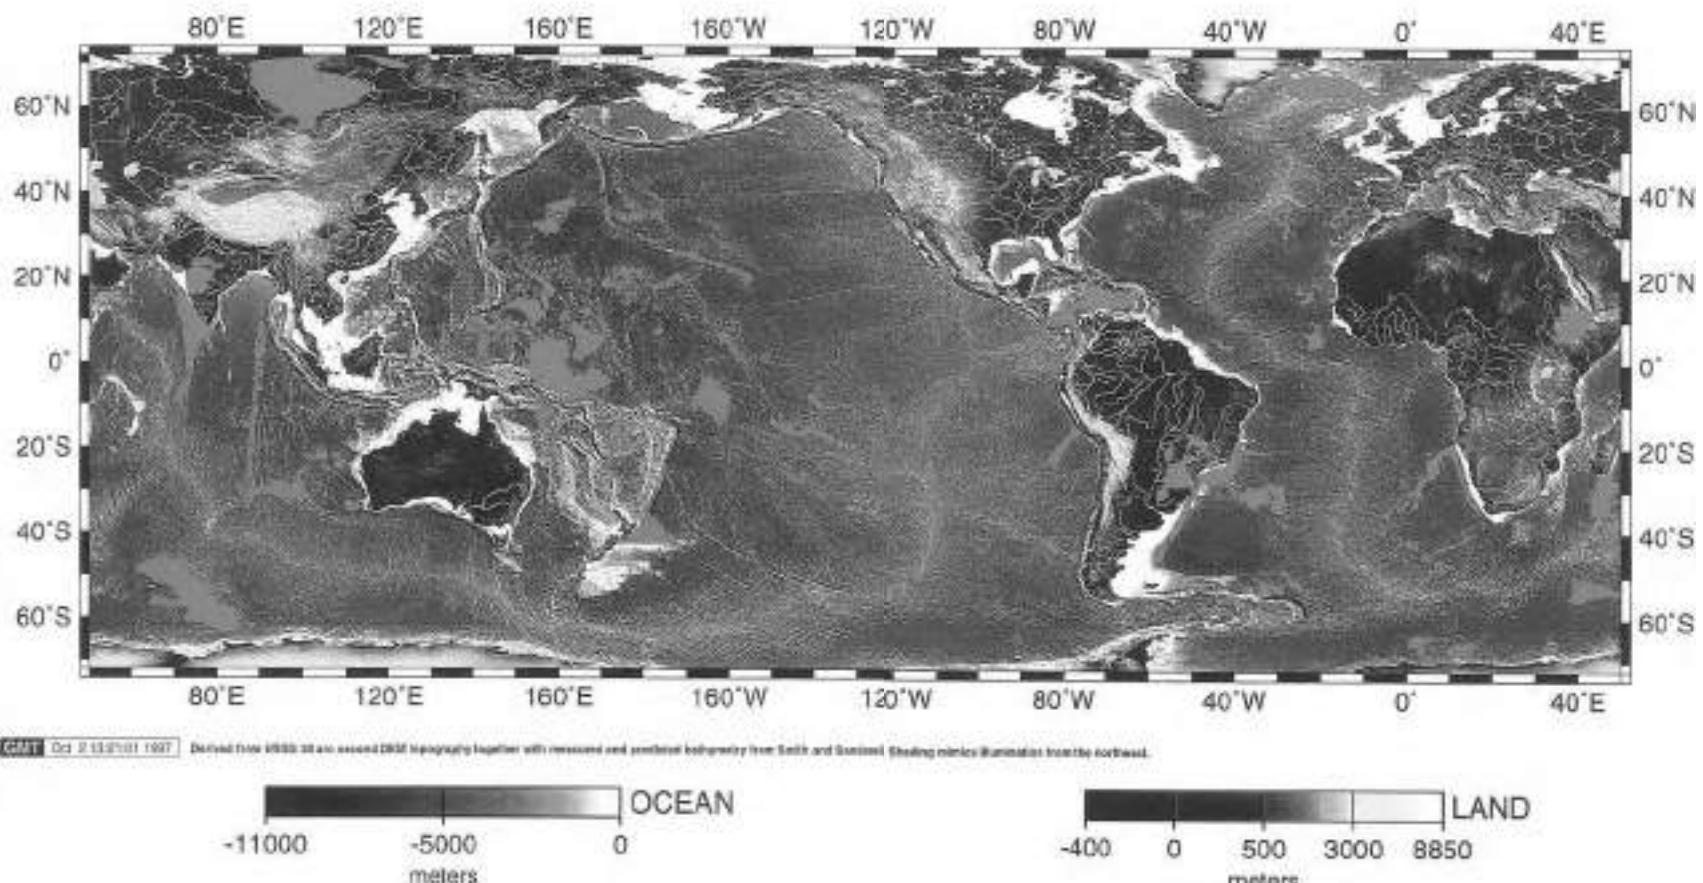

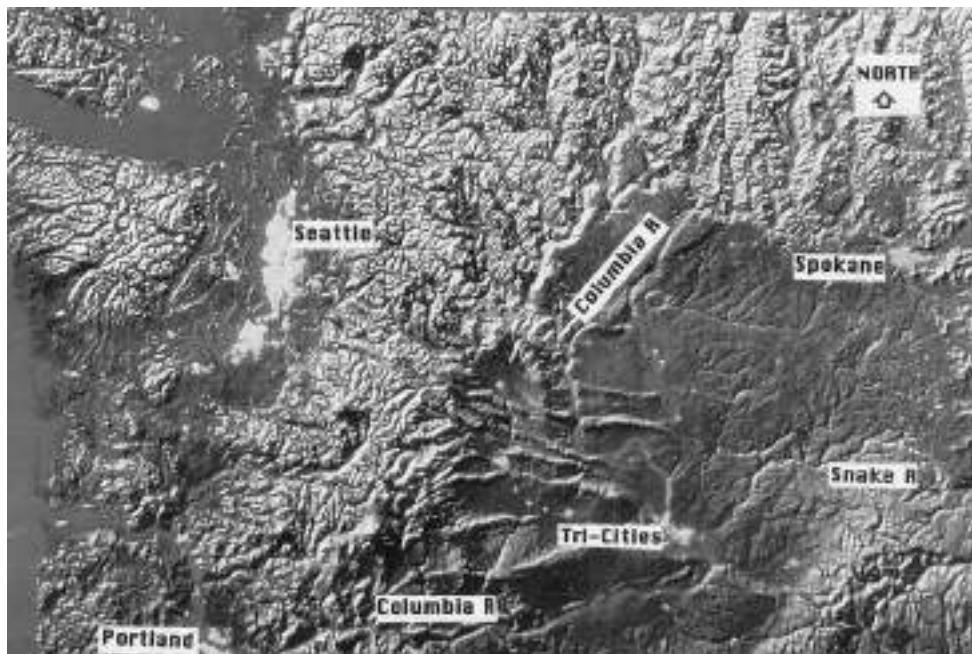

FIGURE 1 Map showing global distribution of flood basalt provinces. These large basalt provinces are not connected with ocean floor spreading or subduction. [From Mahoney and Coffin, 1987.]

the very large volumes of basaltic magma erupted rapidly from fissures in the Earth's crust to form sheet flows, typically tens of meters thick and covering tens of thousands of square kilometers, instead of the central volcanic cones characteristic of smaller, more normal, eruptions (Figs. 2 and 3). Flood basalt provinces formed episodically throughout the Mesozoic and Cenozoic periods, and remnants of older examples are known from the Proterozoic.

Plate tectonic theory postulates that most new crust is formed at the margins of tectonic plates from magmas produced by partial melting of underlying mantle. At divergent plate margins along midocean ridges, upwelling mantle rock is partially melted by decompression to form new ocean crust from the resulting midocean ridge basalts (MORBs). At convergent plate margins old ocean crust is partly consumed as one plate sinks beneath the other in the subduction process. As the subducted slab sinks, temperatures rise and dehydration occurs. The hydrous fluids driven off act as a flux in the overlying

mantle wedge, which partially melts, the new magma rising to crystallize as new crust in the form of oceanic and continental arcs above the subduction zone. New crust is formed more or less continuously around the plate boundaries by these two processes.

Flood basalt eruptions, in contrast, are not confined to plate boundaries. They are associated with hot spots or mantle plumes and are both more sporadic and more dramatic. A mantle hot spot is anchored in the more mobile asthenosphere underlying the rigid tectonic plates of the lithosphere where its higher than ambient mantle temperature creates a partial melt that rises to the surface. As the plate moves over the hot spot, a chain of volcanic islands is formed across the ocean floor, such as the Emperor Ridge running northwest from the current hot spot beneath Hawaii. Most large basaltic igneous provinces, which include continental flood basalts, their submerged offshore equivalents known as seaward-dipping reflector sequences, and oceanic basalt plateaus, are closely associated with hot spots. Hotspots

**FIGURE 2** Satellite image of the northwestern United States showing the Columbia Plateau, east of the Cascade Range. The plateau is formed of huge flat-lying basalt flows that cover a large part of southeast Washington State and northern Oregon. Ninety-seven percent of the 174,000 km<sup>3</sup> of basalt in this province was erupted in just over 1 million years. Some individual eruptions produced more than 700 km<sup>3</sup> of tholeiitic magma from NNW–SSE fissures on the eastern edge of this image, as exemplified by the Pomona flow. The Pomona lava flowed down the Snake River, filled the Pasco Basin where the Snake and Columbia Rivers join in the center of the plateau, then continued down the ancestral Columbia River, across the rising Cascade Arc to plunge beneath (invade) the wet sediments along the Pacific Ocean coast line on the extreme west of this image. Over the 600 km that the Pomona flow can be traced, the concentrations of all 27 elements analyzed remain the same, implying minimal loss of heat and little crystallization.

**FIGURE 3** View of the Western Ghats, which form the western escarpment of the Deccan Plateau, India. The view shows flows of the upper part (Wai subgroup) of the main tholeiitic eruption ( $65.5 \pm 1$  Ma). The Deccan flood basalt province had an original estimated volume of  $1-2 \times 10^6 \text{ km}^3$  and all but a few percent of that volume was erupted within 1 million years. (See also color insert.)

are probably formed by plumes of hot material rising from the deep mantle; while they are not the principal means of creating new crust, because their eruptions are too intermittent, their contribution to this process is not trivial. The Ontong Java Basalt Plateau beneath the southwestern Pacific, one of the largest flood basalt provinces, covers almost 1% of the Earth's surface and has an estimated volume of  $10^7 \text{ km}^3$ .

We know from recent events such as the eruption of Mount Pinatubo in 1991 that major volcanic eruptions have profound effects on the Earth's climate. The large prehistoric eruptions of flood basalts must have had much more severe climatic effects. Indeed, the relatively tiny fissure eruption of Laki in Iceland in 1783, the only fissure eruption of historic times, caused a devastating famine across northern Europe. It is not surprising, therefore, that the dates of two of the largest continental

flood basalt eruptions, the Siberian Traps (248 Ma) and the Deccan Traps (65.5 Ma), coincide as closely as current radiometric dating permits ( $\pm 1$  Myr) with dates of the two most dramatic mass extinction events in the Earth's history, at the Permian–Triassic and the Cretaceous–Tertiary boundaries. Less convincing correlations have been made between extinction events and some other flood basalt eruptions.

In addition to their roles in the formation of the Earth's crust and on the evolution of life on our planet, we know that continental flood basalts and their associated mantle plumes are intimately associated with the breakup and separation of tectonic plates. The nature of these associations remains controversial, but it is clear that knowledge of the origin of flood basalts is a critical factor in our understanding of mantle dynamics and plate motions.

## II. DIVERSITY OF FLOOD BASALT PROVINCES

“Flood basalt” is a broad and somewhat ill-defined term. The classic continental flood basalts are relatively well studied in that an outline of a flow-by-flow stratigraphy is available and adequately dated radiometrically. But knowledge of ocean basalt plateaus and seaward-dipping reflector sequences is rudimentary. Other large basaltic igneous provinces have flood basalt affinities but are less well exposed, less well studied, and may possess many atypical features. Discussion of current knowledge of flood basalt provinces must therefore be uneven, concentrating on the younger and better exposed continental flood basalts, with less reference to both the older and sometimes more controversial continental provinces and the larger but relatively unstudied oceanic provinces. For ease of description the large basaltic provinces are arbitrarily divided into four categories:

1. Classical flood basalt provinces include the Siberian Traps, the Karoo province of South Africa, the Parana-Etendeka province of South America and South Africa, the Deccan Traps of India, and the Columbia River province of the American Northwest (Table I);
2. Less well studied or less typical provinces include the Rajmahal Traps of India, the basalts of Madagascar, the small province of Ethiopia-Afar-Yemen, and the huge province of the North Atlantic with its well-recognized seaward-dipping reflector sequences separating the exposed flood basalts from true MORB. These last two provinces, unlike all the classic continental flood basalt provinces, are still centered above their respective mantle plumes.
3. The apparent remnants of pre-Mesozoic flood basalt provinces include the Proterozoic Keweenawan of north-central United States and the Proterozoic Coppermine River basalt with its associated McKenzie dike swarm of northern Canada (Fig. 1).

TABLE I Estimated Physical Dimensions of the Various Types of Large Basalt Provinces, Including Continental and Oceanic Flood Basalts

	Age (Ma)	Area (km <sup>2</sup> )	Present volume (km <sup>3</sup> )	Original volume (km <sup>3</sup> )	Plume
<i>1. Classic Continental Flood Basalts (CFBs)</i>					
Columbia River	16	$1.6 \times 10^5$	$1.8 \times 10^5$	$1.8 \times 10^5$	Yellowstone
Deccan, India	66	$5 \times 10^5$	$5.2 \times 10^5$	$1-2 \times 10^6$	Reunion
Parana, S. America	132	$1.2 \times 10^6$	$8 \times 10^5$	$1.5 \times 10^6$	Tristan
Karoo, S. Africa	183	$3 \times 10^6$	n/d <sup>a</sup>	$1-2 \times 10^6$	? Bouvet
Siberian Traps	248	$3.4 \times 10^5$	$3.4 \times 10^5$	$>2 \times 10^6$	? Jan Mayen
<i>2. Basaltic Provinces with Flood Basalt Affinities</i>					
North Atlantic	Phl	$1.3 \times 10^6$	$6.6 \times 10^6$	$6.6 \times 10^6$	Iceland
	Phll	54			
Ethiopia-Afar-Yemen	25 (40–0 My)	$6 \times 10^5$	$3.5 \times 10^5$	n/d	Afar
Madagascar	88	$1 \times 10^6$	n/d	n/d	Marion
Rajmahal	116	$2 \times 10^5$	n/d	n/d	? Kerguelen
<i>3. Precambrian CFBs and Major Dike Swarms (Selected)</i>					
Keweenawan, USA	1100	n/d	$1.5 \times 10^6$	$>2.0 \times 10^6$	Lake Superior
Coppermine River	1267	n/d	n/d	n/d	?
<i>4. Oceanic Plateaus (Selected)</i>					
Ontong-Java	I	122	n/d	$1.5 \times 10^6$	$>5.7 \times 10^7$
	II	90			
Kerguelen		112	n/d	n/d	$10^7$
Wrangellia		230	n/d	n/d	?
Caribbean-Colombian		88	n/d	$6 \times 10^5$	Galapagos

<sup>a</sup> n/d, not determined.

4. Oceanic plateaus include Ontong Java in the southwest Pacific, Kerguelen in the southern Indian Ocean, Wrangellia wedged on to the northwestern margin of North America, and the Caribbean-Colombian ocean flood basalt (Fig. 1).

---

### III. PHYSICAL PARAMETERS

Continental flood basalts form exceptionally large plateaus of flat-lying flows with a uniform tholeiitic basalt composition (Fig. 3). Table I lists the estimated area, volume, and age of the better known provinces and the mantle plume with which each province is associated. The typical continental flood basalt province erupted between 1.0 and  $2.0 \times 10^6$  km<sup>3</sup> of basalt, but the most comprehensively studied Columbia River province is smaller by one order of magnitude. Lack of sedimentary interbeds and absence of erosion or even significant weathering between flows, particularly at the base of these lava piles, imply that eruption followed eruption without substantial time gaps, although a slowing of the eruption rate and frequency is indicated by more frequent thin sedimentary horizons and boles toward

the top in many cases (e.g., the Columbia River and Deccan). In each province most of the huge volume of magma erupted within a time span of 1–2 million years, often during a shorter period than can be recognized by current radiometric dating techniques. More than 96% of the 175,000 km<sup>3</sup> of Columbia River basalt erupted in 1–2 million years, while all but the very earliest and latest eruptions of the much larger Deccan and Karoo flood basalt eruptions appear to have occurred within a similar time span. This implies an average eruptive rate in the larger provinces of 1–2 km<sup>3</sup>/yr, a rate 20–50 times greater than rates measured at a typical hot spot such as Hawaii, but less than that reported for the only historic single fissure eruption, that of Laki, Iceland, in 1783–1784.

Individual flows are huge. On the Columbia Plateau, for instance, some sheet flows with volumes of at least 700 km<sup>3</sup>, derived from a single eruptive event, can be traced for 600 km (Fig. 2). Volumes of 2000–3000 km<sup>3</sup> have been plausibly suggested for some Columbia River flows, but not yet proven. The magma for these eruptions was supplied through fissure systems, now dikes (Fig. 4; see also color insert), some of which are more than 100 km long. Shield structures are rare. Small cones, including spatter cones, are occasionally preserved and appear to represent the dying phase of an

FIGURE 4 NNW–SSE-oriented feeder dikes in the southeast corner of the Columbia Plateau. Many of the dikes in this swarm can be connected to individual basalt flows by their spatial position and chemical composition. (See also color insert.)

eruption, confined to restricted parts of the fissures as the magma supply dwindled.

Although the distances traveled by individual basalt flows across the Earth's surface are demonstrably huge, flood basalt magmas may be able to flow even greater horizontal distances in dike systems within the crust below the surface. The great McKenzie dike swarm of northern Canada covers an area of  $2.7 \times 10^6 \text{ km}^2$  and extends for 2600 km from its focal point where the Muskox layered intrusion and the Coppermine River lavas occur. The entire suite is interpreted as the remnants of a large Proterozoic flood basalt province. The dikes have been dated to  $1267 \pm 2 \text{ Ma}$ . Similar ages for the Muskox intrusion and Coppermine River flows, together with their very similar tholeiitic compositions, imply that all were derived from the same source. Study of the magnetic fabrics within the dikes indicates steep to vertical flow of magma in dikes close to the focus of the swarm and increasingly horizontal flow at their distal ends.

In the Karoo and Deccan provinces extensive lateral flow within the crust, rather than surface flow, may account for the huge areas covered by basalt flows of almost exactly the same age and composition. Karoo flows in central Namibia are of the same age and composition as flows 1500 km away in Lesotho. An intense complex of dikes and sills of similar age and composition occurs in the intervening area, cutting the older Karoo sediments. Similarly, on the Deccan, flow sequences more than 900 km apart display similar changes in chemical composition with time, but may be fed by separate, local, feeder-dike systems. In some cases such flow-dike systems with indistinguishable chemical compositions have distinctive isotopic signatures. This has led to the suggestion that such magmas are derived from the same mantle source but have followed different paths through the crust, the isotopic differences being ascribed to contamination by the different types of crust encountered during their extensive horizontal flow along dike systems. Lateral flow along fissures within the crust for thousands of kilometers may also provide an explanation for the atypical elongation of the Antarctic flood basalt province. This province forms a narrow extension from the Karoo province of Africa into Queen Maud Land and across Antarctica along the length of the Transantarctic Mountains to Tasmania, possibly following an old and weakened structural zone.

The rate of magma eruption onto the earth's surface in flood basalt provinces is critical to an understanding not only of the origin and evolution of these provinces but of their effect on the environment and world climate. But measuring the rate of magma eruption and the ve-

locity of magma flow in flood basalt eruptions has proved controversial. Only on the relatively small province of the Columbia River (Table I) has enough detailed work been done to gain some insight into the eruptive processes. Individual sheet flows on the Columbia Plateau (Fig. 2) show virtually no change in chemical composition and a very small drop in temperature from point of eruption to flow termination ( $0.05^\circ \text{ C/km}$ ). This consistency has been used to imply very rapid rates of extrusion and led to an early model of a fast-moving turbulent lava flow in which large volumes of magma erupted from 100-km-long fissures, with lava fronts many meters high advancing across the plateau at fast walking speed, covering the plateau in days or weeks. More recent studies suggest that the flows were formed by repeated internal injection and laminar flow, a mechanism similar to that observed in the growth of smaller flows through lava tubes on Hawaii. This second model interprets the simple structures of the typical Columbia River basalt sheet flow, a colonnade of thick vertical columns at the base supporting an entablature of smaller irregular columns of finer-grained basalt, topped by a glassy vesicular zone, as interlocking sequences of very large, flattened, lava tubes. The chemically homogeneous individual eruptions are interpreted as large flow fields of compound flows growing by inflation of pahoehoe lava. Both the turbulent and laminar flow models require the rapid and sustained emission of very large volumes of magma. In the second model the mass eruption rate is calculated to be 5 or more million kilograms per second with rates of lava flow from fissure to flow termination of the order of 1–2 km/hour so a whole flow field might take 10 or more years to be emplaced, rather than the few days or weeks envisioned in the earlier turbulent flow model.

Many of the Columbia River basalt flows carried phenocrysts on eruption and the longer the emplacement process continued the greater the degree of fractionation to be expected as the crystals separated from the remaining liquid. Chemical analyses of the flows using high-precision x-ray fluorescence techniques have indicated very consistent compositions, which allow subtle differences between flows to be traced across the province. In the absence of turbulent flow, such remarkable chemical homogeneity provides a potential constraint on the time between eruption and final crystallization.

The rapid eruption of huge volumes of homogeneous magma in short periods requires large reservoirs of well-mixed magma. Yet surface collapse structures, typical of the eruption of large volumes of silicic magma, are not observed. From this it is concluded that the magma reservoirs formed deep in the crust. The most obvious place for these magma reservoirs to develop is at the

crust-mantle boundary where the contrast between the dense mantle-derived basaltic magma and the less dense crust would tend to prevent farther upward migration of the magma through the crust until it had fractionated enough at the crust-mantle boundary to decrease the magma density to that of the crust above. Modeling the observed chemical differences between flows supports this conclusion. Either these magmas were derived from an unusually iron-rich mantle or the original mantle melts underwent significant crystal fractionation under deep crustal conditions.

#### IV. CHEMICAL AND ISOTOPIC PARAMETERS

One of the most unusual aspects of flood basalts is the consistent chemical composition of huge volumes of basalt. Examples are the Lesotho Basalt of the Karoo, the Ferrar of the Antarctic province and the Grand Ronde Basalt of the Columbia River. But significant chemical differences do occur both within and between provinces, and these differences have led to distinct petrogenetic models.

Most provinces show greater compositional variation at the beginning and at the end of the main tholeiitic eruption. In the larger classic continental flood basalt provinces, relatively small volumes of alkalic and picrotic magmas signaled the first signs of magmatic activity, whereas silicic magmas tend to be concentrated in the later phases of the eruption. Although normally small in volume, compared to the huge volumes of tholeiitic basalt, these more exotic magma types provide clues to the origin and evolution of the province as a whole.

Each of the five classic continental flood basalt provinces (Table I) has been subdivided into formations or chemical types on the basis of changes in major and trace element concentrations (Fig. 5). These changes may be reflected in mineralogical differences recognizable in the field and are typically accompanied by changes in isotopic ratios. Variation between flows within a formation is usually confined to subtle but remarkably consistent differences in minor and trace element abundances. This is best illustrated on the Columbia Plateau (Fig. 6), where chemical fingerprinting has been used to map individual flows across the province. Similar, if less detailed, chemical distinctions have been made in the other classic continental flood basalt provinces.

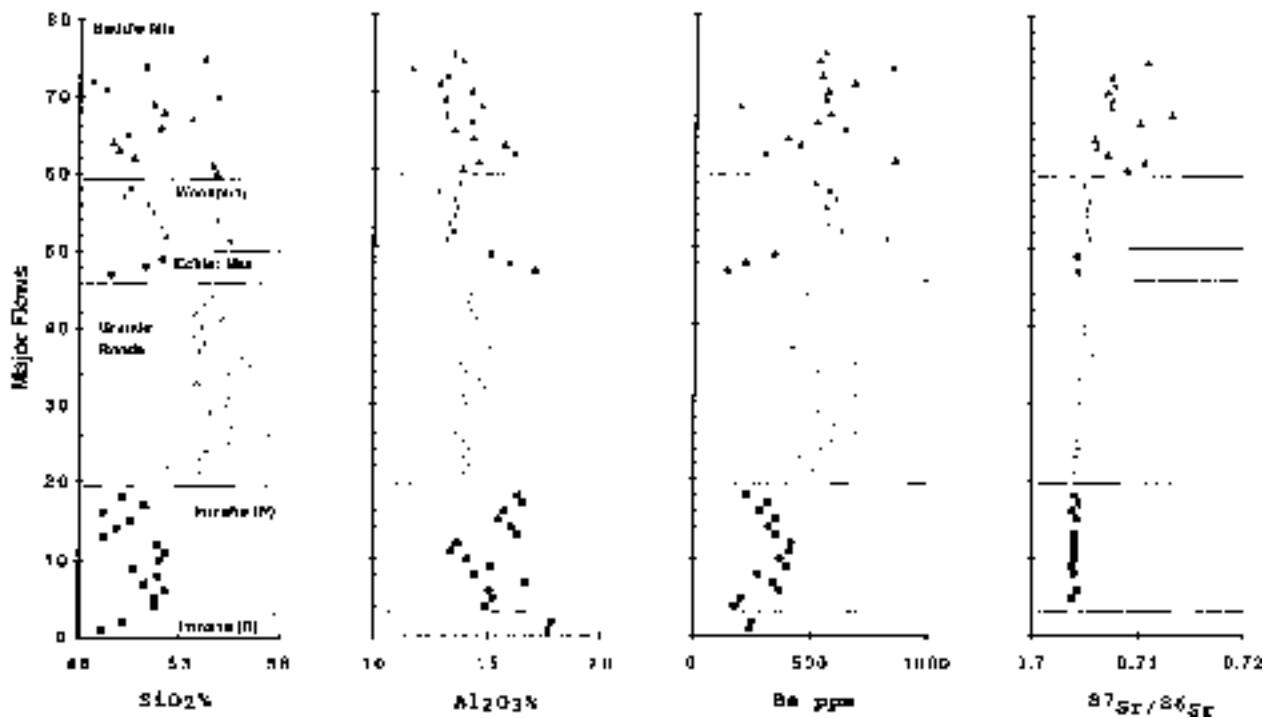

FIGURE 5 Division of the Columbia River Basalt Group into formations by variation in major and trace elements and in isotopic ratios. Other classical flood basalt provinces have been similarly divided.

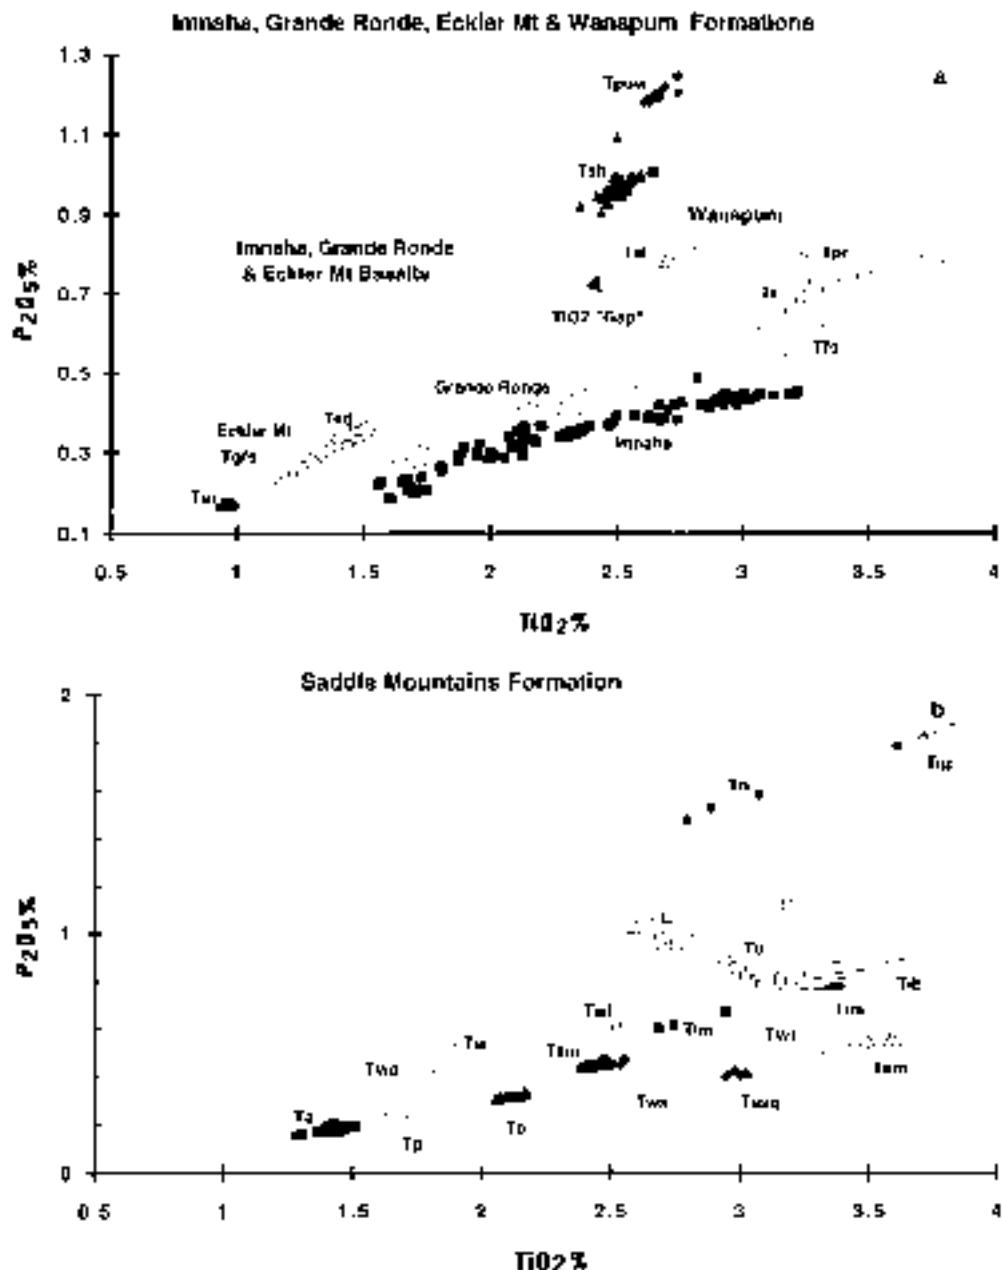

FIGURE 6 Identification of individual flows of the Columbia River Basalt Group on element oxide plots. (a) Phosphorous oxide ( $P_2O_5$ ) versus titanium oxide ( $TiO_2$ ) for Imnaha, Grande Ronde, and Eckler Mountain flows. (b)  $P_2O_5$  versus  $TiO_2$  for the Saddle Mountain flows. Each symbol represents a single eruption or flow, except that the Umatilla member (Tu) represents two similar but separate magmas erupted from the same vent, which mixed immediately before or during eruption. This chemical fingerprinting has allowed many individual eruptions to be mapped for hundreds of kilometers across the Columbia Plateau.

The Columbia River lacks early alkalic or picritic magmatism or late eruptions of rhyolitic magma. The Karoo, Parana-Etendeka, and Deccan provinces all include early alkalic magmatism and later silicic magmatism. In the Siberian Traps alkalic and pyroclastic

silicic magmatism appear to be dispersed throughout the main tholeiitic event. In the Karoo the earliest magmatic events included the intrusion of syenites and extrusion of nephelinites (approximately 192 Ma), followed by a thick sequence of alkalic picrites in the northern part of

the province (Nuanetsi) where their eruption coincides with ancient structural zones of weakness. This was followed by the huge volume of tholeiite that was extruded over most of southern Africa and extended into and across Antarctica (182 Ma). The final Karoo eruptions were dominated by silicic material (Jozini Rhyolites; 178 Ma), again confined to the northern part of the province along the Lebombo monocline, a structure that was probably developed by thinning of the lithosphere as the Antarctic and African plates separated, following the main eruptive event.

A similar sequence is found on the Deccan. Early syenite intrusions and flows of alkalic picrite (68.5 Ma) occur along the Narmada-Son-Tapti zone in the north, an ancient structural zone dating back to the Precambrian. This volumetrically insignificant activity was followed 2 or more million years later by the huge volume of tholeiite that forms Kalsubai Mountain and the Western Ghats (65.5 Ma; Fig. 3), which was erupted from north to south in less than 1 million years as the Indian plate moved rapidly north over the Reunion hot spot. Subsequent to this enormous outburst of tholeiitic magmatism, the western edge of the new basalt plateau was disrupted as east–west extension thinned the lithosphere and the Seychelles plate began to separate from the Indian plate, leading to normal NNW–SSE faulting and to the Panvel monoclinal flexure parallel to the coast. This extension brought the uppermost tholeiitic flows on the top of the adjacent part of the western Ghats down to sea level along the Bombay coast and created a series of horsts and grabens in the much thinner basaltic sequence offshore. A strongly oriented dike swarm parallel to and clearly associated with these NNW–SSE structures is made up of a mixed assemblage of compositions, from rhyolites through trachytes and lamprophyres to more normal tholeiites, some of which appear to have acted as feeders to the rhyolites, trachytes, and tholeiites of the small volume volcanic sequence that forms Bombay Island (61–64 Ma) and probably correlate with later alkalic intrusions farther north in the Cambray Basin dated at 53–64 Ma.

In South America, around the east edge of the Parana province, large alkalic intrusions such as the Jacupuranga complex predate or are contemporaneous with the earliest tholeiitic magmatism. On the Etendeka (African) side of this province, large syenitic complexes are contemporaneous with the later basalt eruptions and continued after the basalt eruptions had ceased. These large intrusive complexes, apparently oriented along ancient structural zones, are believed to have acted as the eruptive centers for the large volumes of silicic lava extruded in the latter part of the Etendeka basalt sequence and which cap the tholeiites on both sides of the South

Atlantic. They vented immediately prior to the separation of the African and South American plates. In the Keweenawan province alkalic complexes are concordant with the earliest picritic eruptions, while large volume silicic eruptions, up to 600 km<sup>3</sup>, occur later in the sequence.

In all flood basalt provinces, the dominant tholeiites have a simple mineralogy of plagioclase, clinopyroxene (augite and often pigeonite), and Fe-Ti oxides, often with olivine and more rarely orthopyroxene. They may be porphyritic or aphyric, with plagioclase by far the dominant phenocryst phase, followed by olivine, which is frequently replaced by iddingsite and other secondary products. But significant differences occur between provinces. The Grande Ronde Basalt formation of the Columbia River, for example, which forms 85% by volume of the Columbia River Basalt Group, is a very homogeneous aphyric basaltic andesite to andesite with SiO<sub>2</sub> content varying from 53 to 57%. This is significantly more silicic than tholeiites from other provinces with the possible exception of the Ferrar Basalt from the Antarctic. These and the more typical tholeiites of continental flood basalt provinces have the relatively high incompatible element abundances, high iron-to-magnesium ratios, and iron-rich olivine compositions that indicate these magmas could not have been in equilibrium with normal peridotite mantle mineralogy. Either they have undergone considerable crystal fractionation in the crust or they are derived from an unusually iron-rich mantle source. Furthermore, with the exception of some formations like the Ambenali Formation of the Deccan, major and trace element abundances and the isotopic ratios of these tholeiites imply that a component from a lithospheric source has contributed to their origin. Reconciling the chemical and isotopic evidence that indicates a lithospheric source with the large melt fractions that require a hot mantle plume source remains a fundamental problem in modeling the origin of flood basalt provinces.

## V. SOURCE OF FLOOD BASALTS

The large volumes of basaltic magma erupted in such short intervals of time can only be formed if temperatures in the mantle source are higher than normal; that is, a mantle hot spot source. The most widely accepted model of a hot spot is a plume with a large head and a much narrower tail rising from the core–mantle boundary or from the lower–upper mantle boundary at about 670-km depth. Modeling of the impingement of a plume

on the underside of the lithosphere shows that the large plume head spreads out to form a thermal dome with the potential to form basaltic eruptions by decompressional melting over an area that may be as much as 2000 km in diameter. The unusually large melt fractions formed in the mantle by this process cause the high extrusion rates that typify flood basalt provinces. As lithospheric plates move across a plume, the plume head disperses, leaving only the plume tail erupting basaltic magma at a lower rate. Such plume tails create chains of volcanic islands that terminate in active volcanoes marking the current position of the plume such as Hawaii or Reunion.

Mantle hot spots, like Hawaii, have characteristic chemical and isotopic compositions, including enriched helium isotopic ratios, which are probably derived from the deep mantle. Some flows in flood basalt provinces also contain these deep mantle signatures, but most flows in continental flood basalt provinces are chemically and isotopically distinct from the ocean island basalts of typical ocean hot spots. Continental flood basalts are typically more silicic than ocean island basalts. Most continental flood basalts also have enriched isotopic ratios with decoupled light ion lithophile (LIL) and high field strength (HFS) incompatible trace element concentrations, a decoupling that cannot be explained by partial melting or crystal fractionation processes but may be explained by the variable solubilities of the LIL and HFS incompatible elements in the hydrous fluids emitted by the dehydration of a subducting slab as it sinks. These chemical signatures are typical of rocks formed above subduction zones and of the lithosphere in general and their presence in continental flood basalts is evidence of a lithospheric source component. The isotopic enrichment also requires the incorporation into the magma of older lithosphere, either an enriched lithospheric mantle or older crustal rocks.

The large ocean basalt plateaus appear to have compositions intermediate between the plume-related basalts of the ocean islands and the MORB of the normal oceanic crust. Thus, flood basalt provinces on both continents and oceans appear to be formed from a plume component mixed with a lithospheric component.

The Deccan Plateau provides the most persuasive evidence to date of the origin and evolution of a classic continental flood basalt. The earliest alkalic and picritic units in the Deccan have helium and radiogenic isotopic values that suggest small degree partial melts of two original mantle sources. The first is equivalent to the Reunion hot spot (ocean island basalt) source; the second is similar to Indian MORB. The great majority of the Deccan flows can be modeled, chemically and isotopically, as mixtures of large degree melts of these

two mantle source components to which different lithospheric source components have been subsequently added. The first lithospheric component was added early and could be an enriched lithospheric mantle component or a deep crustal component, characterized by high  $^{87}\text{Sr}/^{86}\text{Sr}$  and low  $^{143}\text{Nd}/^{144}\text{Nd}$  isotopic ratios. A later lithospheric component is more variable, characterized by low  $^{206}\text{Pb}/^{204}\text{Pb}$  ratios, and is almost certainly of crustal, probably of upper crustal, origin. On the Deccan Plateau both field and petrographic evidence for crustal contamination may be evident in partially digested sedimentary and other silicic inclusions and in reaction rims around phenocrysts. In addition to the complex mixing patterns between the products of these various sources, which have been defined largely from their isotopic arrays, these magmas appear to have undergone extensive crystal fractionation within the crust.

There is equally strong evidence of crustal contamination in the North Atlantic province. Detailed studies in northwest Scotland have been able to identify the specific crustal components involved. In the Siberian Traps crustal contamination of mantle magmas is seen to cause the segregation of large volumes of sulfide, which host giant deposits of nickel, copper, and platinum group metals in associated intrusions. In contrast, detailed chemical and isotopic work on the Karoo has persuaded most petrologists that the main lithospheric component in the basalts is derived from an enriched mantle, not from the crust. Only in the earliest basalts in Lesotho is there evidence of significant crustal contamination. The high-titanium group of Parana basalts in the north of that province contains little evidence of crustal assimilation (little variation in isotopic ratios), but those in the south show an isotopic and chemical spread that may be due in large part to crustal assimilation accompanying crystal fractionation. But, again, the differences between the main magma types of the Parana province appear to require different mantle melting regimes and/or multiple sources.

In the large Proterozoic Keweenawan province early picritic eruptions are interpreted as small degree melts of a plume head at great depths ( $>75$  km) and were followed by larger degree melts from the same source at lesser depths mixed with melts from an enriched lithospheric mantle to form the huge volumes of the tholeiitic magma that dominate the province. Strong evidence of crustal assimilation is found in silicic magmas erupted after a hiatus in magmatic activity, perhaps because of reduced extension and consequent ponding of the mantle-derived magmas in crustal reservoirs. This process appears to have created very large volumes of rhyolite ( $>600$  km $^3$ ) by direct melting of the crust. On the Columbia Plateau both crustal and mantle lithospheric

sources have contributed, but opinion is divided as to their relative importance.

Detailed studies of the early Karoo picrites point convincingly to these being asthenospheric melts mixed with enriched lithospheric mantle. On the Deccan, the early picritic rocks may represent small degree partial melts, able to work their way to the surface only along the older fracture systems. The youngest Deccan eruptions, the small volumes of chemically diverse flows (alkalic, silicic, and basaltic) and highly oriented (NNW–SSE) dikes around Bombay, are spatially and temporally related to extensional structures. They have similar isotopic signatures to the main tholeiites and may have been formed by the decompression melting of the earlier tholeiites at the base of the crust as the lithosphere was thinned by extension. A similar crustal melting of the earlier basalts is proposed as the origin of the Jozini Rhyolites in the extension-related Lebombo monocline of the Karoo.

In summary, it is clear that continental flood basalts carry the chemical and isotopic signatures of a hot spot or mantle plume, especially in their earliest eruptions, but that these signatures are effectively masked in the majority of flood basalts by a dominant lithospheric component that imposes its own signature on the most voluminous tholeiites. Opinion on the origin of the lithospheric component remains divided. For the Deccan and the North Atlantic provinces, workers are generally agreed that crustal contamination is dominant, but in the Parana and Karoo researchers are equally convinced that the main lithospheric component in the basalts is derived from an enriched lithospheric mantle. On the Columbia Plateau and in the Keweenawan provinces, participation of both crust and mantle lithosphere can be convincingly demonstrated. But the source of the lithospheric component, apparent in all continental flood basalt provinces, remains ambiguous in many examples and has yet to be resolved.

## VI. OCEANIC FLOOD BASALTS

Many oceanic flood basalt provinces are an order of magnitude larger than the classic continental flood basalt provinces. They form broad, flat-topped plateaus, typically remote from continents, lying approximately 2000 m above the surrounding ocean floor. They are dominated by tholeiitic basalt and, although data are still very scarce, they appear to have been erupted in only a few million years and to be younger than the

surrounding ocean floor. Chemically and isotopically, ocean basalt plateaus have values intermediate between MORB and ocean island basalt, suggesting that magmas were created by decompressional melting of a plume head (ocean island basalt source) derived from the deep mantle, which was then mixed with a component derived from the depleted upper mantle, the source for MORB.

The two largest oceanic plateaus are the Ontong Java and the Kerguelen (both  $>10^7$  km<sup>3</sup>) of Cretaceous age in the southern Pacific and southern Indian oceans, respectively. Wrangellia, of Permian age and accreted to the northwest coast of North America, is also believed to have formed as an ocean plateau on top of island arc crust, which was subsequently obducted, or thrust over, the continental coast of western North America. The age of the Ontong Java plateau is about 125 Ma, similar to that of adjacent basalt plateaus in the south Pacific. If all of these adjacent plateaus are part of a single province, as their similar ages suggest, the area of ocean floor covered by this basalt plateau is approximately  $5 \times 10^6$  km<sup>2</sup>, or 1% of the Earth's surface.

Such huge volumes of basalt and their apparent high eruption rates require a source area in the mantle above ambient mantle temperature, like those of their continental counterparts. As yet there is no clear evidence that oceanic flood basalts are associated with lithospheric extension. As for their continental counterparts, the most obvious explanation for their formation is the initial impingement of a mantle plume head on the base of the oceanic lithosphere. The even larger volume of oceanic, as compared to continental, flood basalts can be ascribed to the relative thinness of the oceanic as compared to the continental crust, which would permit a larger melt volume to form at the same temperature. However, the connection between oceanic plateaus and currently active hot spots is less obvious. If the Hawaiian–Emperor volcanic chain represents the end of such a sequence, then the original basalt plateau has already been subducted. The only probable connection between an oceanic plateau and a current hot spot yet proposed is the Caribbean oceanic flood basalt province, which may represent the initial pulse of the plume that now lies beneath the Galapagos Islands.

## VII. TECTONIC IMPLICATIONS AND GENETIC MODELS

Once plate tectonic theory was well established during the early 1970s, it became apparent that the onset of

major plate separation, such as the opening of the South and North Atlantic Oceans, the separation of Antarctica from South Africa, or the separation of the Seychelles platform from the Indian plate, was associated both with hot spots or mantle plumes and with the formation of a continental flood basalt province. Clearly these three apparently diverse phenomena are somehow related, although the associations are more obvious for some provinces (Afar, North Atlantic, Parana, and the Deccan) than for others (Siberian Traps and the Columbia River). What is not well understood is how these different phenomena affect each other.

Of the three temporally and spatially associated phenomena—plate separation, flood basalt eruption, and mantle plume—a mantle plume originating deep within the mantle would have much the longest history; it would take millions of years for a plume to ascend through the mantle to the surface. So suggestions that some surface event, even as dramatic as a meteorite impact or an extension-related breakup of a lithospheric plate, could trigger the plume is not plausible. If the hot spot is due to a mantle plume and if these three phenomena are associated temporally and spatially, then it is reasonable to conclude that the mantle plume is a primary driving force in the origin of large flood basalt provinces and of plate separation.

It is widely accepted that some additional factor beyond the 200–300°C higher than ambient temperatures of a mantle plume is required to produce the exceptionally large melt volumes of flood basalt provinces. Suggested additional factors include an extending and thinner than normal lithosphere, a hydrous-enriched lithospheric mantle, or an eclogite component in the plume. These three factors are not mutually exclusive.

In one model for the origin of flood basalt provinces the presence of one or perhaps a line of mantle plumes is assumed to weaken the lithosphere enough to focus the point of breakup of a plate already under lateral tension due to the horizontal pull of the subduction process. It has been suggested, for example, that a line of hot spots beneath Gondwanaland created not only the Parana-Etendeka flood basalt province but also a zone of weakness in the lithosphere, which permitted South America and South Africa to pull apart in the early Cretaceous. In this model extension is a consequence and not a cause of the flood basalt eruption, but either an enriched mantle source or an eclogitic component in the plume may be necessary.

An alternative model suggests that hot spots may incubate for long periods beneath continental plates and only create flood basalt eruptions when the continental lithosphere is thinned enough by extension to allow

significant decompressional melting. This model contends that previous lithospheric extension and thinning is a necessary prerequisite for the formation of the large volumes of melt that flood basalts represent. It cannot be disputed that flood basalts and extension are intimately associated and it seems probable that lithospheric thickness plays an important role in controlling the much larger volumes of oceanic flood basalt provinces than their continental equivalents. There is also circumstantial evidence that the precise positions where flood basalt eruptions began is controlled by local “thin spots” in the lithosphere caused by earlier extension or simply deep fault zones. Yet the field evidence in those provinces studied most intensely, the Karoo, Deccan, Keweenawan and Columbia River, demonstrates that early extension is directly associated with the rise of the plume and that the major extension leading to plate separation always postdates the main tholeiitic eruptions. This implies that the extension is a consequence not a cause of flood basalt eruptions.

Plume heads would be larger and hotter than the tails that now form ocean island basalts. The large volume differences between flood basalt provinces and ocean island basalts formed above current hot spots (Hawaii, Reunion, Galapagos) strongly suggest that flood basalts are caused by the initial impact of plume heads on the lithosphere and that oceanic island magmatism represents the plume tails.

Recent geophysical evidence has supported the sinking of a subducted slab all the way to the core–mantle boundary. The chemical disturbance caused by this material at this depth could initiate the formation of a plume. If so, the resulting plume is likely to carry a substantial eclogite (basalt) component derived from the recycled subducted crust. This component in the plume may be the origin of an unusually iron-rich mantle source capable of providing the large melt fractions observed in flood basalts. Recent experimental evidence has confirmed that the Grande Ronde Basalt of the Columbia River could be derived from such a source, thus decreasing the need for a lithosphere previously thinned by extension. An eclogite component in the plume would also explain the relatively evolved composition of continental flood basalts without the extensive crystal fractionation within the crust which is otherwise needed but for which the evidence of intermediate compositions is embarrassingly rare. With its significant garnet component such a source might also melt at somewhat lower pressures and still retain a residual garnet signature in its trace element pattern.

No single genetic model can account for all flood basalt provinces. The impingement of a mantle plume,

with temperatures 200–300°C above normal, on the base of the lithosphere is probably the driving force in all cases. But the extent to which lithospheric extension is required or the extent to which an enriched lithospheric mantle or an eclogite component in the plume contributes to the unusually large volumes of evolved basaltic magma available in these provinces remains controversial. The very significant physical, chemical, and isotopic differences between provinces may well result from the variable contributions of lithospheric thickness, availability and composition of an enriched lithospheric mantle, and the proportion of an eclogite component in the mantle plume.

---

### VIII. ENVIRONMENTAL EFFECTS

That these large basaltic eruptions had a profound effect on the world climate appears inevitable. Basalts have greater potential than most lavas to emit large volumes of sulfur dioxide ( $\text{SO}_2$ ) or hydrogen sulfide ( $\text{H}_2\text{S}$ ). In the only historic fissure eruption known, the relatively tiny 1783–1784 Laki eruption in Iceland, it is estimated that 1.7 megatons of  $\text{SO}_2$  was erupted per day in the first few weeks of the 8-month-long eruption. This is more  $\text{SO}_2$  in a month than was emitted by the entire 1991 Mount Pinatubo eruption, the second largest volcanic eruption of this century. Very large volumes of hydrochloric acid and hydrofluoric acid were also erupted from Laki. The aerosols created a thick haze that persisted over Europe and into Asia for 3–4 months.

In comparison, a single flow of the Columbia River flood basalt province is estimated to have produced more than 12,000 megatons of  $\text{SO}_2$  over a 10-yr period—and this is but one of the 200–300 large flows that erupted across the Columbia Plateau in 1–2 million years. The effect on the world climate of the eruption of the even larger flood basalt provinces, the Deccan, Parana, Karoo, Siberian Trap, and Keweenawan provinces which are at least an order of magnitude larger than the Columbia River province, must have been devastating. The climatic effect appears to be confirmed by the coincidental timing of the largest mass extinctions with the formation of flood basalt provinces, of which the Deccan, at 65.5 Ma, and the Siberian Traps, at 248 Ma, are the most dramatic.

The extinction of the dinosaurs and many other fauna and flora at 65.5 Ma has caught the public imagination. The story is enhanced by evidence that this mass extinction event was caused by the impact of a meteorite from

space as shown by a striking increase in the iridium content at the time of the most massive extinctions. Although the evidence for a meteorite impact at about 65 Ma is now very strong, paleontologists have long made it clear that the extinction of dinosaurs, and other fossil groups, actually took place over a protracted period starting well before the 65-Ma impact. In attempts to explain evidence for meteorite impacts and major flood basalt eruptions both coinciding with some but not all of the most dramatic mass extinctions in the Earth's history, it has recently been suggested that the world climate may first have been severely stressed by a flood basalt eruption causing significant disruption to the flora and fauna, which was then further augmented by the impact of a major meteorite. In this model the spectacular extinction event at about 65 Ma resulted from a major meteorite impact during the large Deccan flood basalt eruption. Recent evidence from the Deccan places an iridium anomaly, which implies a meteorite impact, between flows of the Deccan flood basalt eruption. But regardless of whether one believes that flood basalts participated in the mass extinction events of the past, it is quite certain that even a modest flood basalt eruption today would dramatically affect the world climate and put the future of mankind in some jeopardy.

---

### IX. SUMMARY

1. Continental and oceanic flood basalt provinces are characterized by very large volumes of relatively evolved tholeiitic basaltic magma erupted over a short period of time.
2. The fundamental cause of a flood basalt province is probably the impingement of a mantle plume head on the base of the lithosphere.
3. Lithospheric extension and plate separation are thought to be the result and not the cause of continental flood basalt eruptions, although this remains controversial.
4. Lithospheric thickness may control the volume of basalt erupted and may explain the greater volumes of ocean as compared to continental flood basalts, while local thin spots may control the exact location of the eruptions.
5. Isotopic and chemical data on continental flood basalts and probably ocean flood basalts require a mixture of mantle plume and lithospheric source components.
6. The lithospheric component in continental flood

- basalt provinces is derived from both an enriched subcontinental mantle and from older continental crust. Which of these is dominant remains controversial.
7. An eclogite component within the plume has become increasingly plausible. This would increase the melt volume of the plume head and reduce the necessity for contemporaneous extension. It would also answer some awkward problems such as that relating to the apparent presence of garnet in the source, implying melting at considerable depth if an eclogite component is absent, and decrease the need for the large degree of fractionation in the crust for which adequate evidence of intermediate fractionation stages is absent.
  8. The many differences between continental flood basalt provinces may result from the varying influences or availability of suitably enriched lithospheric mantle, an eclogite component, and lithospheric thickness.
  9. Finally, the coincidence of the largest mass extinctions with some of the largest eruptions of flood basalt strongly support the suggestion that these extraordinary eruptions, together with meteorite impacts, have played a major role in the biological evolution of our planet. Flood basalt eruptions may have degraded the Earth's climate over periods of a few million years, and caused progressive extinctions so that a major meteoric impact, occurring within this period, would have had catastrophic effects on climate, fauna, and flora.

## GLOSSARY

**hyaloclastite** A deposit consisting of fragments of volcanic glass formed by nonexplosive shattering (sometimes used broadly to include explosively formed fragments as well).

**hydroclastic rocks** A general term applied to volcanic rocks formed by fragmentation of magma in the presence of water.

**hypabyssal intrusive complex** Formed by intrusion of magma at shallow levels into unconsolidated sediment.

(“Hypabyssal” is derived from old terms referring to injection of deep-seated magma to shallow levels.)

**limu fragments** Parts of glass bubbles, or balloons, formed by expansion of vapor through the surface of fluid lava.

**lobate lava** Submarine lava type consisting of elongated, flattish lobes with smooth outer glassy skins.

**peperite** Genetic term for a rock formed by essentially in-place disintegration and active mixing of molten lava or magma and poorly consolidated, typically wet sediment

**pillow breccia** A mixture containing coarse, typically glassy, broken to whole pieces of pillow lava together with smaller fragments formed by shattering of pillow lava crusts.

**pillow lava** Submarine lava type consisting of rounded and tubular shapes with striated outer glassy surfaces.

**pillow volcano** Small conical or ridgelike edifices of pillow lava found on the seafloor and in on-land ophiolites.

**quenching** The process of cooling magma rapidly to form a glass. It is accompanied by a volume decrease that can lead to fragmentation of the glass (cooling-contraction granulation).

**sheet flows** Submarine lava type with smooth, lineated, folded, or jumbled surface textures resembling subaerial pahoehoe.

**spall fragments** Formed by shattering of the brittle, quenched, crust of a lava by a combination of thermal contraction and flexure at the margins of a still-flowing lava.

**spatter** Fluidally shaped vesicular fragments that are deposited hot, typically deformed, and sometimes welded together.

associated deposits that erupted under water, and in most cases, fairly deep water. We start with modern and ancient submarine lava flows, then discuss hyaloclastites and their associated lava flows and breccias, finally addressing hypabyssal complexes.

## I. INTRODUCTION

Submarine lava flows are important because they are the most widespread and abundant surficial igneous rock type on earth. They are erupted at a variety of ocean water depths, display a wide spectrum of sizes, shapes, and compositions, and comprise up to a 1- to 2-km thickness of the upper parts of the ocean crust created at midocean ridges or spreading centers (see chapter on Plate Tectonics and Volcanism). Ocean crust is also created in small seas called *backarc basins* (e.g., the Japan and Caribbean seas), lying between continental land masses and offshore chains of island-arc volcanoes resulting from subduction of oceanic crust into the deep mantle. Active volcanoes of the island arcs themselves begin as small submarine volcanoes in deep water consisting of submarine lavas, *hyaloclastite*, and intrusive rocks. In young spreading centers adjacent to landmasses, and where new volcanoes are initiated along island arcs, erupting magma commonly encounters thick successions of water-saturated, unconsolidated sediments. In this situation, much of the rising magma may fail to reach the seafloor to produce lava flows, and instead spreads laterally into the soft sediments to form complex hypabyssal intrusive complexes. Eruptions in the Gulf of California, formed by recent spreading at the tip of the East Pacific Rise system, are known from drillcore studies to have produced a hypabyssal complex, but such complexes are not easily observed in modern settings. They are, however, increasingly recognized as an important component of ancient island-arc and young spreading ridge settings.

After oceanic crust is formed, either at midocean ridges or in backarc basins, newer volcanoes, called *seamounts* may be built on it, and these also are made largely of submarine lava flows. Hot spots can build huge volcanic plateaus like the submarine Ontong Java plateau or long chains of seamounts and volcanic islands like the Hawaii–Emperor chain. Interestingly, rocks from midocean ridges, backarc basins, and seamounts can be preserved in the on-land geologic record of continents as a result of plate collisions. In this chapter we compare modern seafloor deposits with ancient examples preserved on land, considering only lava flows and

### A. What Controls Eruption Style?

Volcanic eruptions can in general be divided into those that produce lava flows or hypabyssal intrusive complexes (effusive activity) and those which produce explosive eruptions. One fundamental control on this behavior is the chemistry of the magma that erupts: Basaltic magma with about 50% SiO<sub>2</sub> is hot and very fluid (low viscosity) so it commonly erupts as a spray of droplets (fire fountains) or quietly as lava flows. In contrast, magmas that are richer in SiO<sub>2</sub>, such as andesite (55–60% SiO<sub>2</sub>), dacite, and rhyolite (>70% SiO<sub>2</sub>) generally erupt at lower temperatures, higher viscosities, and with more dissolved volatile components that can form gas bubbles, all of which tend to produce more explosive eruptions.

Most submarine eruptions in deep water are basaltic in composition and so are generally not explosive. The basalt magma does contain some volatiles, but the high ambient pressure keeps most of them in solution. Those that come out of solution form bubbles, or vesicles; as expected, vesicles become progressively less abundant as eruption depth increases.

Explosive eruptions can be caused also by rapid transfer of heat from magma to water. At low pressures, boiling of water results in a ca. 1000× volume expansion, and rapid interaction of magma and water is highly explosive. Under greater pressure, however, expansion is much reduced and explosions far less feasible. At pressures greater than the critical pressure of water (at about 3-km water depths), steam explosions are not possible, at least under equilibrium conditions.

The nature of the eruptive site, particularly whether covered with thick loose sediment or formed of rigid rock, provides a final control on eruptive behavior. Magma approaches the surface in dikes that advance by crack propagation. Unconsolidated sediment is insufficiently rigid to crack, and the dike tip “stalls.” Simultaneously, the heat of the magma boils water in the sediment, the expansion pushing grains apart and allowing the mixture to behave as a soft plastic or viscous fluid. These effects combine to allow the magma to spread laterally into the sediment at shallow levels, commonly resulting in complex mixtures of magma and sediment termed *peperite*.

### B. Modern versus Ancient Examples

We discuss submarine lava flows and associated rocks (hyaloclastites, various types of breccias, and hypabyssal complexes) from presently active deep-sea midocean ridges, backarc basins, and seamounts and their ancient equivalents on land. Modern and ancient deposits are each useful in improving our overall understanding of submarine volcanism and are complementary in the sense that modern seafloor rocks can provide information that cannot be obtained from ancient rocks—and vice versa.

For example, volcanic rocks from modern deep-sea settings are fresh and chemically unaltered, in contrast to ancient examples that are usually chemically altered by burial at moderately high temperatures for long periods of geologic time. Moreover, on the modern seafloor it is possible to map the areal distribution and surface features of lavas and related rocks over large areas, sometimes many tens of square kilometers, which is not possible in ancient successions. Also, modern seafloor deposits have the advantage that their eruption depth is known. In the case of ancient deposits, the depth of eruption must be estimated, and this is difficult to do with accuracy.

On the other hand, modern ocean basins are much more poorly explored than the continents, and are geologically young (less than about 200 million years) compared to the age of the Earth (about 4.5 billion years); modern ocean basins are not representative of the full diversity of submarine volcanic products erupted over Earth's long history. Ancient succession also provide stratigraphic exposure, which allows investigation of the succession of events through time at a single site. In contrast, our view of modern seafloor deposits from bottom cameras, manned submersibles, and remotely operated vehicles (ROVs) is restricted to largely two-dimensional surface exposures, providing a snapshot of the present. Drilling into the deep seafloor by the Deep Sea Drilling Project (DSDP), the International Program for Ocean Drilling (IPOD), and the Ocean Drilling Program (ODP) has provided invaluable information about site histories, but drill holes cannot substitute for good three-dimensional exposure. Geologic work on the seafloor is also inherently more difficult (and more expensive) than comparable work on land, particularly at the outcrop (50- to 100-m) scale.

Another advantage of ancient deposits is that some important rock types, such as peperites, may produce no visible signs at the surface and are thus difficult to find, much less study, in modern deep-sea environments.

Ancient and modern deposits provide complementary pieces of the puzzle, together providing a better understanding of submarine eruptions.

## II. SUBMARINE LAVA FLOWS

Actively advancing submarine lava flows have been observed at shallow depths by scuba divers, but no deep-water eruptions have ever been witnessed. In the absence of direct observations of how deep-water lava flows behave, volcanologists use laboratory models and study active lava flows on land to better understand modern and ancient submarine flows. In general, the overall shape and small-scale features of lava flows are the result of a balance between cooling, which results in the formation of a solid crust over the lava, and the forces generated by flowing lava to deform and fracture this outer crust and produce a variety of surface textures (Fig. 1). In the case of submarine lava, flows erupting into cold water (about +2° to -4°C for the deep sea), the outer surface of the magma quickly chills to a glass; the rate of crust formation is much faster than for on-land flows. Lava flows erupting under glacial ice experience comparably rapid cooling rates, and subglacial eruptions are good analogs to deep-sea eruptions, not only because of the rapid chilling, but also because of the elevated pressure caused by great thicknesses of glacial ice or meltwater. Surface eruptions on Venus also occur under elevated pressure because of Venus's atmosphere.

Laboratory experiments and theoretical models of flowing lava also provide important clues about lava flows in general and submarine flows in particular. For example, laboratory "eruptions" of polyethylene glycol wax in tanks of cold sucrose solution produce flows very similar in shape and surface texture to several common types of submarine lava flows, including *pillow lava*, *lobate lava flows*, and various types of *sheet flows*. The experiments show that pillows form at the lowest effusion rates and gentlest slopes; gradually increasing the effusion rate or surface slope results in a progression to lobate flows, then lineated, folded, and jumbled sheet flows. By quantifying the cooling rates and physical properties of the wax and with appropriate scaling, it is now possible to estimate the effusion rates and emplacement times of various types of submarine lava flows.

Next we describe various types of known submarine lava flows.

**FIGURE 1** Schematic diagram showing the competing effects of cooling rate and volumetric eruption rate on the shapes and textures of lava flows coming from both point sources and line sources. Rapid cooling leads to the formation of crust (shown shaded), whereas large volumetric eruption rates and slow cooling inhibit crust formation. [Reproduced by permission of Elsevier from Fink, J. H., and Griffiths, R. W. (1992). A laboratory analog study of the surface morphology of lava flows extruded from point and line sources. *J. Volcanol. Geotherm. Res.* **54**, 19–32.]

### III. PILLOW LAVA

One of the most common types of submarine lava is called *pillow lava* because it consists of roughly spherical or rounded pillow-shaped forms. Pillow lava forms not only in the deep sea, but also when on-land lava flows into the sea, rivers, or lakes. Pillow lava has been observed forming in shallow water off the coast of Hawaii, where lava from Kilauea volcano enters the sea and continues to flow underwater.

The glassy surfaces of pillows are not smooth but have cracks, corrugations, and linear grooves, many of which intersect at right angles (Fig. 2). The outer crust of pillows forms adjacent to spreading cracks, which act like tiny versions of midocean ridges. Corrugations form at right angles to the spreading cracks, and together, the corrugations and spreading cracks define a cross-

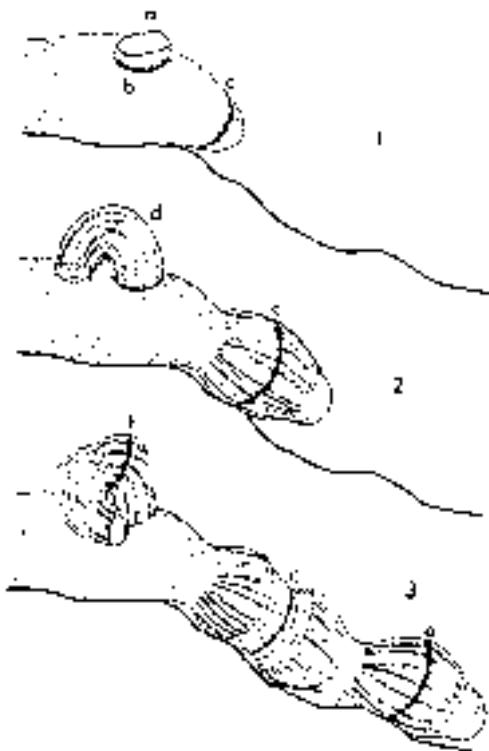

hatched pattern on the pillow surface. The spreading cracks form when the outer pillow crust fractures (Fig. 3).

Lava pillows are found in a wide variety of shapes including near-spherical bulbous pillows, flattened pillows, elongate and tubular pillows, and trapdoor pillows. In three-dimensional exposures on land, pillows commonly consist of interconnected tubes. A great variety of pillow shapes is shown in deep-sea photographic atlases listed at the end of the chapter and in many journal articles. They vary in diameter from several tens of centimeters to several meters, with typical sizes of 0.5–1 m. In many places, leakage of lava from cracks in pillows leads to the formation of small (5- to 15-cm) ellipsoid or ovoid pillow buds. These are commonly found on the undersides of pillows and, if abundant, appear to form a nest. In other cases, buds may decorate most of the pillow surface, and knobby pillows may be covered with elongate and knobby buds and elongate networks of pillow fingers. Buds differ from their parent pillows in that their outer surfaces are smooth, probably indicating such rapid growth that surface tension can reshape the still-liquid magma and destroy extrusion markings (Fig. 4).

The interiors of pillows cool more slowly than the quenched glass rind, and so are more crystalline. Progressive crystallization at slower cooling rates toward

**FIGURE 2** Submersible photo of a pillow on the Mid-Atlantic Ridge. The T points to a spreading crack from which the mirror-image pillow lobes grew. Prior to this growth, points S and U were adjacent. Note the cross-hatched pattern of tension cracks and perpendicular corrugations. [From Ballard, R. D., and Moore, J. G. (1977). "Photographic Atlas of the Mid-Atlantic Ridge Rift Valley." Springer-Verlag, Berlin.]

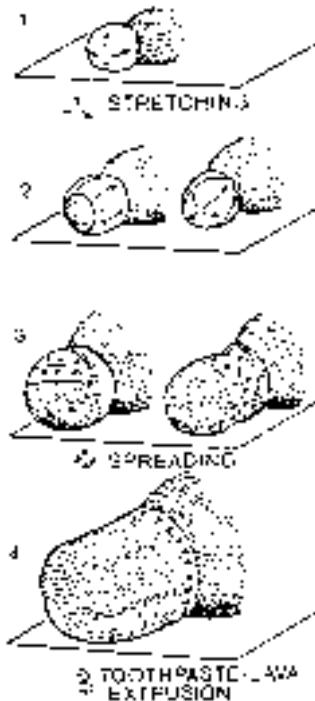

**FIGURE 3** Schematic diagram to show growth of pillow lava. Growth from a circular crack (b) produces a trap door pillow (a), which eventually grows to a toothpaste pillow (d) with a spreading crack (f) producing another lobe. Spreading at tension crack (c) produces corrugated pillow lobes, then slows down and stops, after which a new crack develops at (e). [Reproduced with permission from Ballard, R. D., and Moore, J. G. (1977). "Photographic Atlas of the Mid-Atlantic Ridge Rift Valley." Springer-Verlag, Berlin.]

the interior produces a variety of rock textures, and the interiors of large pillows may be almost entirely crystalline. Vesicles are common and are usually concentrated in concentric layers parallel to the outer surface. In on-land pillows, radial pipe vesicles are common. Many pillows are completely solid, although it is common for pillows to have central cavities ranging from small tubular channels in a mostly solid pillow to pillows that are entirely hollow. These cavities form when lava drains back out of a newly formed pillow (Fig. 5), or when lava pushes aside a portion of the outer pillow crust and drains out through the hole to form a spilled pool outside the broken pillow. On locally overhanging slopes, these pillow outflows can form thin strings or ropes of lava several meters long resembling thin stalactites. Drainage can also produce thin tabular lava shelves (Fig. 6) formed during discrete events. The shelves usu-

ally have glassy upper surfaces that may be decorated with stringers of lava that dribbled onto the shelf from above, and lower surfaces have frozen lava drips but little or no glass, probably because of their closer proximity to magma (not seawater or steam) during episodic draining.

Pillow lava is a common eruptive product at midocean ridges and its abundance is related to spreading rate. Slow spreading ridges tend to have more pillow lava than fast spreading ridges. Fast spreading ridges with broad cross-sectional shapes and inferred high magma budgets have fewer pillows in the immediate vicinity of the axis, although fresh pillows become more abundant a few kilometers from the axis, suggesting that they represent small-volume, low-magma-supply eruptions slightly off-axis. Pillow eruptions are also common on seamounts. Seamounts near fast spreading ridges have arcuate summit benches composed of pillow lava, and

**FIGURE 4** Schematic showing four possible modes of pillow growth. Stippling represents crust and lack of stippling indicates incandescent lava. (1) Uniform stretching leads to smooth outer surface, as in pillow buds and lobate pillows, (2) localized stretching, (3) symmetrical spreading, as in Fig. 2 above, and (4) toothpaste-like extrusion, as in Fig. 3 above. FIGURE 6 Sketch showing the development of drain back ledges in pillow or lobate lava. The dotted pattern indicates fluid lava, glass is shown by hatching, and water-filled regions are blank. [Reproduced with permission from Ballard, R. D., and Moore, J. G. (1977). "Photographic Atlas of the Mid-Atlantic Ridge Rift Valley." Springer-Verlag, Berlin.]

their steep flanks are composed almost entirely of tubular pillows oriented downslope.

Seafloor that is covered with pillow lava is topographically irregular, with relief of 1–5 m defined by networks of intertwined pillows piled irregularly over one another. Usually pillow flows build either conical piles 5–20 m high (Fig. 7) called haystacks, or linear steep-sided pillow ridges. At midocean ridges and the linear rift zones of large island volcanoes and seamounts, haystacks and pillow ridges tend to form discontinuous linear arrays, which may be fed by relatively narrow feeder dikes. In ancient seafloor preserved on land (ophiolites), larger piles 100–200 m high, called *pillow volcanoes*, are commonly recognized, and these are similar in size to modern pillow volcanoes at the axis of the Mid-Atlantic Ridge.

Pillow volcanoes identified in the Troodos ophiolite of Cyprus consist of megapillows, which grade upward into the main mass of normal pillows and tubes, and finally to upper parts consisting of minipillows and breccia. Megapillows are large (up to 6 m and larger) volcanic masses in the core of the pillow volcano and are interpreted as feeder systems for the pile (Fig. 8). It is possible that the cores of modern seafloor pillow volcanoes and haystacks also have megapillows or their equivalents in their interiors. Similar to the Cyprus pillow volcanoes, pillow lavas of the Archean Abitibi greenstone belt in Quebec, Canada, are parts of larger units that grade from nonpillowed lava at the base, to pillow lava, and finally to *pillow breccia* and stratified hyaloclastite at the top. As with the Cyprus deposits, megapillows are found just beneath normal pillows, and the pillow lava is believed to have formed at lower flow rate than the nonpillowed lava, consistent with wax experiments and other data indicating that pillows form at low extrusion rates. A nearly universal feature of well-studied pillow lava

FIGURE 7 Sketch of a 5–10-m-high haystack of the Mid-Atlantic Ridge. [Reproduced with permission from Basaltic Volcanism Study Project (1981). "Basaltic Volcanism on the Terrestrial Planets." Pergamon Press, New York.]

sequences, including those from present ocean basins, Cyprus, Canada, Cedros Island, and the seamount series of La Palma Island, is the decrease of pillow size toward the tops of individual pillow units.

Finally, in addition to conical and linear piles, pillows occur as important components of steep-sided prograding sequences that include flow-foot breccias (Fig. 9). Deposits of this type form in shallow water lava deltas and deep water lava prisms prograding outward from active volcanoes, and consist dominantly of breccia and hyaloclastite. On a small scale, steeply dipping pillow tubes and breccia are components of most deep-sea deposits of seamounts and ridge crests. Breccia and hyaloclastite are important components of flow-foot breccias and are inferred to form by three processes: thermal-shock granulation, *spall fragmentation* (the outer, solidified margins of lava break apart as the interior of the lava deforms and flows), and impact shattering, which occurs as lava pillows become detached from the flow on steep slopes and move as rockfall down to the foot of the flow prism. Modern seafloor pillows are relatively fragile because of the abundance of cooling cracks, whose radial distribution explains why pillows tend to break into tetrahedral pie- or wedge-shaped pieces.

Pillows in the deep sea and on land are generally basaltic to andesitic in composition although rare pillows of dacitic or rhyolitic composition are found on land. Some pillows of Archean age are ultramafic in composi-

tion (called komatiites), unlike any modern ocean floor deposits. These pillows, much richer in MgO than basalt, erupted at much higher temperatures and were much more fluid than ordinary basalts; their unusual composition provides evidence that Earth's mantle may have been hotter early in its history.

#### IV. LOBATE LAVA FLOWS

Superficially, lobate lava flows resemble pillow lava in having tubular and subspherical shapes (Fig. 10). However, lobate lava is more flattened, and, most impor-

tantly, the outside surface is not striated but rather is smooth or has a tortoise shell texture of contraction-fractured glass. Probably, individual lobes of lobate lava grow by early formation of a flexible crust that is carried along without further stretching atop an advancing liquid flow (Fig. 4, panel 1). In places where eruptions produce densely packed lobes, the lobes coalesce below the surface crust, as might be expected for lava flowing quickly and carrying its semirigid top crust with it as it advances. At fast spreading midocean ridges with domed or flat cross-sectional shapes, lobate lava comprises a large part of the surface lava (Fig. 11). Commonly, lobate lava flows have abundant drain back shelves or are entirely hollow, and in this they resemble shelly pahoehoe flows. In terms of internal structure, lobate lava closely resembles pillow lava, although lobate lava is more commonly hollow.

At fast spreading ridges, lobate lava appears to form at the surface of filled lava pools, which can subsequently drain away leaving collapsed rubble of lobate flows. At the margins of drained lava pools, lobate flows mark the lava level prior to drainage. A common feature of drained lava ponds is lava pillars (Fig. 11). These pillars may be tens of meters in height, have hollow centers lined with glass, and ragged exterior surfaces of truncated lava shelves that appear to record episodic drainage of the pool around the pillar. It is thought that lava pillars

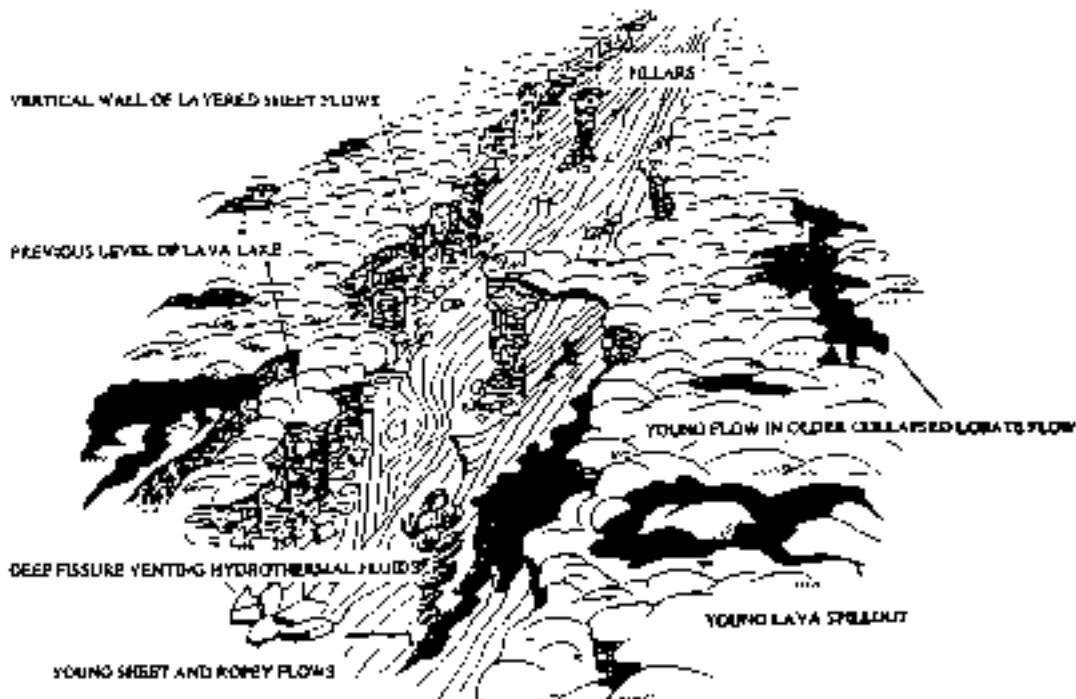

represent pathways for seawater escape at the time that the lava pool first filled with magma, presumably very rapidly. Alternatively, lava pools may “fill” slowly, essentially by inflation of lobate flows. In this case, the lava pillars would form slowly, as the magma level of the pool gradually rises. Because of the strong association of lobate flows with filled and drained lava pools, it is thought that lobate flows are generally tube fed or represent “spillover” from lava ponds that overflow. In some places, lobate flows appear to form at the edges of sheet flows (Fig. 10), possibly as the result of lateral breakouts.

Because lobate lava resembles pillow lava in shape and internal structure, it is possible that some of the flattened tubular “pillow” lava described from ancient submarine volcanic deposits, such as in the Abitibi, is actually lobate lava instead. This is understandable, because lobate lava has only recently been identified on the seafloor, postdating the descriptions of many ancient deposits of “pillow” lava. Moreover, the distinction between pillow and lobate lava can only be made if the exposure and preservation are such that it is possible to differentiate between lineated and striated outer crust (pillows) and smooth crust (lobate lava), which is often difficult in ancient deposits.

In some ancient deposits containing pillow lava and fragmental rock, there occur very thin sheet flows and flattened, somewhat ragged pillows, termed *para-pillow*

FIGURE 10 Bottom camera photo of a lobate flow on the summit of a small seamount near the East Pacific Rise. In this case, the lobate flows seem to emanate from edges of the lineated and folded sheet flow at the right.

**FIGURE 11** Composite sketch of the summit of the East Pacific Rise showing some of the characteristic lava flow morphologies. Most of the lava outside the collapsed region is lobate lava. Dark lava is relatively young. Not shown are young pillow eruptions that occur a kilometer or more away from the axis. [Reproduced with permission from Perfit, M. R., and Chadwick, W. W. J. (1998). Magmatism at mid-ocean ridges: Constraints from volcanological and geochemical investigations. Pages 59–115 in “Faulting and Magmatism at Mid-Ocean Ridges,” Geophysical Monograph 106. American Geophysical Union, Washington, DC.]

*lava* and interpreted as pillow lava that failed to inflate because of an unfavorable balance between cooling rate, flow velocity, and magma supply rate. Para-pillows may form on steep slopes, especially if the magma supply needed to inflate a pillow is unsteady; scuba divers have observed para-pillows forming on the active lava delta of Kilauea volcano. Lobate lava and para-pillow lava may be related in the sense that they both represent significant variants of pillow lava: higher volumetric extrusion rate in the case of lobate flows, and steeper slopes in the case of para-pillows.

##### V. SHEET FLOWS

Sheet flows are found most commonly at fast spreading centers, but also occur at slow spreading centers and seamounts. Sheet flows have a variety of surface features resembling those of subaerial pahoehoe flows including smooth surfaces, lineations, ropes, swirls, coils, folds,

and jumbled surfaces produced by deformation of the lava crust. Sheet flows may be primarily fed by lava tubes, and in a well-documented example from the caldera floor of Axial volcano on the Juan de Fuca Ridge, sheet flows with tumuli and other features indicate thickening of sheet flows by lava inflation. It is well known that there are no systematic differences in the chemical composition of pillows, lobates, and sheet flows in modern submarine settings; thus, these differences in flow morphology are produced by differences in the magma supply rate, underlying topography, and conditions of flow, as discussed previously. Sheet flows are common in ophiolites and other ancient deposits of submarine volcanic rocks. They typically are massive flows and in many places have columnar jointing and vesicles distributed in a variety of different patterns. In the Cyprus ophiolite, edifices consisting mostly of sheet flows, with only small amounts of pillows, have been identified.

A rare type of submarine lava that in some ways resembles sheet flow lava consists of thin (1–3 cm or less) very complexly folded tabular sheets or septa lacking glassy

outer crusts. These intricately folded masses have abundant thin lava septa and curved, even subspherical folds. Informally, such lava has been called “cow-heart” lava and is known mostly from dredges of the East Pacific Rise and near-ridge seamounts. In some places this lava type has abundant tiny fragments of nonglassy basalt weakly welded to its surface, much like how salt crystals are “welded” to pretzels. The absence of glass suggests that the lava was erupted in hot surroundings, then cooled relatively slowly. This may take place within “ceiling spaces” of partly drained flows in which cold seawater is absent. In shape, cow-heart lava resembles the lava making up submarine hornitos on Teahitia seamount in the Society Islands.

---

#### VI. WELDED SPATTER

While fire fountaining activity in deep water is probably a rare phenomenon because the high-pressure greatly inhibits the volatile exsolution needed for fountaining, there are, nevertheless, some deep water *spatter* deposits that appear to be the products of such activity. For example, a deposit about 1 million years old, 135 m thick, and apparently consisting of vesicular basaltic welded clasts was sampled by drilling in the Sumisu rift, a backarc basin behind the Bonin arc. Eruption is inferred to have occurred in water more than 1800 m deep. A somewhat similar deposit of welded spatter, in this case overlying hyaloclastite, was described from Cyprus. Some material in this deposit appears to have flowed for some distance as a rootless flow, and the deposit overall is interpreted as the result of a greatly suppressed submarine fire fountain, with the spatter possibly created within a fissure vent before being weakly expelled onto the seafloor. Products of Archean subaqueous rhyolitic fire fountaining have also been identified and require low-viscosity melt, inferred to have resulted from both high eruption temperatures and some retention of dissolved volatiles (relative to explosive onland eruptions) at the high ambient pressure of the subwave-base eruption site.

---

#### VII. SILICIC LAVA FLOWS

Rhyolitic eruptions are rare on the modern seafloor, perhaps because modern sea level is relatively low and

most rhyolite is erupted subaerially on the thick crust of well-established arc systems. At various times in the past, sea levels were higher, and island arc sequences in which subaqueous eruption of rhyolite was relatively common formed along young subduction systems lacking thick crust. Pillow lava of dacitic or rhyolitic composition has not yet been found in modern deep-sea environments, but ancient pillows of rhyodacite composition have been described from several localities including the Ordovician of Wales, where a 40-m-thick lava flow grades upward from massive lava into pillows and pillow tubes and then into pillow breccia. Other types of silicic lava flows are quite rare at midocean ridges but appear to be more common in backarc basins. Such flows have been described from the Sumisu Rift, the Mariana Trough, the Lau Basin, and others. In the Lau Basin, silicic rocks occur near propagating ridge tips, as at many other locations along the midocean ridge. In backarc basins, these rocks occur mostly as dome-shaped masses of 1 to several kilometers in diameter, consisting of massive and blocky lava with abundant obsidian. Blocky flows of dacitic lava are found on the Kasuga seamounts in the Mariana backarc basin. Vesicularity of silicic rocks varies greatly and it seems likely that most have undergone some degassing because most are not pumicious, whereas in-place pumice has been dredged from the top of a rhyolite lava dome at 3600-m depth on the west flank of the Mariana Trough.

Many submarine silicic flows preserved in the geologic record are laterally extensive (up to 10 km), dome-shaped, or stubby, tabular masses that are massive near the feeder conduits and grade outward to more fragmental distal facies. Commonly, the units have large lava pods, lobes, and tongues with borders of obsidian in a matrix of silicic breccia, hyaloclastite, and lava fragments. Such units have been described from the Archean of Canada, the Miocene of Japan, and other localities; the breccia flow volcanoes of the Troodos ophiolite are similar. The inferred mode of growth of these large domal complexes (Fig. 12) is thought to be similar to that of silicic domes on land. Given the similarity in size and shape between modern and ancient silicic flows, it seems likely that the modern examples have internal structures and facies development similar to that of the better exposed ancient examples. Much more extensive subaqueous rhyolitic flows, with single flow units only tens to a few hundred meters thick yet extending over 2000 km<sup>2</sup>, have been described from the Paleozoic of Australia, but no modern analogs have been recognized.

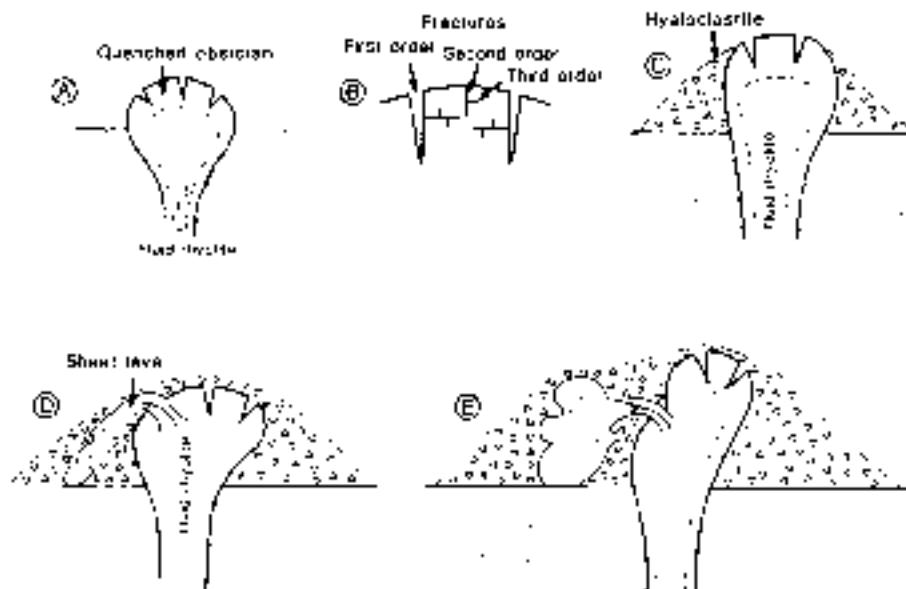

FIGURE 12 Inferred mode of growth of ancient silicic domes and stubby flows from Japan and the Archean of Canada. The hyaloclastite is produced by fragmentation of the rhyolite lava. [Reproduced with permission from Yamagishi, H., and Dimroth, E. (1985). A comparison of Miocene and Archean rhyolite hyaloclastites: Evidence for a hot and fluid rhyolite lava. *J. Volcanol. Geotherm. Res.* **23**, 337–355, Elsevier Science.]

### VIII. HYALOCLASTITES AND ASSOCIATED ROCKS

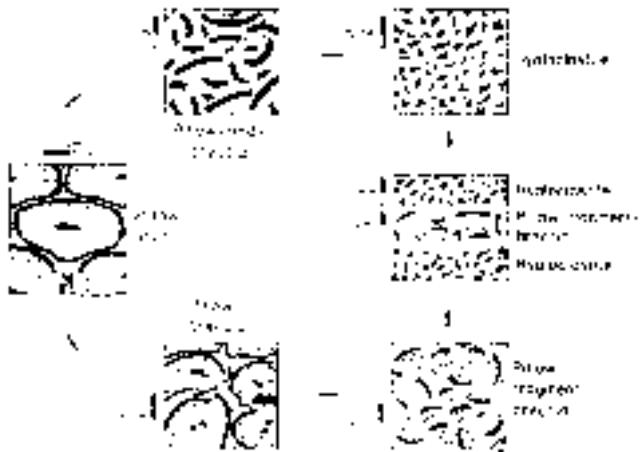

The term *hyaloclastite* means glass-fragment rock. Broadly used, *hyaloclastite* includes all glassy fragmental debris formed by eruptions in which water is involved. Another common usage of the term, adopted here, limits hyaloclastite to glassy debris formed by essentially non-explosive processes related to rapid aqueous cooling of magma. In this sense, *hyaloclastite* is a subset of *hydroclastic rocks*, which include all clastic rocks resulting from fragmentation of magma involving water. Hyaloclastites with a large variety of characteristics are produced from magma erupted at sites that range from subaerial volcanoes to those of the abyssal deep sea. They occur on many types of volcanoes, and virtually all magmatic compositions are represented. Hyaloclastites and other hydroclastic rocks are known to form during subglacial eruptions, by phreatomagmatic fragmentation, under shallow submarine conditions at emergent islands, and in the deep-sea in island arcs, midocean ridges, and seamounts. In ancient submarine volcanic deposits preserved on land, submarine lava flows are almost invariably associated closely with hyaloclastites and a variety of other fragmental breccia deposits. Submarine stratigraphic associations, when studied in detail, can provide

important clues about the nature, causes, and detailed behavior of deep water eruptions. These common associations in ancient rocks probably occur in modern deep-sea environments, but since we are restricted to observing only the surface of the youngest deposits the associations may not always be obvious.

Hyaloclastite forms under a range of conditions, and interpreting the conditions of formation requires detailed study at regional, outcrop, and microscopic scales. On land, ancient hyaloclastites may be exposed in three dimensions and mapped over large areas, and study of the hyaloclastite features and stratigraphy can give a temporal perspective on eruption progress and lateral facies changes (Fig. 13). In contrast, for deep-sea deposits it is very rare to have stratigraphic information. This makes comparisons between ancient and modern hyaloclastite sequences difficult.

### IX. HYALOCLASTITES FROM THE PRESENT SEAFLOOR

Hyaloclastite is rare at midocean ridges, but more common at deep water (>1500– to 2000-m) seamounts. Hyaloclastites from deep-water seamounts near the East

**FIGURE 13** Schematic diagram showing relationships among various types of breccia units that may be produced from lava flows. It is important to note that pillow lava is not the only type of submarine flow that can produce breccia units and, further, that in some cases, moderate volumes of fine-grained hyaloclastite may be produced directly from flows without an intervening breccia stage. [Reproduced with permission from Schmincke, H.-U., and Bednarz, U. (1990). Pillow, sheet flow and breccia flow volcanoes and volcano-tectonic hydrothermal cycles in the Extrusive Series of the northeastern Troodos ophiolite (Cyprus). In "Ophiolites: Oceanic Crustal Analogs, Proc. Symp. Troodos 1987," (J. Malpas, E. M. Moores, A. Panayiotou, and C. Xenophontos, eds.). The Geological Survey Department, Republic of Cyprus.]

Pacific Rise were studied in the late 1980s and an additional submersible study of the deposits on Seamount 6 took place in 1995. It is now apparent that these thin (<1-m-thick) hyaloclastites are the result of thermal shock granulation and spalling of thin lava flows, because the chemical composition of most of the glass fragments in hyaloclastite is identical to that of underlying glassy lava flows. In addition, samples of flow-hyaloclastite couplets show that the flows have very irregular tops, with thin lava tendrils breaking up to shed contorted and shattered glass fragments into the overlying blocky, polyhedral glass grains of contemporaneous hyaloclastite. A small proportion of thin, fluidal particles occurs in the hyaloclastite and resembles "limu of Pele" produced when lava from Kiluaea volcano enters the sea and interacts with seawater. Probably all *limu* are produced by the fragmentation of magma bubbles inflated by seawater steam when thin, very fluid, basalt flows trap small volumes of seawater. In many cases, limu from Seamount 6 are intricately folded and the folds welded together, indicating that the magma was still hot when the bubbles burst. Limu are found also at the underwater summit

of Loihi volcano, south of the big island of Hawaii. The summit of Loihi is ~1000 m below sea level and portions of the summit are covered with loose glass fragments. While the origin of limu-bearing hyaloclastite is still being studied, it appears that local mixing of magma with seawater and production of steam-filled magma bubbles have played a significant role.

Hyaloclastites from Seamount 6 near the East Pacific Rise are thin and in part finely laminated deposits with normal grading and imbrication of platy fragments, consistent with deposition from some sort of suspension density flow. Gravitational potential energy is needed for density flows, but obvious upslope sources are lacking and the glass fragments may have been lofted above the seafloor as they formed. A previous hypothesis was that lofting was accomplished by submarine lava fountaining. While this notion cannot yet be ruled out, several lines of evidence argue against it: (1) vents from fire fountains containing spatter and other vesicular clasts have not been found despite very thorough searches using submersible and bottom cameras; (2) alleged cow-dung bombs identified in the late 1980s are actually thin lava tendrils from the underlying lava flow incompletely covered by hyaloclastite and very thickly covered with manganese; and (3) theoretical models of gas exsolution at high pressures underwater, and low volatile abundances in the Seamount 6 glass, argue strongly against sufficient gas pressure at depths of about 2000 m to produce fountaining.

Alternative hypotheses for a lofting mechanism include gas storage at depth to produce strombolian activity, magma–water interaction to produce steam explosions, and "squirting" of magma at high velocity. The latter notion has been invoked to explain the observation that pillows commonly grade upward into breccia and hyaloclastite. It is proposed that upward growth leads to narrowing of branching magma conduits such that the same volumetric eruption rate and magma pressure that produces pillows from wide conduits would produce breccia and eventually hyaloclastite as the conduits constrict. In this case, production of glass fragments would be by thermal shock granulation.

Hyaloclastites have not been reported from the fast spreading East Pacific Rise, despite fairly intensive study of the ridge axis at many locations. It thus seems likely that hyaloclastite is extremely rare, or perhaps even nonexistent at fast spreading ridges. At the medium spreading Juan de Fuca Ridge, hyaloclastite has been recovered in several dredge hauls at the Blanco escarpment. Along the slow spreading Mid-Atlantic Ridge, hyaloclastite has been found south of the Azores at depths from 1700 to 500 m. The amount of hyaloclastite increases greatly as

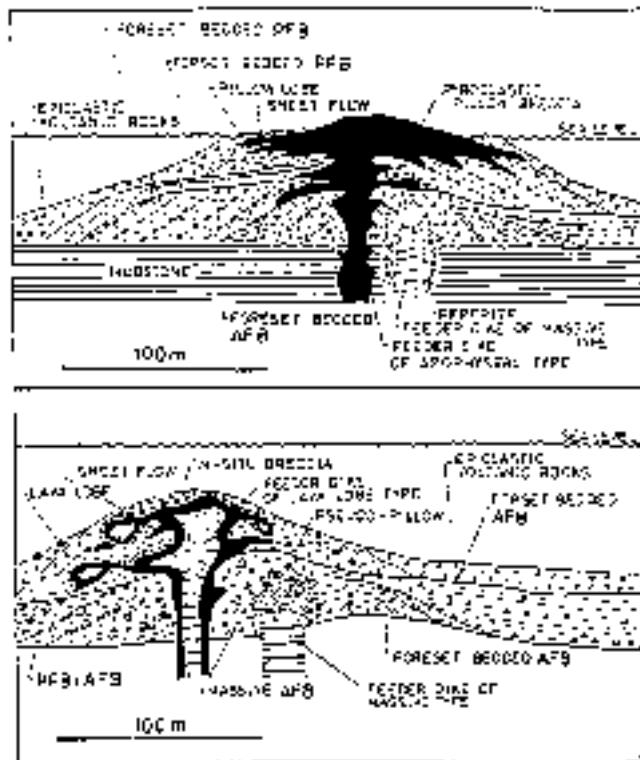

FIGURE 14 Shallow submarine volcanoes illustrating arrangement of lavas, intrusions, and hyaloclastite. Upper frame illustrates mafic to intermediate volcano, with intermediate to felsic products shown in lower frame. Pyroclastic pillow breccia is another name for isolated pillow breccia. Pseudo pillows are concentrically fractured coherent lava. [Reproduced by permission of Elsevier Science. From Yamagishi, H. (1991). Morphological and sedimentological characteristics of the Neogene submarine coherent lavas and hyaloclastites in Southwest Hokkaido, Japan. *Sed. Geol.* **74**, 5–23.]

water depth decreases, and many of the glass fragments, especially from shallow water depths, are highly vesicular. Thus, it is possible that these deposits are partly the result of magmatic explosive activity. In contrast, most hyaloclastite fragments from east Pacific seamounts have no vesicles.

Additional hyaloclastites, probably produced at the Mid-Atlantic Ridge, were drilled by the Deep Sea Drilling Project, Leg 46, at site 396B. Drilling into 13-million-year-old ocean crust penetrated 170 m of pillow basalt and then encountered a 90-m-thick unit consisting mostly of unconsolidated, sand-size, fresh basalt glass fragments. Although this deposit apparently does not contain limu and is very thick, its good layering, sheetlike distribution and sand-size grains strongly resemble those of the hyaloclastites found on East Pacific

Rise seamounts. Study of this deposit indicates that fragmentation to produce glass fragments was roughly synchronous with eruption, and granulation of thin glassy lavas by thermal shock is a good possibility.

The absence of hyaloclastite from fast spreading ridges and its occurrence at slow spreading ridges and

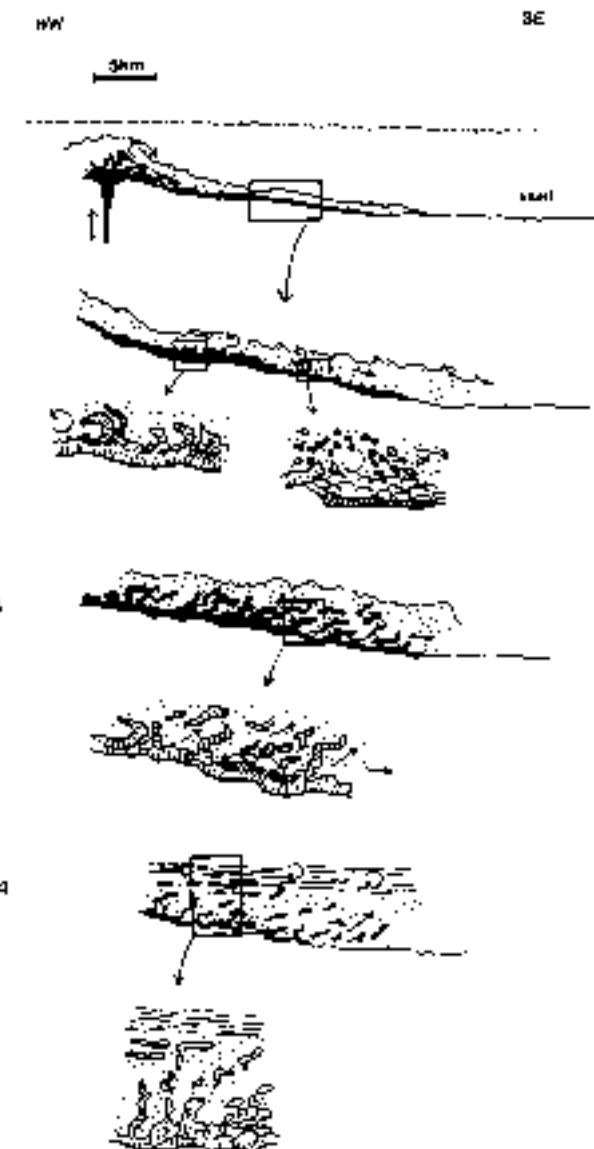

FIGURE 15 Inferred mode of emplacement for lava-hyaloclastite depositional unit from a single subaqueous eruption on the Iceland shelf. Where lava penetrates upward into its clastic capapace, "self-peperitic" mixtures typically result. [Reproduced by permission of Springer-Verlag. From Bergh, S. G., and Gudmundur, E. S. (1991). Pleistocene mass-flow deposits of basaltic hyaloclastite on a shallow submarine shelf, South Iceland. *Bull. Volcanol.* **53**, 597–611.]

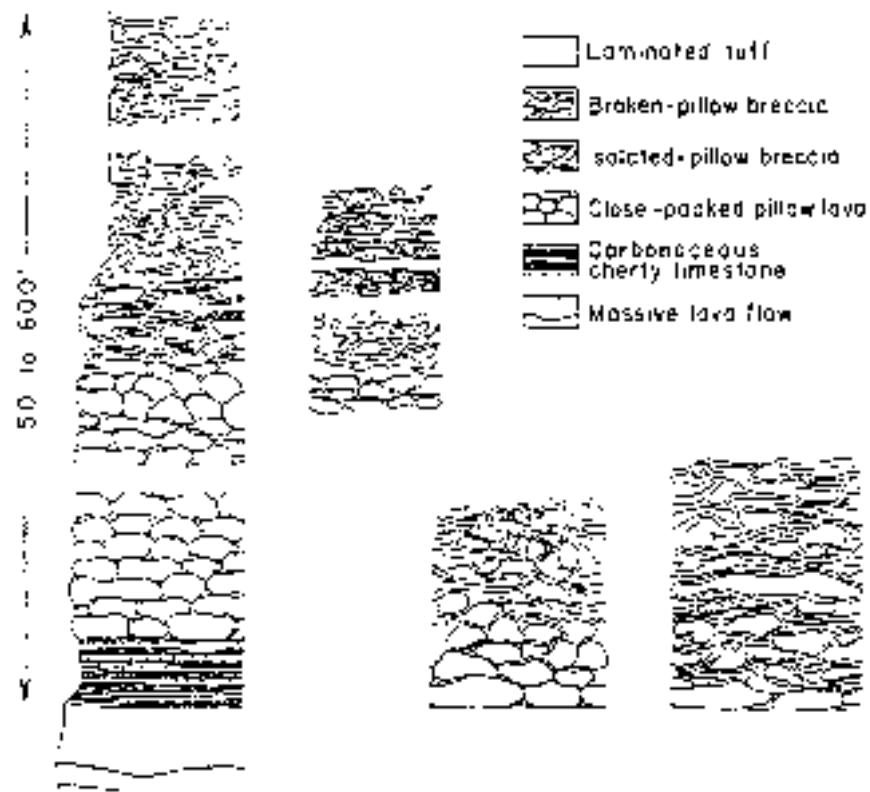

Pacific near-axis seamounts suggest another possible explanation for the genesis of hyaloclastites and the nature of hyaloclastite eruptions. It is particularly surprising that hyaloclastite has not been found along the East Pacific Rise, because there seems to be general agreement that thermal shock granulation is favored by high-volume eruption rates. If so, and given that the flow types at the axis of the East Pacific Rise indicate very high eruption rates, why is there no hyaloclastite? One possibility is that pelagic sediment plays a key role in the production of hyaloclastite; the axis of the East Pacific Rise has virtually no sediment, whereas the axial valleys of medium and slow spreading ridges typically do have pelagic sediment. Likewise, the flat summits and small flank basins of seamounts are known to have abundant pelagic sediment.

Evidence in favor of a role for pelagic sediment is the observation that the thin contemporaneous flows underlying hyaloclastite on Seamount 6 commonly have

large (up to 10 cm across) roughly cylindrical vugs produced by folding, and these vugs are partly to completely filled with pelagic ooze. In addition, the hyaloclastite contains abundant pelagic fossils in the matrix. Fossils could be added by erosion of sediment by a turbidity current or initially during mixing of magma with pelagic sediment. If a submarine lava flow advances over water-saturated, low-density pelagic ooze, there may be opportunity for mixing needed for thermal shock granulation, as well as for ingestion of water-laden sediment to expand and form limu bubbles.

#### X. ANCIENT HYALOCLASTITES

Despite the apparently limited occurrence of hyaloclastite on the modern seafloor, bodies of hyaloclastite

**FIGURE 16** Pillow lava and related breccias typical of the ancient submarine plateau forming the Wrangellia terrane. Pillow breccia consists of whole and broken pillows with or without a finer-grained matrix of polyhedral glass fragments. It forms when pillows break loose and avalanche downslope during extrusion, breaking apart as they travel. Isolated pillow breccia contains a large hyaloclastite component that may include vesicular clasts. [Reproduced with permission from Carlisle, H. (1963). Pillow breccias and their aquagene tuffs, Quadra Island, B. C. *J. Geol.* **71**, 48–71, University of Chicago Press.]

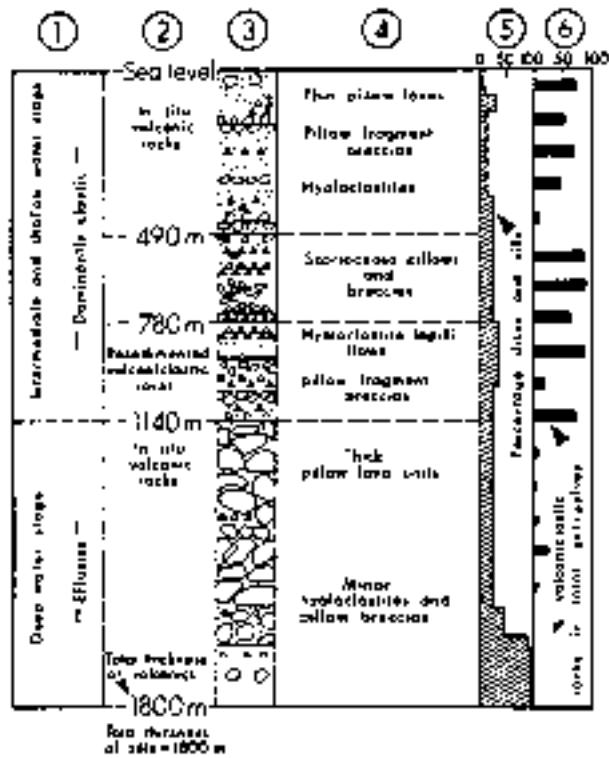

FIGURE 17 A gradual change from pillow lava to hyaloclastite in the uplifted seamount of La Palma is inferred to reflect decreasing depths of eruption. Scoriaceous pillows and breccias have abundant vesicles (cf. isolated pillow breccia, pyroclastic pillow breccia.) [Reproduced with permission from Staudigel, H., and Schmincke, H.-U. (1984). The Pliocene seamount series of La Palma/Canary Island. *J. Geophys. Res.* **89**, 11,195–11,215.]

and related breccias are very commonly associated with subaqueous lavas in ancient seafloor successions. For seafloor formed in open-ocean spreading systems there is only minor hyaloclastite, and it typically occurs as infillings between lava pillows or flows. Study of this material is usually hindered by poor preservation, because the glassy fragments are more easily altered than coherent lava. The zones or layers of fragments also tend to be mechanically weak and thus more strongly affected by tectonic strain that accompanies the incorporation of seafloor into thick crust and its uplift above sea level. No good examples of hyaloclastite similar to the modern ones represented by those at Seamount 6 have yet been recognized in ancient successions.

In contrast, hyaloclastite and related breccias may make up the bulk of deposits formed by eruptions at relatively shallow depths and/or on the steep slopes of seamounts, flanks of island volcanoes, and volcanic plateaus (Fig. 14). Near the source vent, deposits tend to have ragged or irregular tubes of coherent lava surrounded by glassy, ragged to blocky polyhedral and locally fluidal clasts. The most common deposits consist of unsorted breccias comprising blocky polyhedral glass fragments and whole or partial pillows in thick, structureless beds with poorly defined boundaries. The breccias appear to originate largely by spalling of stiff, quenched flow margins (essentially an enhanced-chill version of the subaerial “autobrecciation” process that forms the ragged, clinkery surface of aa flows). Thermal

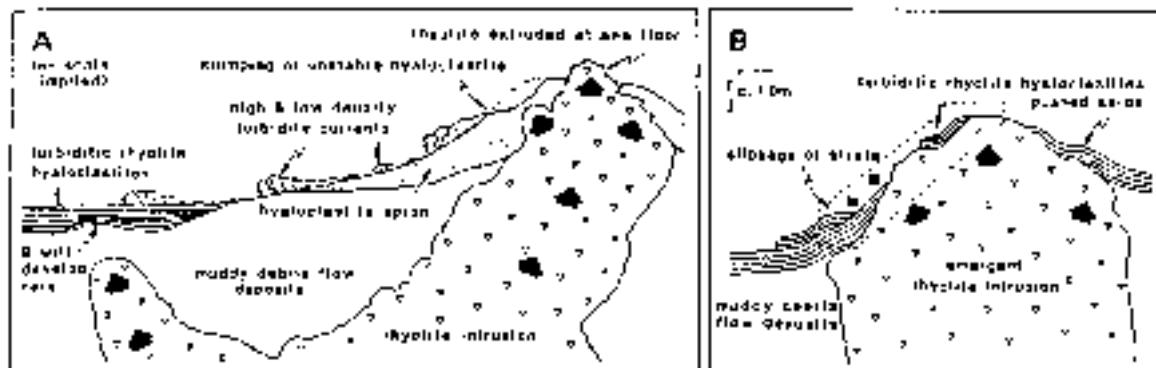

FIGURE 18 Diagram showing rhyolitic hyaloclastite formed as a partly intrusive rhyolite breached the surface and developed a carapace of in-place hyaloclastite. Some of this hyaloclastite was redistributed by debris flow and turbidity currents whose deposits were subsequently intruded by the growing rhyolite. [Reproduced with permission from Kokelaar, B. P., Bevins, R. E., and Roach, R. A. (1985). Submarine silicic volcanism and associated sedimentary and tectonic processes, Ramsey Island, SW Wales. *J. Geol. Soc. London* **142**, 591–613.]

shock granulation probably produced the less voluminous component of finer grains, further augmented by shattering of the margins of larger clasts when they jostle against one another during growth of the lava-breccia flows. Pillows develop by budding from the margins of the fluid lava within the flow, often intruding into the breccia carapace, formed from the same flow. Occasional avalanches disrupt parts of the flow and carry the debris downslope to form the poorly bedded deposits.

Some deposits consist almost entirely of concentric "pillows" which are small (ca. 10–50 cm in diameter) subspherical clasts of basalt containing scattered vesicles that have glassy margins with quench crystallites and concentric joints. Hyaloclastite from thermal shattering fills the interstices of the deposits, which grade downward to pillow breccias, the overall sequence being ascribed to decreasing eruption rate. Angular-fragment breccias consist of polyhedral fragments, some having jigsaw-fit textures indicating in-place fragmentation, with varying amounts of matrix consisting of quench granulated hyaloclastite. Work in Iceland indicates that many such complex mixtures of hyaloclastite, hydroclastic breccia, and coherent to dismembered lava can be generated in a short time by ongoing fragmentation and

remobilization of fragments during emplacement of a lava (Fig. 15). Dikes with highly irregular to periperritic margins wind through the sequences.

Pillow breccia forms an important part of a vast ancient submarine basaltic lava plateau now exposed as the Wrangellia terrane along the northwestern coast of North America (Fig. 16). An early and influential study of these rocks also identified tiny spheres or globules of glass as an additional minor but significant component of some deposits, and inferred that they formed from submarine lava fountaining of a very fluid lava. Individual layers of pillow breccias are up to 200-meters thick where they were studied. Similar thicknesses of pillow breccia and hyaloclastite are widespread in ancient island arc sequences uplifted and exposed in Japan, Baja California, and tectonically accreted island arc terranes in eastern Oregon.

The succession of eruptive products formed as a volcano grows upward from deep water is represented by the well-studied submarine series of La Palma in the Canary Islands, which exposes an almost 2-kilometer-thick succession of volcanic rocks erupted in water depths ranging from about 1800 m to sea level (Fig. 17). An upward increase in the proportion of fragmental debris is characteristic of such successions, and develops

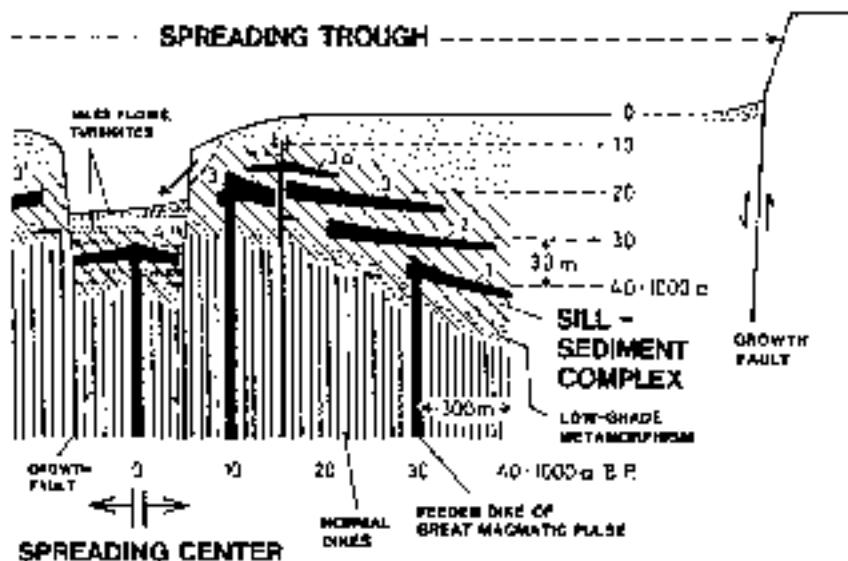

FIGURE 19 Hypabyssal sill–sediment complex developed within seafloor sediments of the Gulf of California. Dikes do not propagate through weak, water-saturated sediment, and the low density of the sediment allows magma to spread laterally into it, aided by fluidization of sediment where steam is formed at the contact between magma and interstitial water in the sediment. [Reproduced with permission from Einsele, G. (1986). Interaction between sediments and basaltic injections in young Gulf of California-type spreading centers. *Geol. Rundsch.* **75**, 197–208.]

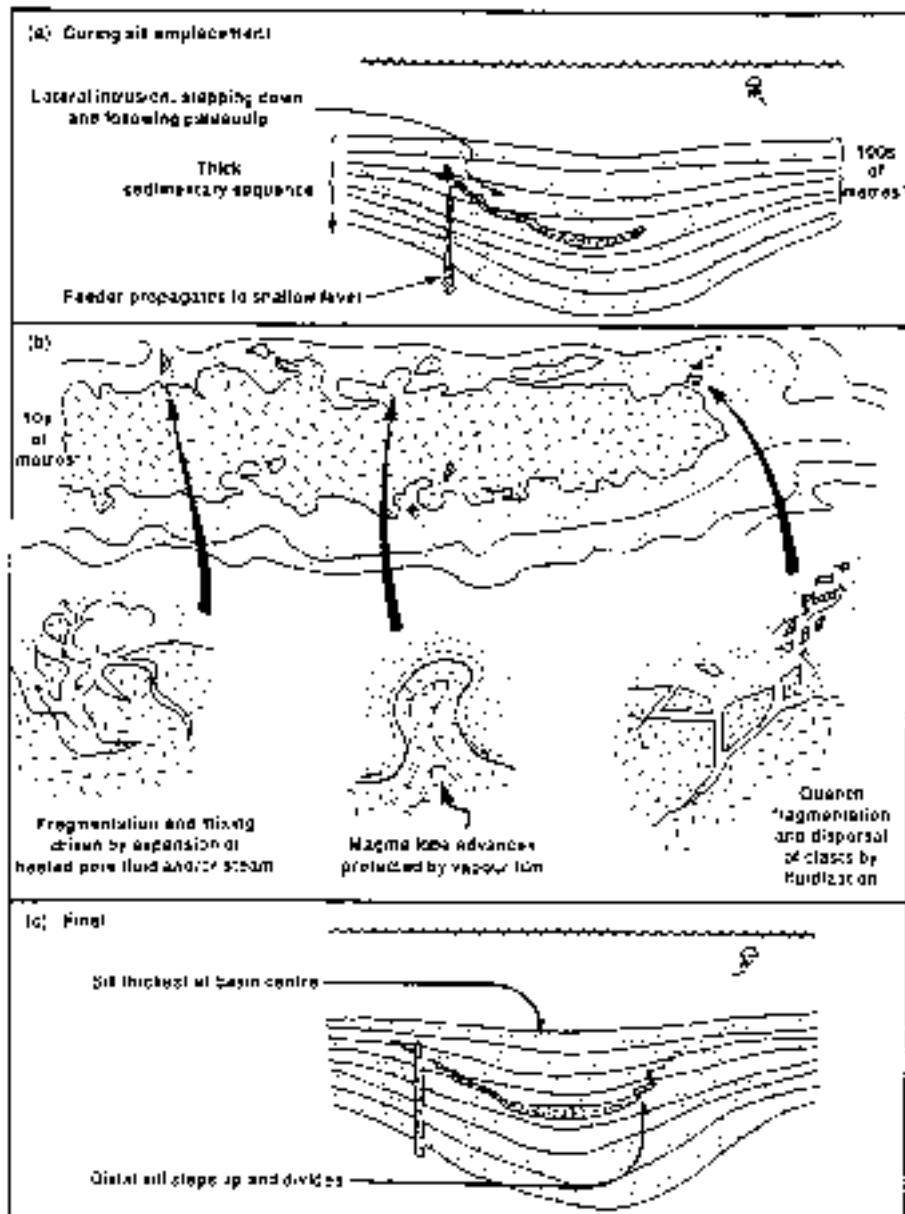

FIGURE 20 Model for emplacement of an extensive hypabyssal silicic intrusion with peperite margins. The lateral scale of parts (A) and (C) is tens of kilometers, and the thin, irregularly tabular geometry is quite different from that of rhyolite domes and stubby flows, and indicates fluidal behavior of the magma where emplaced beneath substantial sediment at sub-wave-base depths. [Reproduced with permission from McPhie, J. (1993). The Tennant Creek porphyry revisited: A synsedimentary sill with peperite margins. Early Proterozoic, Northern Territory. *Austral. J. Earth Sci.* **40**, 545–558, Blackwell Science.]

because both magmatic and steam explosivity are more effective in fragmenting the erupting magma at decreased hydrostatic pressure. Pillow breccias of unusual amoeboid and scoriaceous pillows and hyaloclastite were apparently produced in-place at La Palma by eruptions

at depths of about 800 m and shallower, with pillow lava and minor hyaloclastite produced at deeper depths. Active seamounts whose summits are in water shallower than about 1000 m probably have similar shoaling successions.

## XI. RHYOLITIC HYALOCLASTITES

Like silicic lava flows, silicic hyaloclastites have been far more commonly identified in ancient rock successions than on the modern seafloor. Subaqueous eruption of rhyolite typically occurs in rift settings, which commonly accumulate thick layers of seafloor sediment. Though much erupting magma in such settings is “captured” within seafloor sediments (see ancient hypabyssal complexes below), growing rhyolite domes can breach the seafloor and form thick carapaces of rhyolite hyaloclastite. These hyaloclastites consist of relatively coarse, glassy fragments of nonvesicular to even pumiceous rhyolite and blocky, finer-grained hyaloclastite. Debris flows typically redistribute hyaloclastite breccia from the carapace onto the surrounding seafloor, and finer material winnowed from the flows can form widespread turbidite beds of hyaloclastite ash. Such “emergence” of an intruding rhyolite forms a single rhyolite dome surrounded by in-place hyaloclastite, associated hyaloclastite debris-flow deposits and turbidites, and traceable downward into a hypabyssal intrusion (Fig. 18). Similar sequences have been described from both the Miocene of Japan (Fig. 12) and the Archean, and other examples of various ages are known from Australia.

## XII. HYPABYSSAL INTRUSIVE COMPLEXES: INTRASEDIMENT EXTRUSION

The occurrence of hypabyssal complexes, rather than seafloor lava flows, where subaqueous eruptions occur

in the presence of thick unconsolidated sediment was predicted in the early 1960s on the grounds that the density of rising basaltic magma is greater than that of wet sediment. This prediction was confirmed in a modern setting when the Deep Sea Drilling Program discovered thick hypabyssal complexes in the Gulf of California in 1979. Here seafloor spreading has recently separated peninsular California from mainland Mexico, and the spreading center is flooded with sediment derived from the adjacent landmasses (Fig. 19). Magma erupting from the spreading center encounters these uncompacted, waterlogged sediments and cannot rise upward through them, instead spreading laterally within the sediments to form *sill-sediment complexes*. The margins of such sills would be expected to display peperite or intrusive pillows, but unfortunately the drillcore recovery was insufficiently complete to evaluate the nature of the sill–sediment contacts; to learn more, we must examine ancient examples.

## XIII. ANCIENT HYPABYSSAL COMPLEXES

Hypabyssal complexes are now recognized as a very common component of ancient island-arc volcanic sequences, and are closely associated with a variety of hydrothermal metal deposits. In one example, peperite (a mixture of magmatic fragments and sediment) has been identified along the margins of a Proterozoic rhyolitic body that is tens to a few hundreds of meters thick and forms an approximately 100-km-long outcrop belt hosting gold-bismuth-copper hydrothermal deposits. It is inferred that the body represents a single, rather large

FIGURE 21 Large tabular to tubular andesite bodies and an abundance of co-erupted peperite and intrusive pillows form a hypabyssal complex intruded into host argillite sediments at Unalaska Island. The entire sequence illustrated, >100 m thick and nearly 1 km across, is intrusive except for the argillites. [Reproduced with permission from Snyder, G. L., and Fraser, G. D. (1963). Pillowed lavas, I: Intrusive layered lava pods and pillow lavas, Unalaska Island, Alaska. U. S. Geol. Surv. Prof. Paper 454B, pp. 1–23.]

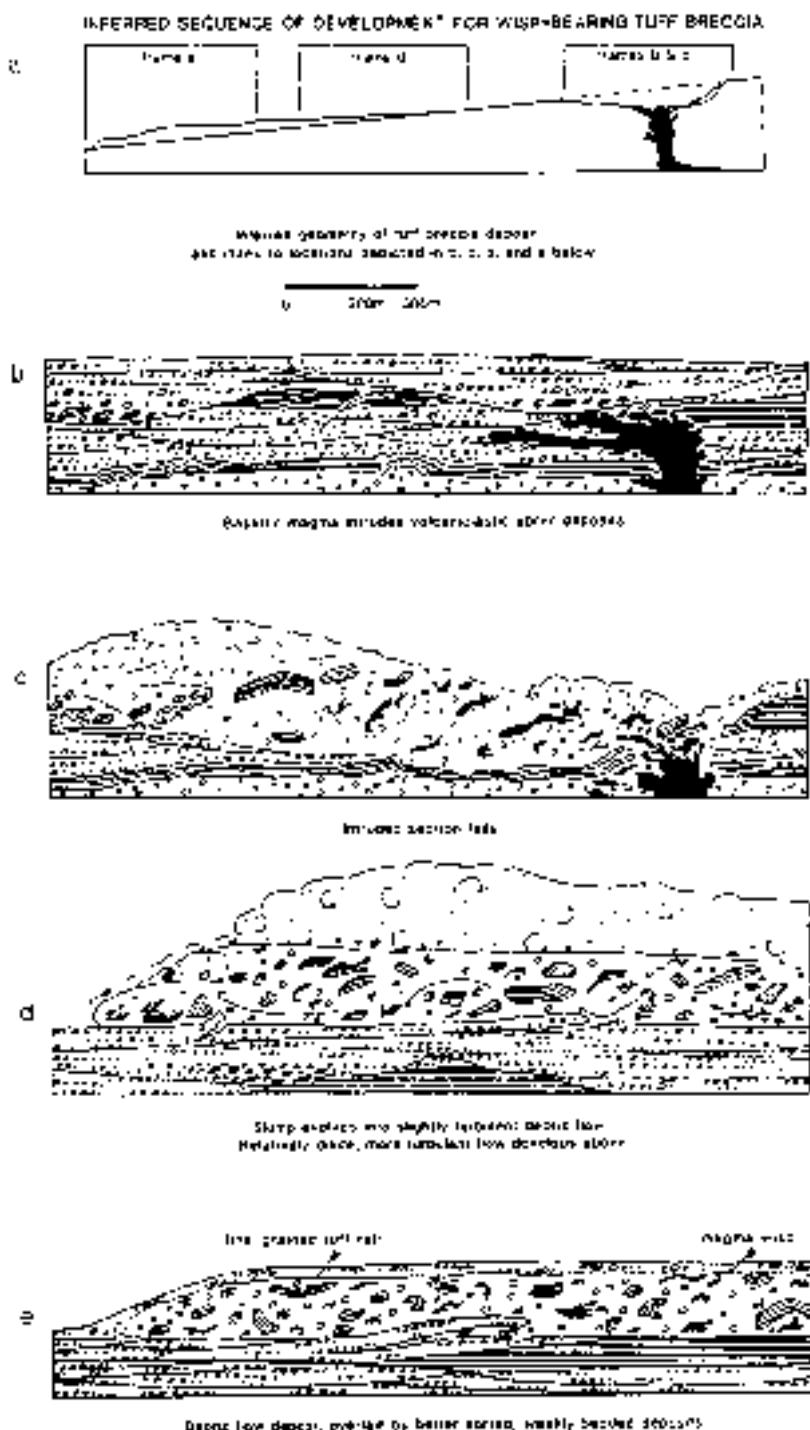

FIGURE 22 Delivery of magma into marine arc-flank environments can result in failure of the flank sediment and incorporation and tearing apart of the magma as the mass flow moves downslope. The degree of magma disruption ranges from simple folding to complete disaggregation and mixing as shown here. [Reproduced with permission from White, J. D. L., and Busby-Spera, C. J. (1987). Deep marine arc apron deposits and syndepositional magmatism in the Alisitos Group at Punta Cono, Baja California, Mexico. *Sedimentol.* 34, 911–928, Blackwell Science.]

volume (ca. 10-km<sup>3</sup>) hypabyssal intrusion emplaced into unlithified sediment at shallow levels beneath the seafloor of a marginal basin (Fig. 20). Under substantial hydrostatic pressure, even rhyolitic melts can have low viscosities because abundant volatiles remain dissolved in the melts. Hypabyssal rhyolite pillows and thin, contorted intrusive tubes of rhyolite encased in seafloor sediment can form from these fluidal rhyolite melts. These are associated with both “emergent intrusions” (Fig. 18) and with extensive peperite development in hypabyssal complexes that can occur over tens or hundreds of kilometers along the axis of extending arcs or young spreading basins, for example, in the Jurassic rocks of southern Chile. Such large-scale hypabyssal complexes have been termed “large-scale peperites” because of the abundance of lava–sediment mixtures along the intrusions, and have been formed by eruptions ranging from basalt to rhyolite in composition. In southern Chile, these vast hypabyssal intrusive complexes of rhyolite are believed to be the subaqueous equivalent of caldera and ignimbrite forming eruptions that occurred further north along the magmatic line under subaerial conditions. Here we focus on subaqueous examples of these complexes, but they also form in sediment-filled basins flooded with groundwater, where the same factors (insufficient rigidity for dike cracking, lower density than magma, and flowage of sediment due to boiling of interstitial water) come into play.

Spectacular exposures of uplifted andesitic hypabyssal complex rocks forming Unalaska Island, Alaska, demonstrate a range of peperites and complicated geometric shapes of intrusive lava (Fig. 21). Peperite forms by mixing of wet sediment and magma, and is typically facilitated by boiling of interstitial water in the sediment to form a steam matrix allowing the sediment to behave fluidly. The resulting deposits range from what are essentially hyaloclastite fragments floating in, and injected by, sediment, to unusual “globular peperite.” The latter consists of fluidally shaped lava in droplets, tubes, and globules enclosed and surrounded by sediment; it forms when magma and liquefied sediment mingle as two immiscible fluids. Intrusive pillows, which have the same features as normal pillows (see earlier discussion), and pillow margins of hypabyssal sills can also form as a result of the fluidal behavior of fluidized or liquefied sediment. In many hypabyssal complexes, intrusive pillow lavas form very thick sequences that may be difficult to distinguish from purely subaqueous pillow piles.

The flanks of marine volcanoes are dominated by volcaniclastic deposits produced by high- and low-concentration turbidity currents. Under the same controls that result in larger hypabyssal complexes, dikes entering

such aprons stall before reaching the seafloor. The magma moves laterally into the flank sediments and can initiate mass flows that “unroof” the magma, taking the upper portion along in the flow and tearing the lava into small “rags” by churning flow (Fig. 22).

#### XIV. SUMMARY

In closing we emphasize that submarine lavas account for the bulk of lavas on Earth. Submarine lavas form with a variety of flow morphologies, controlled largely by the volume extrusion rate and slope angle and their effects on the balance between the rate of crust formation and the deformation of this crust. Deep water lavas are accompanied by little or no hyaloclastite at sediment-free fast-spreading ridges, and by limited amounts of hyaloclastite on slower spreading ridges and seamounts where sediment is also present. Hyaloclastite becomes more abundant at shallower eruption depths. Where sediment on the seafloor is thick, erupting magma is captured within the sedimentary pile to form hypabyssal complexes of peperite, intrusive hyaloclastite and breccia, and intrusive lava in pillows or other forms.

#### ACKNOWLEDGMENTS

We would like to thank the following people for discussions: John Sinton, Patty Fryer, Mike Garcia, Ken Rubin, Jill Karsten, Keith Crook, Ray Cas, Steve Self, Nathan Becker, RV Fisher, Jocelyn McPhie, David Elliott, Chuck Landis, Ian Skilling, Peter Kokelaar, and many others who over the years have shared their knowledge and ideas about subaqueous eruptions and their products. Useful reviews by W. Mueller, L. Ayres, Tracy Gregg, and Ralf Schmidt helped strengthen the chapter.

## GLOSSARY

**abyssal hill** A nonvolcanic low-relief feature of the ocean floor. Abyssal hills range up to several hundred meters in height and several kilometers in diameter. They may originate from tectonic uplift. If located near seamounts or oceanic islands, they may represent remnants of mass wasting deposits such as debris avalanches or slides. Recently, the term has evolved to have a very specific meaning used for linear fault blocks that form the ridge-parallel horst/graben topography on ridge flanks.

**atoll** A truncated, commonly volcanic island capped by a roughly circular to horseshoe-shaped coral reef composed of closely spaced small coral islets that encircle a shallow lagoon. The complex is surrounded by deep water. Atoll formation is restricted to equatorial regions.

**endemic** An organism or a group of organisms restricted to a particular region or environment.

**feeder dike** The conduit through which magma passes from a magma chamber to the Earth's surface.

**fissure eruption** An eruption that takes place from an elongate fissure, rather than from a central vent.

**hot spot (mantle plume)** An area of copious volcanic activity, usually in intraplate tectonic settings, persistent for millions of years, that is thought to be the surface expression of a more or less persistent rising plume of hot mantle material from which magma is released during decompression.

**haloclastite** A deposit formed by the flowing or intrusion of lava or magma into water, ice, or water-saturated sediment, and its consequent granulation or shattering into small angular glass fragments.

**juvenile clast** Volcanic particle (pyroclast or hydroclast) derived directly from magma reaching the surface.

**peperite** A breccia-like mixture of extrusive or intrusive lava with wet sediment.

**pillow lava** Interconnected, elongated lava tubes formed in a subaqueous environment. Cross sections of tubes resemble pillows that commonly show a convex upper

- and flat or concave lower surface, and radial fractures. Pillow tubes are surrounded by a chilled glassy margin.
- pit crater** A small crater formed by subsidence of the surface.
- seamount asperity** Roughness of subducted oceanic lithosphere due to seamounts, volcanic ridges, and oceanic plateaus.
- sideromelane** Fresh isotropic basaltic glass.

7. Active submarine volcanoes may be sites of hydrothermal activity.
8. Last but not least, continuous upward growth may lead to the formation of oceanic islands, most attractive places to spend one's holidays.

The aim of this review is to present a summary of the global importance of seamount volcanism, which is second only in intensity to midocean ridge (MOR) volcanism on the Earth's surface.

---

## I. INTRODUCTION

We discuss the types, morphology, areal distribution, growth stages—including island formation, chemical composition, hydrothermal activity, and significance of seamounts. Volcanic edifices with elevations of more than 50–100 m above the surrounding seafloor are called seamounts. Their total number exceeds 1 million (Table I). Volcanic ocean islands, which are highly productive seamounts that have grown above sea level, number only a few thousands, including small islets like atolls.

Seamounts of volcanic origin are the most abundant—but most poorly studied—volcanoes on the Earth's surface. The study of seamounts provides basic insights into processes concerning the evolution of the oceanic lithosphere:

1. The composition of seamount lavas reflects fundamental mantle and crustal processes not affected by contamination due to passage through thick continental crust.
2. Seamounts, including submerged oceanic islands (guyots, atolls), record vertical movements that reflect upwelling mantle material, thermal subsidence of aging lithosphere, and sea level fluctuations.
3. The age progression of large seamount chains is a fundamental parameter in determining past and present plate vectors.
4. The study of abundance, areal distribution, and composition of seamounts helps to understand accretion processes of oceanic crust.
5. Information about the shape of seamounts and orientation of dikes within the edifices is useful to reconstruct the regional tectonic stress and fracture patterns of the surrounding lithosphere.
6. The morphology of the edifices, flow types, volcanoclastic facies, and clast shapes are the result of submarine volcanic processes including fragmentation and emplacement mechanisms.

---

## II. DEFINITIONS

Seamounts are discrete, morphologically distinct elevations on the seafloor. Most seamounts are of volcanic origin while only few are nonvolcanic. They may be isolated or arranged in clusters or linear chains. The restriction to a minimum height of 1000 m in most current definitions of seamounts seems to be based primarily on practical criteria since elevations of less than 1000 m on the seafloor may enclose morphologic features of diverse origins such as fault blocks or blocks within debris avalanche deposits. These morphologic highs are also called *abyssal hills*. There is little scientific justification, however, for not calling submarine volcanoes less than 1000 m high *seamounts*. Isolated submarine volcanoes, like all volcanoes, start small. In detailed studies on seamounts, the size limit is closer to 50–100 m above seafloor (asf), a usage adapted in this summary.

---

## III. TYPES OF SEAMOUNTS

Volcanic seamounts include (1) submarine peaked volcanoes and (2) flat-topped submerged and eroded oceanic islands (guyots, atolls). The term *fossil seamount* has also been applied to uplifted fragments of oceanic volcanoes, for example, La Palma (Canary Islands, East Atlantic), Porto Santo (Madeira Archipelago, East Atlantic), Tok Islands (Korea), Takashibiyama Formation (Shimane Peninsula, Southwest Japan), and Ba Volcanic Group/Viti Levu (Fiji Islands). Nonvolcanic seamounts are submarine peaks restricted to forearc systems and to the landward slope of trenches. They include serpentinite diapirs and horst blocks consisting of altered and metamorphosed mafic and ultramafic rocks.

#### IV. SIZE AND MORPHOLOGY

Seamounts on the ocean floor are mapped by conventional bathymetric methods including single-beam echo sounder (2-D), multibeam swath echo sounder (3-D), and high-resolution side-scan sonar systems (3-D) such as SeaMARC, GLORIA, and TOBI. The morphology of volcanic seamounts is highly variable. Their shapes are mainly controlled by (1) the size, geometry, and temporal migration of magmatic conduits; (2) eruption rate and magma viscosity; (3) the development of craters and calderas; (4) preexisting topography; and (5) regional and gravitational edifice stresses. During and after growth, the constructional shape is commonly modified by erosion, mass wasting, and tectonic disruption as well as by tilting due to variable subsidence.

Two morphologic end members have been distinguished from each other depending on the geometry of magmatic conduits: (1) extrusion of magma from a single feeder tube system (point source) may build an isolated lava pile whereas (2) fissure eruptions (linear source) produce ridgelike features. Combinations of both are common. Eruption rate, magma viscosity, and preexisting topography account for the morphologic and structural variability of eruptive products such as sheet flows, pillow lava, ponded flows, lobate tubes, and hyaloclastites and thus determine the small-scale morphology of a seamount. Detailed bathymetric studies in the axial zone of the Reykjanes Ridge (south of Iceland) and further south in the inner valley floor of the Mid-Atlantic Ridge (MAR) revealed smooth-shaped seamounts, consisting of numerous sheet flows and "hummocky" seamounts composed of pillow lava.

Summit craters are common, especially on small seamounts. They vary in size from tiny pits, a few tens to hundreds of meters in diameter, to large and complex calderas up to a few kilometers in diameter frequently bordered by stepped crater walls. Small cones are common on the crater floors.

##### A. Intraplate and MOR-Related Seamounts

In plan view, circular to elliptical to irregular polygonal and ridgelike shapes are typical. Profile shapes of isolated seamounts vary from shields (resembling Hawaiian volcanoes), to overturned soup-bowl shapes (resembling Galapagos volcanoes), to dome shapes and more complex forms. Many of the larger seamounts display truncated cones with more or less flat summit regions, in

some cases the result of postcaldera lava filling from circumferential feeder dikes. The morphology of seamounts is commonly modified by satellite cones and flank rift zones. In general, small volcanoes are more irregular in shape than their larger counterparts. Many large and small edifices display large-scale asymmetries due to tectonic activity and/or flank collapses.

Conical seamounts often show slightly concave flanks steepening toward the top. Moreover, there seems to be a relationship between slope angle and summit height. In the eastern and southern Pacific, seamounts less than 1800 m high show an average slope angle of  $18^\circ \pm 6^\circ$  with individual values ranging from  $5^\circ$  to  $36^\circ$ , while taller seamounts ( $>2600$  m high) exhibit more uniform values and lower mean gradients, averaging  $15^\circ$ . Similar results were obtained from Nazca plate-seamounts near the Easter Islands (Southeast Pacific). Two seamount populations were distinguished from each other: one composed of small seamounts ( $<1200$  m high) characterized by slope angles from  $5^\circ$  to  $32^\circ$ , whereas a second group, consisting of larger edifices ( $>1200$  m high), displays more gentle slope angles from  $5^\circ$  to  $15^\circ$ . Thus, seamount slopes are much steeper compared to slopes of subaerial shield volcanoes, which average about  $4^\circ$  to  $9^\circ$ .

Quantitative studies of seamount morphology have been carried out using single-line wide-beam echosounding profiles of well-surveyed regions in the Pacific. Based on the analysis of shape parameters (basal width, summit width, maximum height, slope angle, height-to-basal-radius ratio and flatness), obtained from a wide height range of seamounts (140–3800 m), summit height seems to be generally about one-fifth the basal radius. Moreover, the mean flatness decreases with increasing summit height, resulting in isolated conical shapes for large seamounts.

Depending on the magma production rate, seamounts range in volume and height from huge submarine intraplate volcanoes such as Hawaii more than 4000 m high above sea level and volumes exceeding 50,000 km<sup>3</sup>, to small MOR-related volcanic cones that only reach 50 m in height. Basal diameters range from a few tens of meters up to more than 100 km. On average, intraplate seamounts are much larger than seamounts formed along the axis or on the flanks of MORs.

##### B. Island-Arc Seamounts

The morphology of seamounts in island-arc settings in many aspects resembles seamounts in intraplate settings

and at MORs, as described earlier. The main difference is the abundance of submarine caldera volcanoes (e.g., northern Izu-Ogasawara arc, Japan), reflecting explosive volcanic activity along island arcs. The global average rate of island-arc caldera volcanoes is about 20%, whereas in the northern submarine portion of the Izu-Ogasawara arc the rate reaches 60%.

The seamounts are conical or elongate in shape, but this morphology can be modified by abundant summit calderas (4–9 km in diameter), some with satellite cones and postcaldera dome complexes inside (e.g., Myojinsho area, Izu-Ogasawara arc, Japan). The height of caldera volcanoes composed of felsic ejecta (dacitic to rhyolitic pumice) is significantly lower than that of more mafic cones. A remarkable symmetric submarine cone, the so-called Myojinsho cone (Izu-Ogasawara arc, Japan) located on a caldera wall, has slopes of almost precisely 21°, interpreted to be the result of angle-of-repose deposition of volcaniclastic gravity flows.

### C. Nonvolcanic Seamounts

Two morphologic types of nonvolcanic seamounts occur at convergent margins between the trench axis and the active volcanic front (forearc). Tectonically uplifted blocks are bordered by faults and thus show angular outlines in plan view, whereas diapir-driven serpentinite seamounts (e.g., Conical seamount, Mariana forearc, Japan) are characterized by crescentic and conical shapes. They reach up to 30 km in diameter and are as much as 2–3 km high.

---

### V. AREAL DISTRIBUTION

Seamounts occur in different tectonic settings such as (1) intraplate terrains including passive oceanic margins, (2) MORs, and (3) island arcs above subduction zones. Larger seamounts are commonly grouped into (1) volcanic ridges (e.g., Cocos Ridge in the Pacific, Ninetyeast Ridge in the Indian Ocean, Walvis and Rio Grande Ridges in the South Atlantic) composed of closely spaced volcanoes, (2) large seamount/island chains (e.g., Hawaiian–Emperor chain, Pacific), and (3) patchy clusters (e.g., Canary Islands and associated seamounts, East Atlantic) as well as isolated seamounts (e.g., Shimada seamount, East Pacific; Vesteris seamount, North Atlantic), including guyots (e.g., Great Meteor seamount, East Atlantic) and atolls (e.g., Muroroa Atoll, Tuamotu Ar-

chipelago, French Polynesia, Southwest Pacific), which, of course, may also be part of seamount chains.

#### A. Intraplate Setting

Intraplate seamounts are commonly located far from plate boundaries. Their origin is interpreted to be the surface expression from roughly stationary mantle plumes (hot spots). In fast spreading ocean basins (60–90 mm/yr), such as the Pacific Plate, they are commonly arranged in large linear seamount/island chains or volcanic ridges. As the volcano is carried away from the center of the hot spot, the magma supply is cut off and the volcanic activity ceases, creating a trail of extinct, progressively older volcanoes parallel to the direction of seafloor spreading. This scenario is best illustrated by the Hawaiian–Emperor chain. Most chains show a more complex age progression (e.g., seamount chains in the Gulf of Alaska), the result of a combination of intraplate seamounts and seamounts associated with spreading ridges, variable degrees of magma storage, and interaction with lithospheric fractures. The Hawaiian–Emperor chain shows a sharp bend that separates the younger westward-trending Hawaiian islands from the older northward-trending Emperor seamounts (Fig. 1A). This bend is commonly interpreted to reflect a dramatic change in Pacific Plate motion about 43 Ma ago. Recently, paleomagnetic studies of some Emperor seamounts have shown that the Hawaiian hot spot may not be fixed, but may have moved in late Cretaceous to early Tertiary times (81–43 Ma) at rates similar to those of lithospheric plates (>30 mm/yr). Nevertheless, bends of seamount/island chains in the South Pacific (e.g., Gambier-Tuamotu Line, Austral-Cook, and Gilbert-Marshall) occur roughly at the same time (40–50 Ma), favoring the interpretation of synchronous changes in plate motion direction across a large part of the Pacific Plate.

Aseismic ridges of volcanic origin lacking earthquakes are linear volcanic structures not restricted to fast spreading ocean basins. They are composed of coalesced seamounts rising 2000–4000 m above the surrounding seafloor and may reach a few hundred kilometers in width and a few thousand kilometers in length. Most are attached to continental margins and may continue to active spreading centers. Aseismic ridges are assumed to have formed during the early history of opening of ocean basins due to initial hot spot activity. If the hot spot is located on the active spreading center, paired aseismic (volcanic) ridges may originate on both sides

of the MOR (e.g., Walvis and Rio Grande Ridges, South Atlantic). Numerous isolated or clustered seamounts and seamount/island chains occur on volcanic oceanic plateaus. These areas (e.g., French Polynesian Superswell, Southwest Pacific; Ontong Java Plateau, West Pacific) are several hundred kilometers in diameter, may be elevated more than 1000 m above the surrounding seafloor, and are characterized by thickened oceanic crust. They are interpreted to originate mainly from hot spots. Along passive oceanic margins far from MORs (e.g., East Atlantic), seamounts tend to occur in isolation or in clusters (Fig. 1B).

Some solitary seamounts in intraplate settings are associated with fractures caused by extensional stress fields. Such seamounts are assumed to be of nonplume origin (e.g., Vesteris seamount, Greenland Basin, North Atlantic).

## B. MOR Setting

Statistical studies of seamount distribution are based on counting isolated peaks on bathymetric charts and on single-line wide-beam echo-sounding data in order to estimate the regional and global seamount abundance. All sizes of seamounts can be taken into consideration depending on the resolution of bathymetric systems used. In contrast to satellite altimetry, data acquisition of smaller MOR-related seamounts is based on single ship tracks covering a very limited area of ocean basins. Hence, the distribution of small seamounts has to be estimated using statistical methods.

The regional abundance of seamounts (Table I) focuses on truncated or elliptical edifices with aspect ratios (ratio of maximum to minimum basal diameter) of less than 2. Estimated seamount abundances are, therefore, minimum values. These studies show that seamount populations generally follow an exponential size–frequency distribution over a large range of summit heights, inasmuch as most small seamounts form very close to the spreading axis, while only few larger volcanoes are added off-axis. The mean seamount abundance estimates are calculated using an exponential model (Table I).

Statistical studies of seamount distribution have been carried out mainly along fast and slow spreading MORs including ridge sections both affected and unaffected by hot spots.

### 1. Fast Spreading Ridges

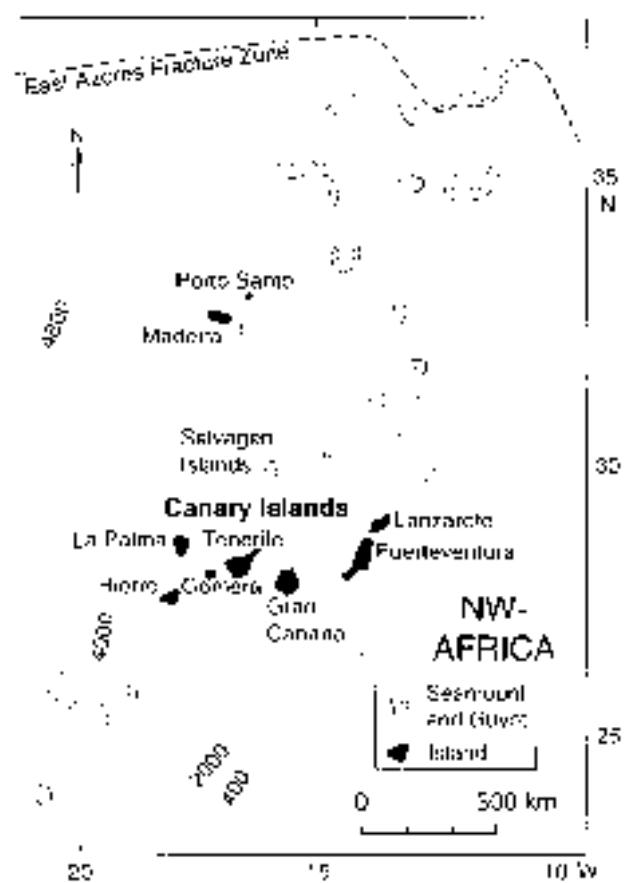

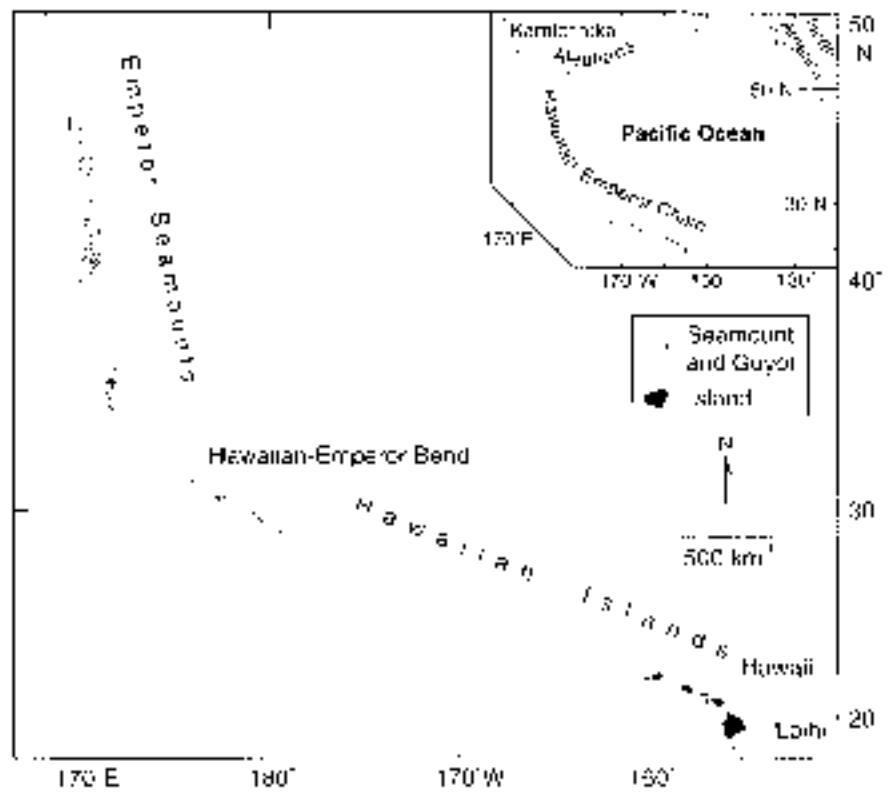

Small cones on the flanks and in the vicinity of fast spreading MORs are the most common type of sea-

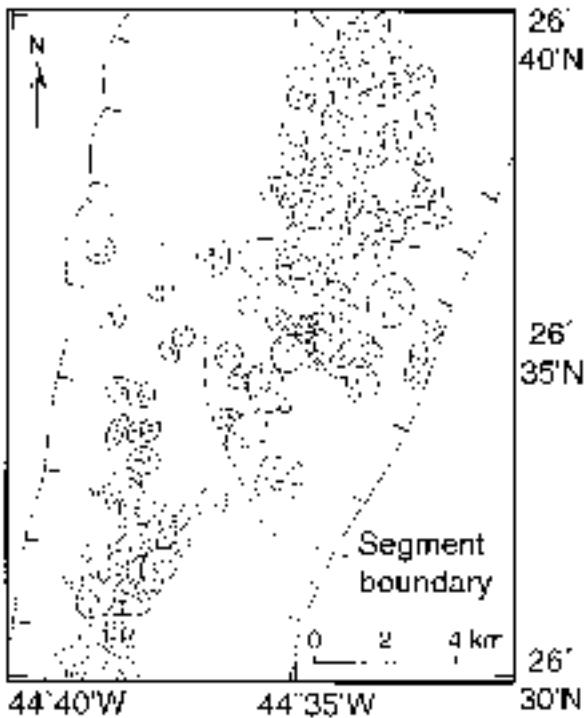

mount in the Pacific Ocean basin, whereas seamounts are absent within the axial zone. The site of seamount formation along the East Pacific Rise (EPR) is restricted to a remarkably narrow band 5–15 km (0.1–0.3 Ma) from the ridge axis, with less significant growth out to ~50 km (~1 Ma) from the ridge crest. The distribution of near-axis seamounts is not random but follows zones of apparent lithospheric weakness including (1) ridge normal, (2) ridge parallel, and (3) oblique directions about 40°–50° to ridge lineation, resulting in clusters and small seamount chains. Short seamount chains are usually oriented either parallel to the relative plate motion (spreading direction) or to the direction of absolute plate motion while others are not. They may originate from moving melting anomalies (i.e., discrete areas of elevated temperatures and partial melt in the upper mantle) possibly associated with large overlapping spreading centers or with major transform offsets in the ridge axis. On the other hand, short seamount chains oriented parallel to the direction of plate motion relative to the upper mantle may originate from stationary melting heterogeneities beneath migrating ridges. Calculated seamount abundances per unit area in the Pacific range from 2 to  $13 \times 10^{-3} \text{ km}^{-2}$  (Table I).

The abundance of seamounts (number of seamounts per unit area) in the Pacific increases monotonically with age from the ridge crest out to seafloor of Eocene age due to off-axis addition of seamounts to the crust over time. This seamount production rate is inversely proportional to the square root of lithospheric age. In other words, seamount production rate decreases with increasing age and thickness of the underlying crust. Young and thin lithosphere is dominated by abundant small seamounts, whereas old lithosphere contains more larger edifices due to increasing load capacity and burial of smaller features by sediments.

### 2. Slow Spreading Ridges

In slow spreading environments such as the Mid-Atlantic Ridge, seamount production is almost restricted to the median valley floor. Isolated volcanoes pile up and coalesce to form the characteristic neovolcanic axial ridges (Fig. 2). Calculated seamount abundance per unit area in the northern MAR axial valley ( $195 \times 10^{-3} \text{ km}^{-2}$ ) is more than an order of magnitude higher than along the MOR in the Pacific (2 to  $13 \times 10^{-3} \text{ km}^{-2}$ ) and South Atlantic ( $7 \times 10^{-3} \text{ km}^{-2}$ ) and further increases to  $310 \pm 20 \times 10^{-3} \text{ km}^{-2}$  at the Reykjanes Ridge due to the influence of the Iceland hot spot (Table I). The estimate of seamount abundance for the North Atlantic Basin of 85 million (Table I) is surprisingly high be-

**FIGURE 2** Distribution of small seamounts (50–600 m high) in the median valley floor of the slow spreading Mid-Atlantic Ridge north of the Kane fracture zone. The two outer solid lines mark the first major faults that begin the steps up the inner valley wall. The volcanic ridge consists of piled-up and coalesced seamounts marking sites of major crustal construction. The segment boundary marks the offset of the volcanic ridge. [Adapted from Smith, D. K., and Cann, J. R. (1990). Hundreds of small volcanoes on the median valley floor of the Mid-Atlantic Ridge at 24–30°. *Nature* **348**, 152–155. cause seamounts formed along the spreading axis cannot be traced out to the ocean basins, due to tectonic disruption along the high-relief ridge crest of the MAR. Ridge flank seamount construction along the MAR in the North Atlantic is restricted to hot-spot-influenced regions, while seamounts along ridge flanks are common in the South Atlantic. Consequently, seamount volca-

nism in the South Atlantic appears to resemble that in the Pacific, regardless of the differences in spreading rates, including its seamount chains.

In conclusion, the spreading rate seems to have an important control on seamount formation along MORs. Along slow spreading ridges, numerous small seamounts form along the ridge axis, whereas along fast spreading ridges few larger seamounts form off-axis. For further discussion see Section XI,C.

### C. Island Arcs

The distribution of seamounts and islands along the volcanic front of island arcs shows an almost linear or slightly curved arrangement parallel to the trench (Fig. 1A, Aleutian seamounts/islands in the index map). Discontinuities from the linear to curved geometry are mainly caused by tectonic segmentation of the volcanic front. Both observations suggest a strong fault control on the distribution of volcanism. The oblique orientation of the Kasuga seamount chain (northern Mariana Trough, Japan), however, is oriented obliquely to the volcanic front interpreted to be the result of interaction between preexisting cross-arc structures, magmatic activity at the volcanic front and in the backarc, and the tectonic activity in the island-arc complex. Large seamounts and islands tend to be regularly spaced at 50–70 km, whereas smaller seamounts are more closely spaced.

### D. Pacific Plate

The distribution of seamounts of the Pacific Plate has also been mapped by satellite altimetry. Each bathymetric high on the seafloor produces a positive gravity anomaly reflected by a rise in the sea surface above the feature. The sea surface bulge has to reach a significant value on the order of a few meters spread over an area of a few hundred kilometers to be measured accurately. This method thus takes into account only large sea-

**FIGURE 1** (A) Linear distribution of seamounts and volcanic islands of the Hawaiian–Emperor chain. Contour intervals are at 2000 and 4000 m. Inset shows the location of the chain in the central North Pacific. The Aleutians display a curved arrangement of seamounts and islands typical for island-arc settings. Inset contour interval at 2000 m. (B) Distribution of seamounts and volcanic islands along the passive continental margin off northwest Africa. Note the irregular, patchy arrangement of seamounts and oceanic islands. The simplified outlines of the seamounts mark the slope break to the surrounding seafloor. mounts with heights exceeding 1.5 km but their total number and distribution is measured very precisely because entire ocean basins are mapped. A total of 8882 large seamounts were detected (Table I) having the highest density (number of seamounts per area) in the central Pacific and French Polynesia. These areas are interpreted to result from numerous closely spaced hot spot trails. The tallest seamounts (guyots) are found in the western Pacific on the oldest oceanic crust. They are of Cretaceous age and perhaps coincide with the time of formation of large igneous provinces (volcanic oceanic plateaus) in the Pacific Ocean.

---

## VI. GROWTH STAGES OF SEAMOUNTS AND ISLAND BUILDING

Seamounts have been studied mainly with bathymetric methods, rarely by submersibles, and exceptionally through drilling. Our knowledge of their internal structure is thus very limited. Three-dimensional correlations of volcanic facies can only be obtained from cross sections in subaerially exposed fossil seamount sequences such as the Crescent volcanic rocks (Olympic Mountains, Washington), Snow Mountain volcanic complex (California), La Palma (Canary Islands, East Atlantic), Porto Santo (Madeira Archipelago, East Atlantic), Ba Volcanic Group (Viti Levu, Fiji), Takashibiyama Formation (Shimane Peninsula, southwest Japan), Masirah Island ophiolite (Oman), and Troodos ophiolite (Cyprus).

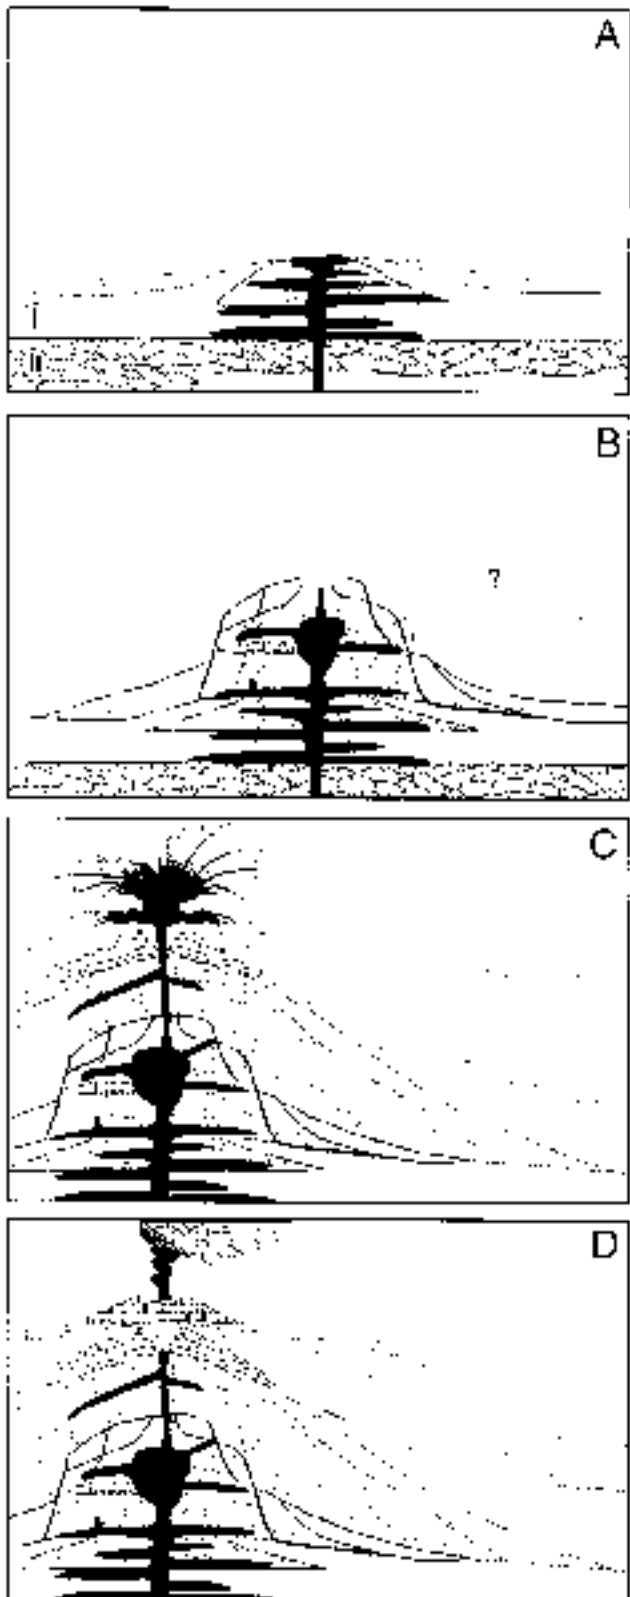

The type of submarine volcanic activity, and thus the emplacement and fragmentation processes, are controlled by (1) hydrostatic pressure (water depth) at which eruptions take place, (2) chemical composition of magma (volatile content, viscosity), (3) topography of the extrusive environment, (4) eruptive rate, and (5) the dynamics of lava–water interactions. Seamounts pass through several growth stages during upward growth characterized by (1) increasing vesicularity of lava flows and clastic particles, (2) increasing proportion of volcanoclastics, and (3) increasing percentage of heterolithologic breccias and mass-wasting deposits. Based on these criteria, a deep-water stage, intermediate water/shoaling stage, and emergent/island stage have been distinguished from each other in some seamount sequences. The uplifted seamount series of the basement complex of La Palma, tectonically undeformed and well exposed, reflects the growth stages particularly well (Fig. 3).

### A. Deep-Water Stage

Most seamounts form on oceanic crust or marine sediments, generally starting in deep water (1000–5000 m). They grow by intrusive and extrusive activity in roughly equal portions (Fig. 3A). Initially, dike and sill intrusions into the marine sediments lead to complex intrusive complexes including nonexplosive peperites formed by interaction of magma intruding wet sediments. Repeated intrusions cause doming of the overlying sediment blanket, resulting in redepositional processes (Fig. 3A). During the deep-water stage, continuous but variable magma production rates under high hydrostatic pressure contribute to nonexplosive extrusive activity resulting in pillow and sheet flow volcanoes. Individual pillow sequences are up to 200 m thick and commonly start with massive pillow flows and/or megapillows at the very base displaying significantly decreasing diameter toward the top. Minor amounts of hyaloclastites, locally accumulating in hyaloclastite flows on seamount summits, are intercalated with the pillows and sheet flows and pelagic ooze. The hyaloclastites consist of nonvesicular sideromelane slivers, which form by spalling of the glassy crust of submarine lavas due to cooling contraction. As the seamount grows, the slopes increase and steep fault scarps evolve, causing redepositional processes. This flank facies is dominated by clastic products consisting of monolithological pillow and pillow fragment breccias caused by fragmentation and breakup of lava flows descending the slopes (Fig. 3B). They are commonly deposited by debris flows on the flanks and in the more distant aprons. The basal extrusive portion of the La Palma seamount consists of 76% pillow lavas and 5% sheet flows, representing the core facies and 19% clastic rocks abundant in the summit region and in the flank and apron facies of the seamount. The extrusives are intruded by (1) a massive sheeted “sill swarm,” making up roughly 50% of the seamount series, and (2) feeder dikes. The deep-water stage is dominated by quiet effusive activity but there is also some evidence for explosive activity at abyssal depths. Summit regions of deep-water seamounts may show calderas, craters, and pit craters, while many seamount flanks are modified by satellite cones and volcanic ridges.

### B. Intermediate Water/Shoaling Stage

The intermediate water/shoaling stage (Fig. 3C) is defined by the onset of (1) increasing vesicularity of pillows and hyaloclastites and (2) hydroclastic and/or pyroclas-

tic explosive activity. The critical depth for explosive volcanism is a function of volatile content of the magma. Explosive activity of volatile-rich alkali basaltic lavas from La Palma starts at water depths of more than 1000 m as shown by recent dredging, while volatile-poor tholeiitic lavas ( $\sim 0.1$  wt%  $H_2O$ ) start to fragment explosively at shallow depths less than 100–200 m. For more evolved magmas and  $H_2O$ -rich basaltic magmas in subduction zone settings, explosive fragmentation depth may exceed 1500 m.

The intermediate water/shoaling stage of the La Palma seamount consists of 69% clastic rocks, 30% pillow lavas, and less than 1% massive flows. The shallow

**FIGURE 3** Growth stages of seamounts, based on the evolution of the uplifted La Palma seamount, Canary Islands (East Atlantic). I: Layer I of the oceanic crust (sediments), II: layer 2 of the oceanic crust mainly consisting of pillow lava and sheet flow lava. Fish not to scale. (A) Most seamounts on oceanic crust are formed in deep water, on top of marine sediments. Volcanic activity commonly starts with intrusion of feeder dikes and numerous sills into pelagic sediments. Intrusion-related uplift of unconsolidated sediments may cause redeposition processes. Interaction of intruding magma with water-saturated sediments may produce nonexplosive peperites and pillows. (B) In the deep-water stage, the bulk of the seamount deposits consists of extrusives (pillows, sheet flows) and intrusives (sills) roughly in same proportion representing the core facies. Continuous constructional activity produces commonly cratered, steep-sided edifices with abundant faults leading to mass-wasting processes. Mostly nonvesicular pillow breccias and pillow fragment breccias are deposited by debris flows on the flanks and in the aprons. The deep-water stage ends with the beginning of explosive eruptions during the intermediate water/shallow water stage (C). Core and flank facies may be similar to those of the deep-water stage but the deposits are generally more vesicular. During the final subaqueous stage, explosive surtseyan activity produces submarine tuff cones consisting of dominantly coarse-grained deposits in the vent area while more distal grain size decreases. Most of the loose clastic material generated during this stage is redeposited by debris flows on the flanks and in the aprons of the seamount. The upward growth of tuff cones above sea level marks the transition to the emergent stage (D). If the vent area becomes isolated from the sea, lava flows are produced, forming lava deltas when entering the sea. The lava delta sequences consist of coarse-grained, foreset-bedded hyaloclastite breccias, pillows, and sheet flows overlain by subaerial lava flows. The boundary between quench fragmented hyaloclastite breccia and subaerial lava flows marks the sea level at the time of formation. [Adapted from Staudigel, H., and Schmincke, H.-U. (1984). The Pliocene seamount series of La Palma/Canary Islands. *J. Geophys. Res.* **89**(B13), 11,195–11,215. Copyright © 1984 American Geophysical Union, with permission of H.-U. Schmincke.]

water succession can be subdivided into a core and a flank facies, but, compared with the deep-water stage, the deposits are generally more vesicular. The core facies is dominated by scoriaceous, amoeboid pillows and associated scoriaceous lapilli breccias. Accumulation of large tephra volumes, combined with continuous intrusive activity, leads to the instability of the loose tephra pile and generates debris flow breccias deposited on the flanks and in the aprons.

On large seamounts, complex shelves can develop distant from vent areas. These shelves consist of thin units of pillow lava and associated pillow breccias and hyaloclastites with abundant fossil debris and small patch reefs.

During the final subaqueous stage of seamounts (Fig. 3C), surtseyan eruptions generate submarine to subaerial tuff cones. Clast formation is mainly governed by (1) disruption of magma due to explosive release of magmatic volatiles (pyroclastic fragmentation); (2) cooling contraction granulation (quench fragmentation), and (3) steam explosions due to magma–water interactions. The juvenile glassy clasts of variable vesicularity are characterized by blocky shapes and are mixed with accidental clasts. The dominantly coarse-grained deposits are massive to crudely bedded. The occurrence of rounded and oxidized fragments, and aerodynamically formed bombs indicate very shallow water conditions with significant impact of wave action and subaerial volcanic activity.

### C. Emergent Stage to Island Stage

The emergent stage (Fig. 3D) is characterized by the upward growth of tuff cones above sea level. Associated pyroclastic deposits consist of stratified and cross-stratified fine-grained lapilli and ash with abundant bomb sags, originating from base surges and fallout. Accretionary lapilli and armored lapilli are common. Hydrovolcanic cones consist mainly of loose tephra and are therefore easily eroded by wave action. Phreatomagmatic explosions cease only when the vent area becomes isolated from the sea, and quiet effusions start building a resistant lava cap leading to the stabilization of an island (island stage). Lava flows entering the sea (1) may generate littoral cones and/or (2) may quench fragment and produce coarse-grained hyaloclastite deltas and flow-foot breccias, also termed lava deltas. The stable island stage is established once the unstable tephra pile is covered with voluminous subaerial lava flows forming massive shield volcanoes such as at Kilauea (Hawaii).

### D. Erosional Stage

Seamounts that reach the island stage will get truncated in time due to wave erosion and thermal subsidence of aging lithosphere and thus submerge and reestablish as a seamount. Throughout the evolution of volcanoes (seamount stage, island stage, drowned island stage), constructional shapes are frequently modified by destructive processes such as landslides. The most reasonable mechanism providing the impetus for such mass wasting events is earthquakes triggered by magma injections along rift zones. The enormous dimensions of large-scale submarine mass wasting were first recognized along the Hawaiian ridge where landslides cover about one-half of its submarine flanks. Based on morphology and degree of dislocation, landslides can be grouped into (1) slumps and (2) debris avalanches. Slumps are slow rotary movements of largely undeformed masses along discrete shear planes. The slump deposits commonly display transverse ridges with incorporated blocks up to several kilometers in diameter. In contrast, debris avalanches are fast long-runout mass movements (debris slides) up to several tens of kilometers in length in which fragmentation has reduced the landslide mass to individual blocks during sudden slope failures. Debris avalanche deposits form aprons of distinctively hummocky terrain and are generally thinner (0.05–2 km) than slump deposits (<10 km). The largest submarine landslides off Hawaii may reach volumes of up to 5000 km<sup>3</sup>, and appear to occur late in the period of active shield growth (island stage) when the volcanoes are close to their maximum size and unstable. In the Canary Islands (East Atlantic) and on Reunion (Indian Ocean), large landslides also have occurred during subaerial volcanic phases (post-shield building). The source areas of landslides are marked by subaerial and submarine scars, embayments, and amphitheaters commonly in strike with submarine canyons.

### E. Drilling Results

Similar emplacement and fragmentation processes and corresponding rock types of a shoaling seamount can be deduced from drilling the volcaniclastic apron of ocean islands. The lowermost cores of a systematic study of a volcanic apron (Ocean Drilling Program, Leg 157) extending seaward off Gran Canaria (Canary Islands, East Atlantic) consist of fine-grained hyaloclastite debris flow deposits rich in nonvesicular sideromelane shards formed during eruptions in moderate water depth (>500

m). Vesicularity increases upward, culminating in extremely vesicular ash and lapilli thought to have been produced during very shallow-water explosive activity. The change from shallow submarine to emergent volcanism is represented by coarse-grained lithic-rich breccias and hyaloclastite debris-flow deposits interpreted to originate from collapsed lava deltas at the island–shore interface. The deposits of the island stage consist predominantly of sand-sized epiclastic turbidites. The thin turbidite beds (1–40 cm) are composed dominantly of tachylitic and lesser amounts of altered vesicular sideromelane shards, rounded basalt fragments chiefly derived from erosionally fragmented scoria and lava flows, and minor thick-walled biogenic debris from the littoral environment.

Ten comments and sketches of naval officers indicate continuous white steam plumes with intermittent explosively ejected masses of dark cinder and ash resembling cypress trees or cock's tails, a typical scenario characteristic for shallow water to emergent hydrovolcanic, or surtseyan, explosive activity. A painting of a late-stage eruption of Graham Island illustrates a steep-sided edifice resembling tuff cone morphology. Inside the central crater, an active scoria cone ejecting ash and incandescent lava lumps provided evidence for insulation of magma from seawater and thus transition from surtseyan to strombolian activity. By the end of August, the constructional activity had ceased. Since the island consisted of abundant tephra and was lacking in resistant lava flows, the edifice was rapidly eroded by wave action. By the end of October, after only 3 months, the island was more or less leveled to sea surface and by the end of December it had almost disappeared.

---

## VII. HISTORICAL OBSERVATIONS OF EMERGENT SEAMOUNTS

Why are there huge numbers of seamounts on the seafloor and only a very small number of volcanic islands? First, and probably the main reason, constructional volcanic activity of most seamounts ceases before the edifices reach the water surface because of insufficient magma production rates. Second, as mentioned earlier, the very small number of seamounts that grow large enough to become islands are stabilized only once hydrovolcanic activity changes to continuous strombolian/hawaiian eruptions including lava flows, which begin to weld the island into a more solid structure. But most emerging seamounts never develop beyond the point of hydrovolcanic activity and disappear quickly due to wave erosion.

### A. Graham Island (Mediterranean)

A famous example of a shallow submarine to emergent hydrovolcanic eruption took place in the Mediterranean in 1831, located between Sicily and Libya, resulting in an ephemeral island (Graham Island). On June 28, earthquakes were followed by discolored and spouting water, and vigorous steam jets were observed by English seamen on July 10. By July 18, a small cratered islet with a breach to the southwest appeared, rising only a few meters above sea level. Its maximum dimensions of almost half a kilometer in diameter and about 60 m high were reached by the middle of August. During early August, when the eruption was nearing its climax, writ-

### B. Metis Shoal (Tonga Islands, Southwest Pacific)

Metis Shoal is one of the most active volcanoes of the Tonga-Kermadec volcanic arc. Throughout historic times, the normally submerged volcano has been reported to be the site of numerous submarine eruptions, five of which produced ephemeral islands. The island-forming eruptions in 1967–1968 and 1979 generated tuff cones consisting mainly of dacitic pumice and lithic clasts, but no lava flows. The loose tephra piles were soon washed away by wave action and ocean currents, leaving a shoal. In contrast, the most recent eruption of Metis volcano in June 1995 generated a voluminous lava dome accompanied by discolored water and minor explosions that were producing ash-laden eruption columns but no pumice. The maximum dimensions of the island were reported to be 200–500 m across and 50–80 m in height. In contrast to the tuff cones, the 1995 lava dome is more resistant to erosion and may persist for some time.

### C. Myojinsho Area [Izu-Ogasawara (Bonin) Arc, Japan]

The Myojinsho area, located close to the Bayonnaise Rocks about 420 km south of Tokyo, is reported to have erupted more than ten times since 1952. The island-forming eruptions in 1952–1953—one of the best documented shallow submarine silicic eruption periods in historic time—included hundreds of phreatomagmatic

explosions characterized by episodic dome extrusions, explosions, and associated dome collapses punctuating intervals of relative quiescence. The deposits are mainly composed of dacitic nonvesiculated lithic clasts derived from dome collapses forming a symmetric cone. Moreover, significant amounts of pumice were produced during large pyroclastic eruptions, some of which took place subaerially while others were submarine. On three occasions, dacite domes protruded above sea level forming ephemeral islands as much as 300 m long and up to 100 m high (September 1952 to August 1953). Dome growth was accompanied by discolored water and intermittent phreatomagmatic eruption columns rising up to 2000 m above the sea surface.

The danger of such shallow submarine explosive eruptions is illustrated by the tragedy that befell Japanese research vessel No. 5, *Kaiyo-maru*. When approaching the temporarily quiescent Myojinsho area on September 24, 1952, a vigorous phreatomagmatic eruption destroyed the ship, killing all 31 people aboard.

Many emergent seamounts were reported in historical time in addition to the three examples just described. The most famous example, the island-forming eruptions of Surtsey from 1963–1967, is excluded here because it is treated in the chapter on Surtseyan and Related Phreatomagmatic Eruptions.

---

### VIII. GUYOTS AND ATOLLS

Volcanic islands become submerged after volcanic activity ceases because of thermal subsidence of the underlying oceanic lithosphere, the load of the edifice, and erosion. Charles Darwin first identified drowned ancient volcanic islands, later termed *guyots*. Guyots are characterized by flat to hummocky summit regions covered with beach pebbles, cobbles, and boulders of volcanic rocks.

Guyots may have complex flattish summits (Fig. 4). The irregular topography of the summit regions results from simultaneous shoreline erosion and thermal subsidence of oceanic lithosphere leading to plateau relief ranging from several hundred meters for smaller guyots to more than 1 km for large ones. Ideally, truncation leads to conical summit forms, whose apex represents the last speck of the island to disappear into the surf. Small-scale topographic irregularities result from differences in erosional resistance of different rock types. The flattish tops are located between 200 m and more than 5000 m below sea level. Summit plateau areas range from 14 km<sup>2</sup> (Thomas Washington, Geisha guyot chain,

Northwest Pacific) up to 5328 km<sup>2</sup> (Seiko guyot, Mid-Emperor chain, Central Pacific). The height of guyots varies from 5500 to 1000 m when buried by sediments. Guyots of the northeastern Pacific are remarkably small compared to those in the western Pacific probably because most of the guyots in the western Pacific are of Cretaceous age, a period of unusually intense midplate volcanism. Some guyot chains represent hot spot tracks; others occur in clusters and subclusters.

Most guyots are circular to oval in plan but many have star-shaped outlines due to fissure eruptions along radial flank rift zones (Fig. 4). Guyots and atolls are characterized by thick clastic aprons developed during the shoaling to emergent stages, where abundant loose tephra is produced, and during the island stage (erosion, debris avalanches). Consequently, guyots are characterized by apron-related lower slopes averaging 2°–8°, whereas upper slope angles steepen as much as 24°. In general, upper slope angles decrease with increasing edifice volume and plateau area, probably due to higher effusion rates and more voluminous lava flows.

Volcanic islands located at equatorial latitudes may develop fringing reefs, and may be converted into ring-shaped atolls due to continuous upward growth of the coral reefs as the island subsides (Fig. 5). Atolls are constructional features displaying an outer rim consisting of corals while the inner lagoon consists mainly of fine-grained carbonate sediments burying the volcanic basement topography. Atolls also can originate from subaerial erosion of carbonate platforms. Sea level lowstands may lead to the emergence of carbonate platforms modified into hummocky karst landscapes including caves, channels, pinnacles, and sinkholes during subsequent subaerial weathering and dissolution of carbonate sediments. The resulting erosional landscapes include central basins surrounded by perimeter rims resembling atoll-like morphology. Thus, many atolls inherit their form from subaerial landscapes.

---

### IX. CHEMICAL COMPOSITION

The wide range in chemical composition of seamount lavas largely depends on the tectonic setting.

#### A. Intraplate Setting

Magmas erupted in intraplate seamounts far from spreading ridges are interpreted to originate from rising mantle plumes. Volcanic rocks chemically resemble

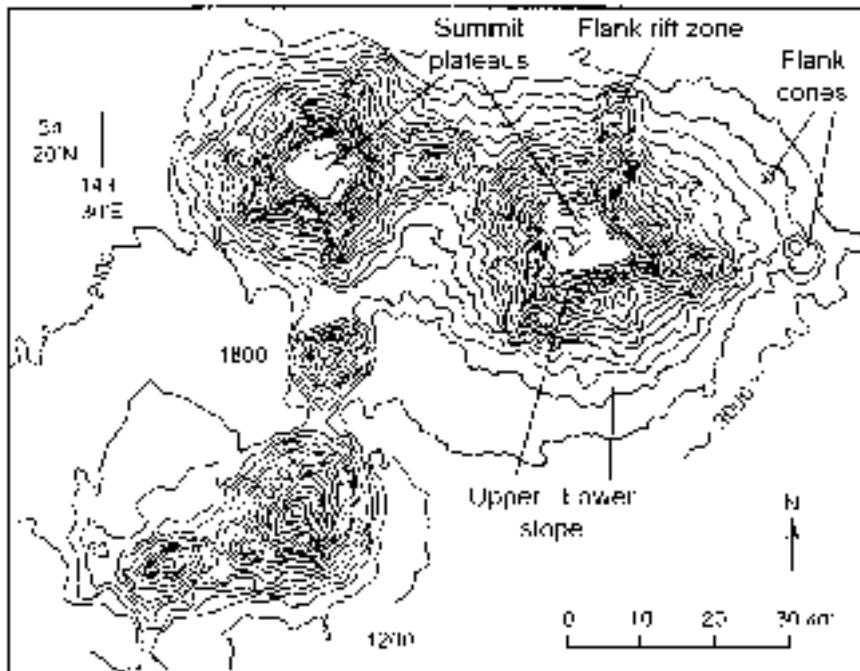

FIGURE 4 Bathymetric chart of the Seiko seamount/guyot cluster illustrating major morphologic features of the Geisha seamount chain (northwest Pacific). The two major edifices in the upper part of the figure show flattish summit regions located 800 m below sea level, steep upper and gentle lower slopes (volcanic apron), and star-shaped outlines characteristic for guyots. The three single-peaked edifices in the lower left display uniform slope angles typical for seamounts. [Adapted from Vogt, P. R., and Smoot, N. C. (1984). The Geisha guyots: Multibeam bathymetry and morphometric interpretation. *J. Geophys. Res.* **89**(B13), 11,085–11,107. Copyright © 1984 American Geophysical Union, with permission of P. Vogt.]

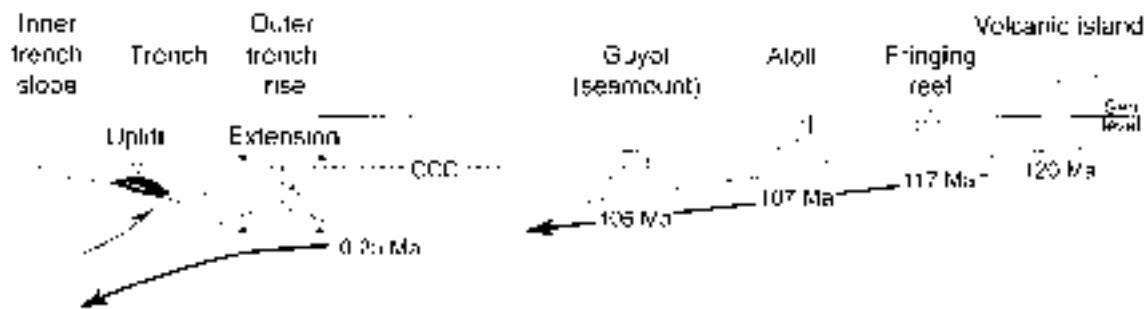

FIGURE 5 Evolution of volcanic island to guyot stage, ending with subduction of the edifice: the Daiichi Kashima seamount (Japan trench) illustrated. The Barremian to early Aptian midplate volcano originated on 20-Ma-old oceanic crust in equatorial regions of the Pacific. Combinations of plate motion, thermal subsidence of the lithosphere, load of the edifice, erosion, and sea level fluctuations led to the truncation of the island, formation of a fringing reef, and an atoll in early Albian time. After more than 100 Ma of drift, the guyot approached the outer trench rise (bulge) and subsequently became fractured by a trench-parallel normal fault system due to extensional stresses. The sediments of the lower inner trench slope were uplifted by the colliding guyot and subsequently redeposited. Note the existence of the reef complex below the carbonate compensation depth (CCD) due to thermal subsidence outpacing carbonate dissolution. [Adapted from Konishi, K. (1989). Limestone of the Daiichi Kashima seamount and the fate of a subducting guyot: Fact and speculation from the Kaiko "Nautilus" dives. *Tectonophysics*. **160**, 249–265. Copyright © 1989 Elsevier, with permission from Elsevier.]

ocean island basalts (OIB) and are characterized by an enrichment in incompatible trace elements. They range widely in chemical and isotopic composition depending on the depth and degree of partial melting and the composition and mineralogy of the mantle source. Loihi, which is the youngest volcano of the Hawaiian–Emperor chain, features a complex range of basalts including older alkali basalts and basanites, and younger tholeiites and transitional basalts. Seamount lavas of the Society hot spot region (South Pacific) consist of ankaramites, picrites, alkali basalts, basanites, tephrites, and trachytes and thus show a wide compositional range in their LILE (large ion lithophile elements, e.g., K, Nb, Zr, and Ba) and compatible element variations. Lavas recovered from seamounts and guyots in the Gulf of Alaska and from an uplifted seamount (Porto Santo, Madeira Archipelago, East Atlantic) include alkali basalt, hawaiite, mugearite, benmoreite, and trachyte, reflecting a temporal evolution of alkali-rich magmas that is typical for intraplate volcanoes.

The chemical evolution of intraplate seamounts may resemble the four eruptive stages of Hawaiian volcanoes (e.g., some seamounts northwest of Samoa Islands, West Pacific). Initial volcanic activity (preshield stage) is dominated by alkalic and transitional basalts as well as basanites. During the shield stage, when more than 95 vol% of the edifices are built, tholeiitic basalts are erupted. The post-shield stage consists of alkalic/transitional basalts to trachytes. Finally,  $\text{SiO}_2$ -undersaturated lavas such as nephelinites and melilite nephelinites with minor alkalic basalts and basanites are produced resembling the rejuvenated or posterosional stage in the Hawaiian cycle.

## B. MOR Setting

The lavas of most small cones built at the axis of MORs or in their vicinity are chemically identical to depleted midocean ridge basalts (N-MORB) in terms of major and incompatible trace elements. Both low-relief seamounts formed in the axial valley of the MAR (50–600 m high) and very close to the ridge crest of the EPR (50–300 m high) are interpreted to originate from spreading center magmas. However, many larger edifices (300–>1000 m high) in the vicinity of the EPR show a more complex chemical evolution. Basal parts consist of tholeiitic MORBs, whereas the upper parts contain transitional and locally more enriched alkalic lavas comprising a continuous mixing line.

Despite the fact that most off-axis seamount lavas compositionally resemble MORB they are generally more primitive (higher MgO content) and chemically and isotopically more diverse than axial MORB. Major element concentrations and isotopic variability indicate that near-ridge seamounts are produced by smaller extents of partial melting at slightly higher pressure than axial lavas, preserving evidence of small-scale heterogeneities in the mantle source region. Seamounts formed at progressively greater distances from active spreading ridges may exhibit a shift from depleted to enriched mantle sources and thus mark the transition from ridge-to hot spot-related magma sources.

## C. Island-Arc Setting

Island-arc seamount lava compositions range from basaltic to rhyolitic and are dominated by andesitic lavas while tholeiitic basaltic and shoshonitic (very alkalic) lavas are rare. Chemical and isotopic compositions vary widely suggesting that (1) a mantle source with affinities to MORB is contaminated by variable degrees of crustal components such as sediments and/or fluids derived from the subducted slab, (2) subducted oceanic crust is hydrothermally altered, and (3) primary heterogeneities of the mantle wedge underlying the volcanic arc may exist. Generally, arc lavas are characterized by selective enrichment in incompatible trace elements of low ionic potential (Sr, K, Rb, Ba) which become easily mobilized from the subducted slab. Lavas of the Kermadec arc (Southwest Pacific) both from seamounts and islands contain more radiogenic Pb and have higher heavy rare earth element (e.g., Tm, Yb, Lu) concentrations than lavas of the southward extending Tonga arc interpreted to be the result of variable amounts of sediment being subducted beneath the arc. Along the Kermadec trench, oceanic crust is covered with a 1000-m-thick layer of sediments compared with approximately 200 m in the southern extension along the Tonga trench. In contrast, the strongly calc-alkaline series (andesites to rhyodacites) of Piip seamount (western Aleutian arc, North Pacific) is not enriched in radiogenic Pb probably because the sediment cover has been scraped off by the long, oblique subduction path beneath the forearc. Sediments were accreted rather than subducted and thus do not affect melt composition.

In the uplifted Tok Islands (Korea), for example, the submarine sequence is made of potassic trachytic lavas and related trachytic breccias, whereas the underlying rocks are basaltic in composition.

The lavas of the submarine volcanoes of the Northern Seamount Province (NSP) in the northern Mariana arc (Japan) belong to low-K to very high-K (shoshonitic) series. They include tholeiitic basalts, andesites, dacites, and rhyolites significantly enriched in LILE and light rare earth elements (LREE, e.g., La, Ce, Pr, Nd). The alkalinity increases along-strike toward the north. Moreover, the shoaling to emergent dome of Myojinsho and the ejecta of the caldera-forming submarine pyroclastic eruption at Myojin Knoll and others, also part of the NSP, are more silicic including dacite and low-K rhyolite.

The lavas of the Kasuga backarc basin seamounts (northern Mariana Trough, Japan) vary widely from basaltic to dacitic including low-K calcalkaline basalts to high-K shoshonites.

## X. HYDROTHERMAL ACTIVITY

Hydrothermal exhalations at seamounts, discovered in the early 1980s, are important as (1) sources of mantle-derived fluids and gases and as locations of (2) Earth's heat release, (3) polymetallic sulfide deposits, and (4) geochemical exchange between oceanic crust and seawater. The toxic environment generates unique biological ecosystems with abundant bacteria supporting a community of exotic and specialized macrofauna.

### A. Hot Spot Seamounts on Active Spreading Centers

Hydrothermal activity of Axial Seamount, an active ridge axis volcano at the intersection of the Juan de Fuca Ridge and the southeastern end of the Cobb-Eickelberg seamount chain (East Pacific), is influenced by both hot spot volcanism and seafloor spreading.

Hydrothermal vents are concentrated within the Axial Seamount Hydrothermal Emissions Study (ASHES)-vent field ( $200 \times 1200$  m) located adjacent to the southwest wall of the summit caldera. Low-temperature exhalations ( $19^{\circ}$ – $35^{\circ}\text{C}$ ) are dominantly diffuse while focused venting is rare and commonly fracture-controlled or associated with cracks in nearly cooled lava flows. Typical deposits are orange, Fe-rich, amorphous silicates, rarely forming chimneys up to 1 m high.

High-temperature vents ( $136^{\circ}$ – $330^{\circ}\text{C}$ ) are restricted

to an area of  $80 \times 80$  m within the fracture-controlled ASHES-vent field. They emanate directly from young lava flows. High-temperature vents predominantly form irregularly shaped massive sulfide chimneys,  $<2$  m in basal diameter and about 1–5 (10) m high, while anhydrite edifices are subordinate. The sulfide chimneys are composed of primary Zn-rich and Cu-poor mineral precipitates contrasting with other Juan de Fuca Ridge hydrothermal sulfide deposits in having higher concentrations in Ra, Au, and Ag. High-temperature hydrothermal fluids are commonly acidic ( $\text{pH } \sim 3\text{--}4$ ) and range in composition from gas-enriched ( $\text{CO}_2$ )/low-chlorinity (66% depleted relative to seawater) fluid to gas-depleted ( $\text{CO}_2$ )/high-chlorinity (16% enriched relative to seawater) fluid. The large compositional variability is interpreted to result from phase separation (liquid and vapor) of a single fluid rising through the oceanic crust. High- and normal chlorinity vent fluids compositionally resemble vent fluids found at other MOR hydrothermal areas while low-chlorinity, metal-depleted fluids have no counterparts in the literature on MORs. The sites of active low- and high-temperature venting are colonized by specialized, endemic fauna representing unique ecosystems. Typical communities are composed of vestimentiferan tube worms, clams (*Calyptogena* sp.) hosting sulfide-oxidizing endosymbiotic bacteria and bacterial mats.

### B. Intraplate Hot Spot Seamounts

Only a few intraplate hot spot seamounts of alkalic composition are known to be hydrothermally active, for example, Loihi seamount south of Hawaii (Central Pacific), Teahitia and Moua Piha seamounts, and Macdonald seamount (Southwest Pacific). Low-temperature ( $<30^{\circ}\text{C}$ ) vent fields from the summit region of Loihi seamount, recently destroyed by younger volcanic activity, were associated with brecciated pillow lava cones. Acidic vent fluids ( $\text{pH } \sim 5.4$ ) are enriched in, for example,  $\text{CO}_2$ , Fe, and  ${}^3\text{He}$  and depleted in Mg,  $\text{SO}_4$ , and Cl relative to ambient water. Their composition is very similar to low-temperature hydrothermal fluids of MORs but differs in having a very high concentration of dissolved  $\text{CO}_2$  more than 10 times the highest reported values for MORs. Combined with high  ${}^3\text{He}$  concentrations, the enrichment of these volatiles is interpreted to originate from degassing of an alkalic, volatile-rich magma body into seawater-derived hydrothermal fluids. Venting is characterized by diffuse flow regimes re-

sulting in nontronite, iron-rich smectite, iron-rich oxide, and silica deposits with abundant bacterial mats. High-temperature hydrothermal mineral assemblages were discovered subsequently after formation of a pit crater in 1996. Acidic vent fluids ( $\text{pH} \sim 5.6$ ) are significantly enriched in Fe, Mn,  $\text{CH}_4$ ,  $\text{H}_2$ , and  $\text{CO}_2$  with respect to ambient seawater. Sulfide and sulfate minerals such as pyrite, pyrrhotite, wurtzite, and barite are abundant near fractures and fissures associated with the pit crater. The sulfide mineral assemblage indicates fluid temperatures of approximately 250°C.

Although Loihi hydrothermal fluids resemble MOR fluids, fluid chemistry, presence of alkalic lavas, and the absence of benthic macrofauna communities suggest that vents at intraplate hot spot seamounts may differ from those found at MORs. Even though bacterial populations are present, which are the base of the food chain at hydrothermal vents, the expected macrofauna is lacking, probably the result of spatial isolation and the young age of Loihi volcano.

### C. Seamounts in Island-Arc Settings

Observations of active venting related to island-arc seamount volcanism are rare. Low-temperature ( $\sim 39^\circ\text{C}$ ), gas-rich vent fluids from Kasuga seamounts are unusually enriched in Mg (+27%) and in  $\text{SO}_4$  (+17%), and depleted in Ca (-64%) relative to ambient seawater, contrasting with Loihi and MOR low-temperature hydrothermal fluids, which show the opposite enrichment/depletion pattern.

Volcanic seamounts in the Papua region (New Guinea, West Pacific) located in extensional forearc settings (e.g., Conical seamount, south of Lihir Island) and in the extensional Woodlark Basin (Franklin seamount) are characterized by Au and Ag mineralizations.

In conclusion, the chemistry of hydrothermal fluids and associated deposits shows small-scale variations. Within a given hydrothermal field (e.g., ASHES vent field) fluid composition, temperature, and deposits may vary significantly due to the (1) location of active vents, (2) cooling history of erupted material, and (3) fracture patterns of the crust. Studies of hydrothermal vents around the world have shown that the chemical composition of hydrothermal fluids correlates particularly well with the composition of the surrounding crust. Thus, the chemistry of the substrate seems to control fluid composition and mineral precipitates reflecting the tectonic setting.

---

## XI. SIGNIFICANCE OF SEAMOUNTS

### A. Plate Tectonics

Some volcanic island and seamount chains within ocean basins (e.g., Hawaiian–Emperor chain) show a progressive decrease in age toward the active spreading ridge and thus help to reconstruct velocities and directions of tectonic plates in time and space. Moreover, the thermal subsidence of the oceanic crust during aging is represented by drowned oceanic islands and subsiding atolls (Fig. 5). Both observations have contributed fundamentally to the acceptance of both “hot spot” theory (mantle plumes) and global plate tectonics.

### B. Thermomechanical Properties of the Oceanic Crust

Seamounts and their volcaniclastic aprons are significant loads on the oceanic lithosphere. The response of the lithosphere to these loads, commonly a downward flexure, is used to infer its thermomechanical properties such as elastic thickness, density, and age-dependent static equilibrium. Thermal rejuvenation of the lithosphere due to reheating caused by thermal anomalies in the mantle and subsequent dynamic uplift as well as underplating processes counteract subsidence.

### C. Formation of Oceanic Crust

The study of seamount morphology and abundance along MORs in the Pacific and Atlantic provides basic insights into the construction of the oceanic crust reflecting the magma plumbing systems in different thermal regimes. Abundant coalescing seamounts and associated fissure-fed lava flows along the axial zone of slow spreading MARs are building central volcanic ridges and thus are primary sites of crustal construction (Fig. 2) in a cool thermal regime with low magma supply. These small cones are probably fed by single feeder tubes associated with temporary intermediate-sized magma chambers, which solidify to gabbros forming the lower crust. Consequently, the structure of the oceanic crust at slow spreading ridges differs fundamentally from fast spreading Pacific crust (hotter thermal regime with higher magma supply) where the main crust-forming volcanism along the axial zone is dominated by fissure eruptions

leading to sheeted dike complexes and lava sequences with abundant sheet flows.

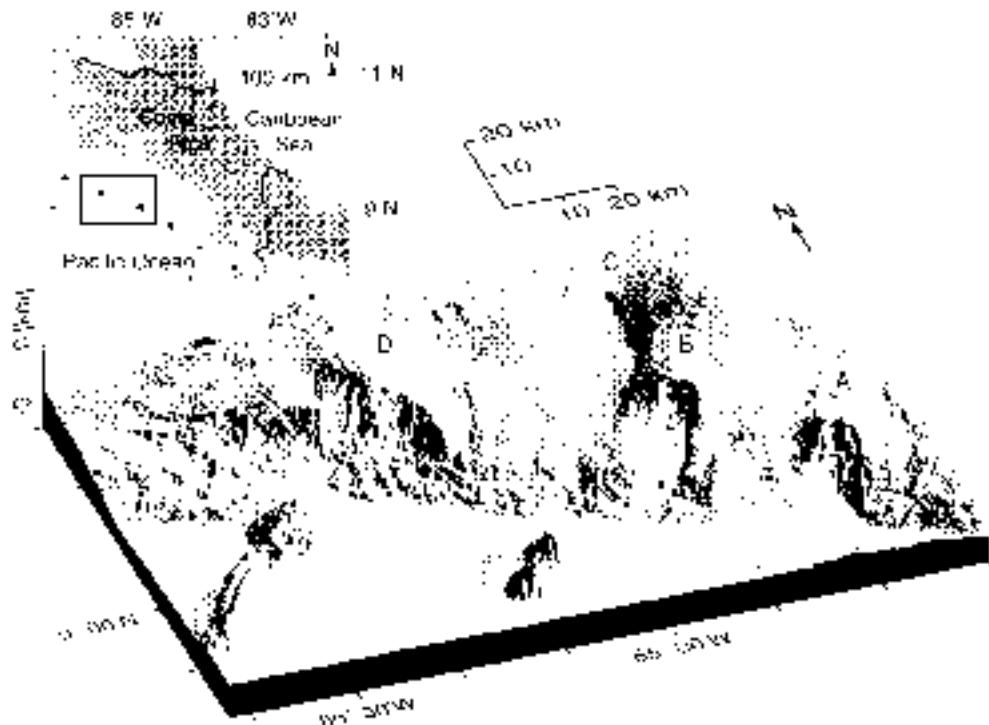

ing in subaxial magma chambers and mush zones resulting in compositionally more uniform magma.

#### D. Composition of the Upper Mantle

The areal distribution and wide compositional range of basalts combined with enriched MgO content of near-ridge Pacific seamounts suggest that they are not fed by the ridge-axis magma chamber. They may originate from numerous, isolated batches of magma generated in a heterogeneous mantle rising through the crust without prolonged storage in magma chambers. Consequently, near-ridge seamount magmas are not affected by crustal-level fractionation processes and thus may characterize the chemical composition of the upper mantle in more detail than ridge-axis magmas that have undergone mix-

#### E. Seamount Asperities

Obduction processes lead to incorporation of volcanic seamounts in accretionary prisms at convergent margins. Seamounts display significant asperities of oceanic lithosphere when subducted. Small seamounts (<40 km in diameter) approaching trenches are fractured by trench-parallel extensional faults at the outer trench rise (Fig. 5) similar to, or to a greater degree, than surrounding seafloor, whereas larger seamounts (40–100 km in diameter) show less evidence of fracturing prior to subduction. Large seamounts may interrupt normal subduction, which may be responsible for gaps in Beni-

**FIGURE 6** Seamount traces at the Pacific continental margin of Costa Rica. The right half of the figure shows three stages of furrows systematically increasing in age from A to C, produced by seamount impact on the continental margin. The youngest and shortest furrow (A) displays a V-shaped embayment, sediment uplift along the sides, and a low landward mound. Subsequent collapse of oversteepened slopes is sending slump blocks from the sides into the center. Point B shows a furrow where the breached lower slope has been reconstructed along the trench axis. Point C is the longest furrow (55 km) illustrating a subdued topography and a low slump scar at its head compared with those from A and B. Note that furrow C is on strike with the two seamounts in the foreground, evidence for subduction of a seamount chain. Impact of more complex features than single seamounts (e.g., volcanic ridges) (D), may produce highly irregular features at the continental margin. [From von Huene, R., Ranero, C. R., and Weinrebe, W., in prep., Subduction of Cocos plate segmentation and convergent margin tectonics of Costa Rica. Preprinted with permission of R. v. Huene.]

off-zone seismicity. At convergent margins where seamounts are subducted, the continental slope is marked by a highly irregular topography lacking at margins where subducted oceanic crust is smooth.

Remarkable features are straight furrows trending parallel to the direction of relative plate convergence (Fig. 6). They are on strike with seamount chains and thus are interpreted to represent traces of seamounts that were thrust beneath the continental margin during subduction. Furrows originate when seamounts initially impact the seaward side of the continental margin and thus thin accretionary prisms. Slope sediments must flow around the subducting seamounts leaving V-shaped embayments and depressions behind. In front, the slope material is ponded, folded, and uplifted during under-thrusting of seamounts producing oversteepened swells, a condition that produces slides. Most furrows show sharp boundaries, whereas others are more obscured by later sedimentation (Fig. 6).

#### F. Faunal Communities on Seamounts

Isolated seamounts and isolated volcanic islands are characterized by a highly endemic marine fauna. Species types and population density on seamounts are governed by the occurrence of hard substrate and the local current regime. High current velocities, commonly found above seamounts, lead to a dominance of suspension feeders such as sponges, horny corals (gorgonians), black corals (antipatharians), ahermatypic (non-reef-building) scleractinian corals, anemones, tunicates, brisingid seastars, and crinoids. Based on faunistic studies of more than 100 seamounts at depths of 29–3000 m, endemism is estimated at approximately 15% among invertebrates (mainly suspension feeders) and 11% among fishes. On seamounts shallower than 1000 m below sea level, provincial species make up ~50% of the entire population, whereas on deeper seamounts (>1000 m below sea level) cosmopolitan/widespread species dominate. The increasing amount of specialized species on shallow seamounts is mainly caused by the onset of explosive volcanic activity, producing highly unstable tephra piles and thus increasing the stress on the inhabitants.

The high degree of endemism cannot be sufficiently explained by the geographic isolation alone. In addition, active seamounts are (1) highly unstable environments because constructional volcanic activity and mass wasting processes may lead to drastic and temporal changes in seamount topography through time, modifying the local current regime which controls sedimentation pat-

terns (substratum) and thus the colonization of flora and fauna on deep hard-bottom seamounts; (2) shallow intrusions and volcanic eruptions locally heat the bottom water generating complex and chaotic convective currents; and (3) volcanic earthquakes, tectonic uplift, or submergence strongly affect the habitat of both benthic and nektonic (actively free-swimming) fauna.

This instability in time, the specific environmental conditions, and the geographic isolation generating a high-stress habitat lead to the evolution of an unusual or even unique biological community with a high degree of endemic species differing qualitatively and quantitatively from those found at continental shelves at the same latitude and at similar water depths.

---

#### XII. SUMMARY

The theories of global plate tectonics and “hot spots” were established based on areal distribution and age evolution of large intraplate seamount/island chains. The global distribution and abundance of seamounts is still highly speculative because large areas of the ocean basins have not been mapped bathymetrically, and satellite altimetry underestimates small seamounts. The size and morphology of seamounts are highly variable. In general, intraplate seamounts are much larger than seamounts in MOR settings.

The morphology of seamounts depends mainly on magma composition, eruption rate and depth, and geometry of magmatic conduits. The constructional morphology of seamounts is commonly modified by mass wasting processes that occur throughout the evolution of seamounts. Small MOR-related seamounts in fast (EPR) and slow (northern MAR) spreading settings reflect different processes in crustal accretion depending mainly on the spreading rate. Along the northern MAR, numerous tiny seamounts form in the axial zone while along the EPR larger but less abundant seamounts form off-axis. Seamounts start small, passing through several growth stages dominated by quiet effusive activity in deep water while explosive eruptions dominate the shallow water succession. If magma supply is high, upward growth may lead to the formation of ocean islands that subsequently become truncated due to wave erosion after volcanic activity has ceased. Guyots are truncated islands that have subsided due to contraction of the lithosphere—the result of cooling away from hot spots. These now inactive seamounts are passively carried on top of the moving plate, eventually ending in subduction

zones. Geochemical studies of seamount lava characterize the mantle source in different tectonic settings (MOR, intraplate, subduction zones) particularly well.

## GLOSSARY

- breadcrust texture** Texture of a volcanic bomb whose surface has cracked open due to vesiculation and expansion of the bomb interior after chilling of its surface.
- continuous uprush** A style of explosive eruption in shoaling volcanoes like Surtsey. Caused by a high frequency of explosions, which combine into a continuous uprush and are characterized by a tall nonspreading eruption column.
- cowpat bomb** Type of volcanic bomb resembling cow dung, whose flattened shape is due to its impact while still viscous.

**eskers** Long, low, narrow steep-sided sand and gravel ridges formed within ice tunnels by retreating glaciers.

**hyaloclastite breccia** Coarse volcanic rock composed of angular glassy fragments formed by quenching of magma by water.

**jökulhlaup** Glacier outburst flood often, but not always, related to eruptions.

**palagonite** Conspicuous yellowish alteration product of hydrated basaltic glass, mainly composed of clay minerals.

**passage zone** Subhorizontal junction between flat-lying lavas and steep-dipping hyaloclastite breccia in a lava delta, representing the water level coeval with eruption.

**pillow lava** Lava, usually basaltic, with close-fitting discontinuous pillow-shaped masses usually <1 m in diameter, formed as a result of subaqueous extrusion.

**tephra finger jets** Parcels of bombs, wet tephra, and gas that follow spreading parabolic trajectories and are ejected by discrete, relatively low frequency shallow explosions.

**tindar** Ridge- and cone-shaped successions of tephra (tuff and lapilli tuff) from subglacial eruptions, deposited in a water-filled vault or lake thawed in a glacier by volcanic heat.

**tillite** Glacial deposit (also known as boulder clay) consisting of clasts up to boulder size dispersed in sandy-muddy matrix.

**trachyte** Fine-grained lava with an alkaline composition, typically with prominent large alkali feldspar crystals.

**turbidite** Sediment or rock deposited from a gravity-driven flow of suspended sediment in water (turbidity current), characterized by well-developed sedimentary structures arranged in a regular sequence.

**tuya** Flat-topped, steep-sided volcano (also known as a table mountain) that erupted into a lake thawed in a glacier by volcanic heat.

## I. INTRODUCTION

Subglacial eruptions are those that occur from a vent situated beneath a valley glacier or ice sheet. They may be explosive or nonexplosive and typically involve substantial volumes of water generated by melting the overlying ice. Construction of the volcano takes place within the ice sheet (i.e., englacially). Because of the intimate association with meltwater, subglacial volcanoes are sometimes indistinguishable from other volcanoes constructed in nonglacial aqueous settings (e.g., volcanoes in lakes or beneath the sea). However, eruptions beneath ice can result in diagnostic structural features in the volcanic sequences. Ice is widely distributed on Earth. It is mainly found in temperate and polar regions, but also occurs in mountainous terranes at lower latitudes and even within the tropics. The largest areas of continuous ice sheets are confined to the polar regions and Greenland, places where human populations are sparse or absent. Conversely, dense populations are commonly present adjacent to active volcanoes with glaciers and ice sheets in mountain ranges at virtually all other latitudes. The potential for devastation during subglacial eruptions may be significant and regions most at risk include parts of the west coasts of North and South America, Japan, and Iceland. Subglacially erupted volcanoes have even been postulated on Mars, where ice sheets may have been formerly much more extensive.

## II. WHEN FIRE MEETS ICE—AN ACCOUNT OF A RECENT SUBGLACIAL ERUPTION

During midmorning on September 29, 1996, an earthquake of magnitude 5.4 (Richter) shook the Vatnajökull ice cap in Iceland. The ice cap is Europe's largest, with an area of 8300 km<sup>2</sup>. It covers part of the Icelandic eastern neovolcanic zone and has been the locus of nu-

merous subglacial eruptions during the last 1000 yr, occurring about every 10 yr during this century. An intense earthquake swarm occurred after the initial event. Activity continued at an enhanced level, culminating in continuous low-amplitude volcanic tremor. The eruption probably commenced some time between 2200 and 2300 hours on September 30. The new site, called Gjálp, was located about midway between the Grímsvötn and Báróarbunga subglacial volcanic centers in the northwestern part of Vatnajökull. It last erupted 60 yr previously. An overflight on October 1 revealed a heavily crevassed depression on the surface of the ice (Fig. 1). The depression enlarged to about 2 km in diameter and 200–300 m deep and other aligned depressions appeared, indicating an eruption along a 4- to 5-km subglacial fissure. Simultaneously, water from the eruption site poured into the subglacial cauldron at Grímsvötn at a rate of about 5000 m<sup>3</sup> s<sup>-1</sup>, raising the 200- to 250-m-thick floating ice shelf.

At about 0500 hours on October 2, the eruption broke through the 400- to 600-m-thick ice over the fissure, forming a hole several hundred meters wide in the ice by the afternoon. Observers noted that the initial white steam column changed to a dark gray column of ash rising vertically to 0.5 km and characterized by rhythmic explosions scattering volcanic bombs. Above that, buoyant steam rose to 3 km and was deflected by a southerly wind although ash fall was minor. Later that day, the eruption column peaked at about 9 km and was associated with spectacular lightning. A large depression formed on the ice surface at another eruptive site on the fissure some 3 km north of the earlier sites. The sites were linked by a shallow linear trough in the ice surface caused by overflow and melting in a subglacial pathway.

Activity continued during the next week. The eruptions were described as pulsating, with periods of quiet alternating with explosive activity. Water was observed about 200 m below the original ice surface at the active vent site and the erupting fissure extended to 9 km. On October 4, explosive eruptions seemed to be occurring through a water column at least 50 m deep. Volcanic tremors ceased on October 13 and there was no explosive activity thereafter. By then, the eruptive fissure was marked by two large ice cauldrons, with the formerly most active crater represented by a low moundlike island of dark steaming ash in the southern cauldron (Fig. 2). A prominent canyon up to 500 m wide with vertical ice walls 150 m high extended south from the island mound. Water flowed rapidly from north to south within the canyon, and disappeared into a large tunnel entrance. Much of the Vatnajökull ice cap was covered by a thin ash layer.

FIGURE 1 Depressions in the surface of the Vatnajökull (Iceland) ice sheet formed by subglacial melting, 15 hours after the start of the October 1996 eruption. The foreground depression is about 100 m deep and both are about 2 km wide. [Photograph by M. T. Gudmundsson.]

FIGURE 2 Eruption column above a pyroclastic cone (obscured by gases) surrounded by glacially confined meltwater derived by melting of the ice. The meltwater overflowed the glacier southward (away from the observer) within a deep ice canyon. [Photograph by M. T. Gudmundsson.]

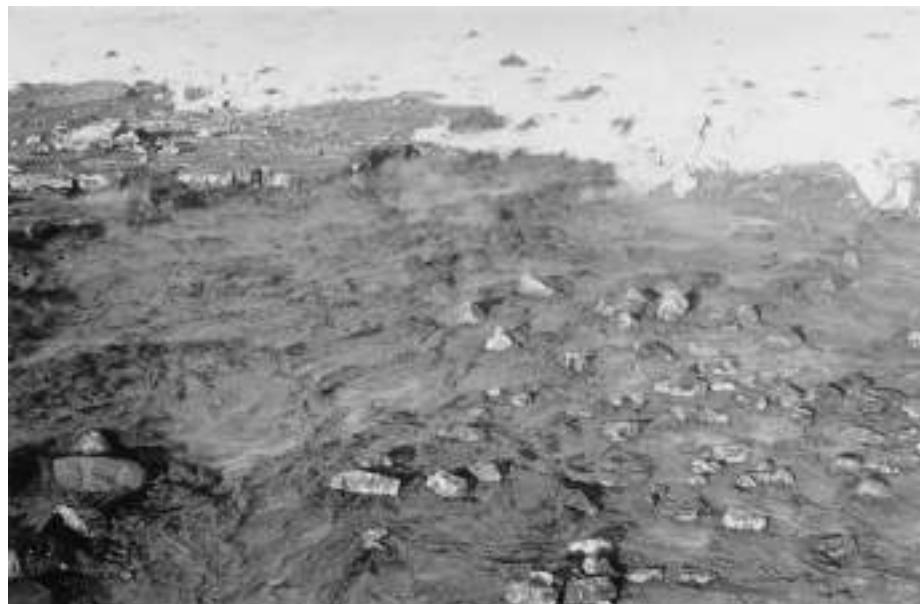

During the eruption, Icelandic scientists anxiously monitored the depth of water in the Grímsvötn caldera. Jökulhlaups (glacier outburst floods) occur every 4–6 yr from the subglacial caldera and the hydrologic characteristics of the system were thought to be quite well known. Past experience suggested that flooding would occur when the lake level reached 1455 m above sea level. That level was reached by October 3 and an imminent jökulhlaup was predicted. By October 4, water levels were higher than at any previous time this century, although a comparatively low flood surge was anticipated. By October 7, with no flooding yet evident, the local experts stopped forecasting. About 3 km<sup>3</sup> of meltwater was stored in the Grímsvötn cauldron, increasing at a rate of about 400–500 m<sup>3</sup>s<sup>-1</sup> even after explosive eruptions ceased. The rate diminished to about half by October 25 and the water rose to a final elevation of 1510 m. The jökulhlaup finally began early on November 5, reaching a rate of 6000 m<sup>3</sup>s<sup>-1</sup> within the first 2 hours and rising to 25,000 m<sup>3</sup>s<sup>-1</sup> late in the afternoon. The flood waters, carrying icebergs the size of houses and weighing up to 1000 tons, destroyed or severely damaged bridges across the Sæluhúsakvísl and Skeiðarár rivers (Fig. 3). The flood waters peaked late on November 5, when about 45,000 m<sup>3</sup>s<sup>-1</sup> streamed out of the Skeiðarárjökull outlet glacier and south across the alluvial floodplain, briefly making it the second largest river on

Earth. The jökulhlaup ceased on November 7. A volume of 0.7–0.75 km<sup>3</sup> of volcanic products formed a new subglacial ridge 6–7 km long. About 4 km<sup>3</sup> of ice was melted above the fissure. Floods affected an area of 750 km<sup>2</sup>, locally extending the coastline by 800 m and creating about 7 km<sup>2</sup> of new land. The eruption and flood were the fourth largest such events to occur in Iceland this century.

---

### III. IN THE GEOLOGIC RECORD, HOW DO WE KNOW THAT ERUPTIONS OCCURRED BENEATH ICE?

Although parts of the Antarctic ice sheet may be half a million years old, and there is also a (disputed) record of 8-million-year-old ice preserved in Antarctic sediments, ice is normally a comparatively short-lived substance not generally preserved in sedimentary and volcanic sequences. Instead we must look at the proxy record of preserved deposits in order to interpret the eruptive environment. Criteria that have been used are listed in Table I and illustrated in Figs. 4 and 5, but it should be understood that unambiguous evidence for the former existence of ice coeval with eruptions is sometimes im-

**FIGURE 3** Glacier outburst flood (jökulhlaup) in Skeiðará caused by the October 1996 subglacial eruption in Iceland. The flood has entrained numerous large ice blocks, some the size of houses and individually weighing up to 1000 tons, which were ripped from the glacier margin seen at the top of the photograph. [Photograph by M. T. Gudmundsson.]

TABLE I Criteria Used to Determine If a Volcanic Sequence Was Erupted beneath Ice

Criteria	<i>Interpretation</i>
History of glaciation	A known history of glaciation(s), documented from other research, can at least raise the possibility that volcanic sequences were erupted in association with ice.
Paleotopography	In very young sequences (<10–15 Myr) it is often possible to assess whether the paleotopography could have been able to form lakes. Where appropriate topography was absent, ice may have been a barrier able to pond water.
Fossils	Even rapidly constructed submarine volcanoes at high latitudes are colonized by marine plants and animals soon after eruption. A lack of fossils indicates either nonmarine or severe, possibly glacial conditions.
Sedimentary structures and rock characteristics	Sedimentary structures caused by flowing or agitated water, and presence of well-rounded clasts are characteristic of shallow water or river settings. Their absence indicates a very protected environmental (possibly lake or englacial vault). The presence of these features does not exclude some subglacial environments. Association with nonvolcanic glacial deposits, such as tillites (glacial boulder clay deposits), containing dropstones or striated and faceted clasts, and sediment structures such as sediment-filled ice wedges, ice-melt collapse pits and cone or ring-shaped mounds of ice-rafted debris indicate coeval glaciation. These features are uncommonly preserved or are hard to recognize.
Structural features of the volcanic sequence	The presence of subaerially erupted and emplaced lavas and tephra, draping subaqueous deposits from the same eruption, indicates that contemporaneous water levels dropped unusually rapidly. Similarly, evidence for water level rising and/or falling between closely spaced eruptions, sometimes by up to a few hundred meters (Fig. 4), indicates a change too rapid to be caused by a (globally) changing sea level and it is more likely caused by a sudden drainage of a glacial lake by collapse of an ice barrier or time-related fluctuations of the surface elevation of an enclosing ice sheet. Outcrop-wide erosional surfaces cut by wave action are absent because of protected englacial (lake/vault) environment. Presence of striated, molded, or ice-polished surfaces within the sequence indicate coeval ice. Bedding back-tilted toward a source vent reflects the proximity of retaining ice walls, later removed by melting, against which the sediments were banked (Fig. 5).

FIGURE 4 Nunatak constructed of three superimposed lava deltas formed between 6.20 and 6.50 Ma, recording very different water levels contemporaneous with each eruption. The approximate elevations of the former water levels, indicated by passage zones, are shown. Passage zone 2 is obscured in this view, but is lower than passage zone 1. The section is about 200 m high. Hedin Nunatak, Antarctica.

**FIGURE 5** Subaqueously emplaced pillow lava (upper left side of section) and breccias and tuffs high on the flank of a subglacially constructed volcano. Bedding in the higher part of the section flattens out rapidly to the right (away from the vent) and is locally back-tilted (to the left), probably because of the proximity of former confining ice walls of a water-filled englacial chamber, against which the sediments were banked. The section is about 35 m high. Kalfstindar, Iceland.

possible to obtain. However, arguments based on several internally consistent observations are often sufficient to identify a subglacial eruptive setting.

---

#### IV. PROPERTIES OF GLACIERS THAT AFFECT SUBGLACIAL ERUPTIONS

The temperature distribution, structure, and hydrology of glaciers exert a fundamental control on subglacial eruptions. A common simple classification of glaciers is based on temperature distribution. *Temperate* glaciers are at the pressure melting temperature throughout their thickness (except in a thin surface layer), whereas *polar* glaciers are well below freezing and they are frozen to their bed. Because movement of polar glaciers takes place by internal deformation of the ice, only temperate (wet-based) glaciers are able to modify significantly their bedrock substrate. Although simplistic, the distinction into two glacier types is important, because unlike polar glaciers, water can migrate in temperate glaciers. This has very important consequences for the course of events in many subglacial eruptions. The influence of polar ice

on subglacial eruptions has not been critically examined and only temperate glaciers are considered in this chapter.

The movement of water in glaciers (glacier hydraulics) is fundamentally affected by glacier structure, in particular the distribution of permeable layers whose presence is predominantly a consequence of the conversion of snow to ice. Snow is a loose aggregation of ice crystals and grains that are essentially unchanged since they were deposited. Compressing snow results in the progressive elimination of trapped air. In ice, the interconnecting air passages between the ice crystals and grains have been sealed off. Snow that is in an intermediate stage of densification (i.e., not yet ice) is called *firn*. Snow and firn are permeable, whereas unfractured ice is essentially impermeable. Fractured (e.g., crevassed) ice is also permeable. Most fractures pinch out at a depth of 30 m due to internal deformation and flow of the ice. Many glaciers thus have a crude layered structure, comprising an uppermost permeable layer (snow, firn, and fractured ice) overlying impermeable unfractured ice. Layer boundaries are gradational.

The direction of meltwater flow in a glacier is determined by the hydraulic gradient, which is itself largely controlled by the slope of the glacier *surface*. The glacier

bed is largely ineffective in determining water flow except in cases where its gradient is about 11 times that of the glacier surface. During eruptions, the ice surface becomes depressed as ice is melted over the erupting vent. This distorts the local hydraulic gradient, causing meltwater to flow in toward the vent, and the site becomes sealed by an encircling ice barrier. A water-filled vault forms, which may become an englacial lake when melting penetrates right through to the surface. When the water becomes deep enough, the encircling ice barrier floats and the vault drains. This results in a jökulhlaup, as occurred spectacularly toward the end of the 1996 eruption in Iceland.

#### V. BASALTIC SUBGLACIAL ERUPTIONS

Recent research into basaltic subglacial volcanism has identified distinctive sequence "types" whose principal characteristics are controlled by the thickness and structure of the overlying glacier (Fig. 6). Distinction is based on the types and relative proportions of the volcanic, volcaniclastic, and sedimentary lithologies present and their organization into distinctive bundles of rock types

separated usually by unconformities. The prominent, mainly erosional surfaces are an expression of the natural internal geometry of the volcanoes and they hold important clues to volcano construction. The sequence types are interpreted to correspond to eruptions beneath "thin" ( $\leq 100$ – $150$  m) and "thick" (mainly  $\geq 150$  m) temperate glaciers. Further subdivision of eruptions beneath thick glaciers is also made depending on glacier structure (see later discussion).

#### A. Eruptions beneath Thin Glaciers

Thin glaciers, either valley-confined ("Alpine") glaciers or the thinned margins of more extensive thicker ice sheets or ice caps, are defined as those formed almost entirely of snow, firn, and/or fractured ice. Measured depths to the firn ice transition range up 115 m, yielding an approximate limiting thickness of 100–150 m for thin glaciers as defined here. However, thicknesses of just a few tens of meters are typical for most temperate glaciers. Because the glacier is permeable, meltwater is able to migrate according to local hydraulic gradients. An eruption will cause extensive melting of the ice and create a cavity or vault but pillow lava effusion is unlikely because meltwater will not pond over the vent. A depres-

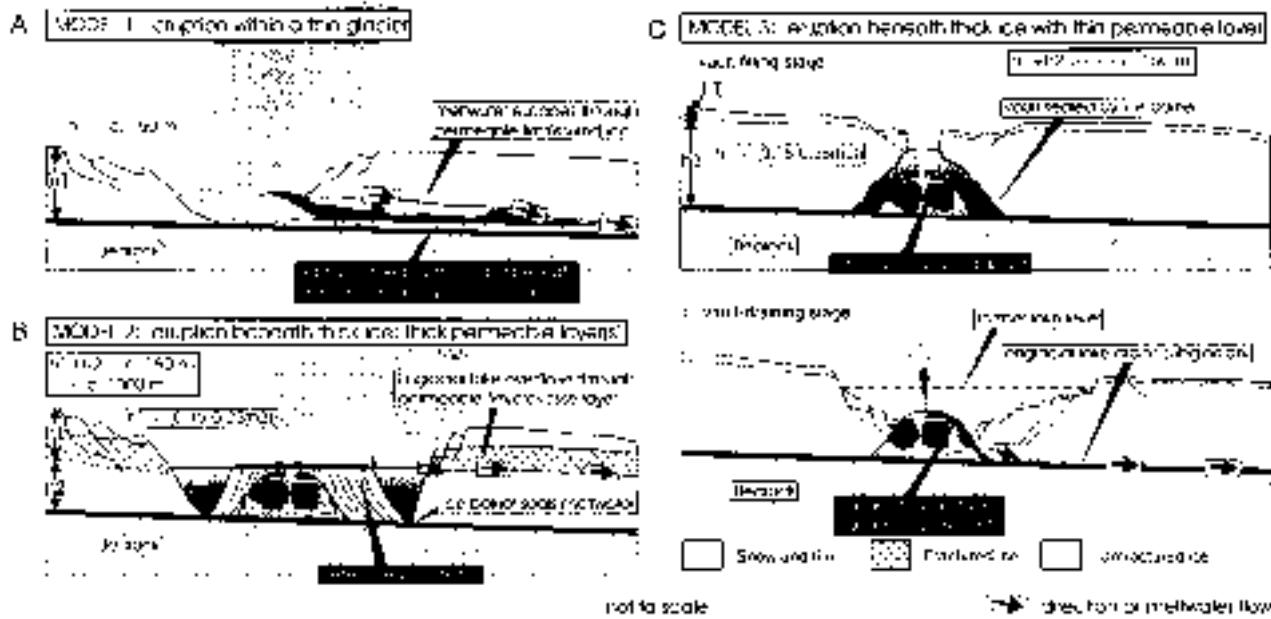

FIGURE 6. Cartoons showing three empirical models for subglacial eruptions beneath glaciers of different thickness. The hydrodynamic conditions are different in each case, resulting in significantly different sequences of rocks and volcano construction.

sion or hole will rapidly form in the glacier surface and meltwater will drain away continuously as a sheet or within thermally eroded channels. The eruption is likely to be explosive (hydrovolcanic) initially, forming a pyroclastic cone. As the vent becomes isolated from meltwater, the eruption will change to relatively nonviolent strombolian or hawaiian explosions or effusion of degassed lava.

The author knows of only one published example of volcanoes formed under conditions broadly similar to these—those formed during a subglacial eruption on Deception Island (Antarctica) in 1969. Examination of two of the eruptive centers by the author showed them to be pyroclastic cones formed of unstratified, loose, highly vesicular gray scoria and fluidal textured bombs overlying brick-red, weakly bound coarse lapilli and abundant flattened (cowpat) bombs. Chilled breadcrust textures are common and lapilli are cube shaped (i.e., bounded by fractured surfaces). In most respects the tephra resemble those formed in Strombolian (“dry”) eruptions, but the abundance of fractured clasts and breadcrusted textures suggests an additional minor influence of water during the eruption.

By contrast, the record of these eruptions deposited off the flanks of the volcano can be very distinctive, particularly if lava effusion has occurred. Although published examples are uncommon, there are well-documented sequences in Iceland and Antarctica. They are typically only a few tens of meters thick although multiple effusive eruptions can build up more substantial thicknesses far exceeding the thickness of the coeval glacier. This reflects the ability of ice to reform or “heal” over an eruptive site. It contrasts with eruptions associated with seawater or lakes, in which the water always remains at a regional base level. A knife-sharp basal unconformity usually separates the sequences associated with each effusive phase. It commonly shows signs of ice-molding, polishing, and striations due to glacial erosion. The overlying succession typically comprises unbedded tillite overlain by, or interbedded with, gravelly sandstone and conglomerate (Fig. 7). The sedimentary deposits are largely formed of resedimented glassy fragments flushed by meltwater down thermally eroded tunnels at the glacier bed. They are prominently stratified, including small-scale channel structures and cross stratification and are the volcanic equivalent of glacial eskers.

Although lava may override or bank against adjacent ice, observations suggest that it will also thermally erode glaciers. Pillow lava bases to some flows are ascribed to limited involvement with surface snow. Interaction with a subglacial tunnel will also cause chilling, granulation,

FIGURE 7 Sequence of massive glacial tillite overlain erosively by paler-colored tuffs deposited from flowing water and succeeded by intermixed hyaloclastite breccia and lava with widely varying columnar joint orientations. The sequence is about 30 m thick and rests on a sharply defined glacial unconformity. It probably formed beneath a relatively thin permeable cover composed mainly of snow and firn. Mount Murphy, Antarctica.

and formation of hyaloclastite breccia on the flow surface, which will be carried to the flow front and overridden. Further breccia is likely to be formed by steam explosions where lava crosses water-rich unconsolidated sediments and pockets of trapped water in bedrock surface irregularities. Meltwater draining over and through the lava may rework and redeposit any hyaloclastite breccia. Molten lava can be insulated by a protective carapace of breccia, with fresh lava capable of traveling long distances to the flow front and/or injected up into overlying breccia.

Thus, a single effusive eruption beneath a thin glacier should lead to an idealized sequence comprising glacial (tillite) and volcaniclastic lithofacies overlain by lava and

hyaloclastite breccia sandwiched between sharply defined glacial unconformities (Fig. 7). An important feature is the evidence for flowing water preserved in the sedimentary lithofacies, which contrasts with the ponded water conditions characteristic of eruptions beneath thicker glaciers (see later discussion).

## B. Eruptions beneath Thick Glaciers

Thick glaciers, corresponding to ice sheets or ice caps, are defined as those formed largely of impermeable ice. They are typically  $\geq 150$  m thick. Under these circumstances, meltwater can be sealed in vaults following distortion of the local hydraulic gradient surrounding the erupting vents. Because ice is less dense than water, the volume change caused by melting at the base of a glacier will rapidly cause a depression to form in the glacier surface. Observed examples suggest that the rate of heat transfer from erupting magma to ice is extremely rapid and several hundred meters of ice may be melted through completely in only a few hours. Simple calculations indicate that the volume of meltwater generated in a perfectly sealed vault must be much greater (possibly by a factor of 10) than the volume of magma emplaced, simply in order to create space for the mass of magma. In reality, however, subglacial leakage is predicted during the first few moments of melting and may create subglacial channels. Depending on rates of thermal erosion, the channels may maintain hydraulic continuity with the rest of the glacier. The water level in the vault depends on a balance between rates of meltwater generation and basal leakage. The few observed examples suggest that vaults fill rapidly and overflow. This may cause widespread sheet flooding, as occurred at an early stage in the 1969 Deception Island eruption (beneath a thin glacier composed mostly of ice), or else more focused overspill and confinement in supraglacial channels, as occurred during a late stage of the Deception Island eruption and exemplified by the 1996 eruption in Iceland.

The structure of the glacier determines the precise course of events during these eruptions. In eruptions beneath thick glaciers with a relatively thick *permeable upper layer*, meltwater will accumulate in a vault until it encounters a layer of snow, firn, or fractured ice, through which it will drain by overflowing. If the thickness of the permeable layer is greater than about 10–25% of that of the underlying impermeable ice, water in the vault can never reach a depth sufficient to float the surrounding ice. The water level will stabilize at the

elevation of the lowest exit point, diminishing slowly as thermal erosion occurs at the exit.

Eruptions involving subaerial lava effusion into a water-filled overflowing englacial lake yield table mountain volcanoes (known as *stapi* in Iceland or *tuyas* in British Columbia). Eruptions that cease before subaerial emergence form steep-sided ridges predominantly composed of palagonitized (clay-altered) tuff and breccia that are sometimes called *tindars*. Table mountains are distinctive landforms consisting of relatively small, isolated, roughly circular or more commonly subrectangular plateaux. Icelandic table mountains are characteristically  $<10$  km wide and a few hundred meters high (up to 1000 m in some compound edifices), with abrupt edges and steep flanks. These dimensions and morphologies are similar to supposedly comparable table mountains on Mars.

The flat or gently convex top of a table mountain is composed of lavas that may construct a small shield volcano with a summit crater or cinder cone(s). It is formed by a combination of subaerial lava effusion and generation of hyaloclastite breccia in lava deltas. The subhorizontal boundary between the flat-lying lavas and steep-dipping breccia foresets is called a *passage zone* and its recognition in a volcanic sequence of this type can be used to identify unambiguously contemporaneous water levels and, by inference, the approximate elevation of the coeval encircling glacier surface (Fig. 8). However, the passage zone elevation will only crudely correspond to the surrounding ice sheet surface. Although probably within a few tens of meters of temperate glacier surfaces, it may be more than 100 m lower than some polar glacier surfaces.

The lava-delta capping sequence overlies a pedestal-like foundation of palagonitized glassy tuff, breccia, and pillow lava. The lithofacies present are identical to those forming tindars. Tindars can be regarded as incompletely formed table mountains. It is thus convenient to refer to an entirely subaqueous *tindar stage* in the evolution of a table mountain. This stage may commence in effusion of pillow lava and hyaloclastite breccia and is analogous to the pillow volcano stage that is well documented in submarine volcanoes. It may also contain sheet flows, and tabular and lensoid intrusions that drive hydrothermal alteration in overlying units.

Effusion of pillow lava is nonexplosive partly because of the suppression of magmatic volatiles by the confining pressure of overlying ice and/or water in the vault, although many factors influence explosivity. For example, observations of submarine eruptions indicate that explosivity can be suppressed by water depths of only a few tens of meters, whereas other explosive eruptions

**FIGURE 8** Subaerial pahoehoe lava flow and coeval steep-dipping subaqueous hyaloclastite breccias, which together form a lava delta. The subhorizontal junction between the lava and breccias (known as a *passage zone*) marks the position of a former water level, in this case, meltwater in an englacial lake. The section is about 75 m high. James Ross Island, Antarctica. [Photograph by I. P. Skilling.]

can take place beneath several hundred meters of water. However, most eruptions become explosive as the lava pile grows upward, probably by a combination of explosive bubble growth in the magma and simultaneous interaction with meltwater and water-soaked tephra slurry in the vent (an eruptive style known as *surtseyan*). Much of the vertical aggradation of the edifice takes place during *continuous uprush* periods of high magma discharge, resulting in the construction of a subaqueous tuff cone. Less efficient thermal to mechanical energy conversion, more rapid deceleration of a subaqueous column, turbulent mixing with water, and difficulty in breaching the water:air interface combine to produce a lower, denser eruption column. Tephra dispersal is mainly by fallout close to the vent.

A continuously collapsing tephra-charged column, dumping wet tephra around the vent, will construct an unstable oversteepened cone. The coarse tephra is rapidly distributed down the submerged flanks mainly by a variety of sediment gravity flows. Their presence indicates ponded water rather than the flowing water conditions characteristic of eruptions beneath thin glaciers. The resulting deposits are formed of sandy-gravelly glassy pyroclasts, which occur mainly in continuous even beds with gradational surfaces that are typically structureless or crudely graded. They form thick unbroken sequences individually a few meters to tens of meters thick. Each sequence is envisaged linked

to a single continuous uprush episode in which the tephra was dumped and more or less instantly transformed into high-density turbidity currents. In some of the sequences, the beds become thinner, finer, and more palagonite altered upward (Fig. 9). These features probably indicate diminishing energy and tephra input, possibly reflecting more pulsed magma discharge in the later stages of the continuous uprush episode. The greater surface area provided by the finer grains caused the enhanced alteration.

At lower discharge rates, discrete pulses of magma initiate spectacular activity known as *tephra finger jetting* in which shallow explosions eject bombs and parcels of wet tephra and gas that follow spreading parabolic trajectories. The tephra-laden jets probably have the potential to transform into sedimentary gravity flows as they pass into water, resulting in gravelly sandstone beds similar to classical turbidites and occurring in thinner sequences with well-defined bedding surfaces (Fig. 10). Thinly bedded graded-laminated fine sandstone and mudstone units, generally just a few decimeters thick, are a minor part of these sequences and probably formed from sandy low-density turbidity currents during short periods of quiescence.

An important feature of the subaqueous successions, and one that is useful in distinguishing products of submarine and subglacial eruptions, is bedding orientation. In both eruptive settings, bedding dips radially away

**FIGURE 9** Normal graded and ungraded beds of redeposited tuff at Kalfstindar, Iceland. The well-developed upward-thining, fining, and better stratification are attributed to waning explosive activity during a continuous-uprush episode. Note the very poor stratification characteristics of the lower thicker part of the sequence. A total thickness of 6 m is shown.

from the vents. However, in some subglacial volcanoes, the bedding flattens out rapidly away from vents by banking against former confining ice walls (cf. Fig. 5). The ice walls move away because of melting, thus removing support from the volcano flanks and precipitating slope failure. Evidence for collapse is widespread and conspicuous in the preserved successions, and includes slump scars on a range of scales up to many tens of meters, deformed sediment packages, and synsedimentary faults. Many coarser breccia beds present are likely to be a result of these slope failures. Like uncorking a bottle, the sudden pressure release from removing overlying sediments can also cause focused discharge of overpressured pore fluids. This is preserved as cross-

cutting slurry-like deposits that terminate at slump scar surfaces.

It is possible for subaerial lava to overlie directly coeval subaqueously deposited tephra or pillow lava sequences, an important relationship that is diagnostic of a subglacial setting. It implies drainage of the vault during eruption and overflow must be exceeded by basal leakage either through early formed channels or expansion of the vault over an appropriate bedrock topography. Note that the surrounding ice “barrier” is not floated. It is a “leaky” barrier.

By contrast, in glaciers formed mainly of *impermeable ice* (i.e., an upper permeable layer less than about 10–25% of the thickness of impermeable ice), meltwater accumulates in the vault and ultimately floats the surrounding ice barrier. This releases the meltwater as a sudden flood whose volume reflects that of the englacial vault. Eruptions that take place within the ice-filled caldera of Grimsvötn volcano in Iceland are apparently of this type. Our knowledge of the internal structure of these volcanoes is minimal. However, it is possible to predict the kinds of structures, principal rock types, and history of construction based on interpretation of the hydraulic history. Meltwater is unable to overflow because the surrounding ice barrier is floated before the water level in the vault reaches the glacier surface or any permeable upper layer. Because the volume of meltwater accumulates at a much faster rate than the magma, the volcano cannot become emergent until after the ice barrier floats and the vault drains. Lava deltas cannot form and there will be no table mountain landform. The volcanoes will be dominated by subaqueous lithofacies, probably mainly pillow lava and hyaloclastite breccia. If eruptions persist after the vault has drained, the subaqueous pile will be unconformably draped by subaerial lava and/or pyroclastic cone(s). Although this juxtaposition is diagnostic of subglacial volcanoes, it has a different hydraulic origin from that found in some table mountains. A failure to interpret correctly the subglacial conditions responsible could lead to meaningless interpretations of the tectonic, volcanic, and paleoenvironmental histories of a region.

Once the meltwater has commenced draining from the vault, the conditions that led to floating of the ice barrier are no longer sustained and the surrounding ice will collapse back into place, thus bringing the flood to a close. However, early leakage of meltwater in subglacial tunnels and enlargement of the tunnel system by enhanced thermal erosion during the massive discharge from the vault will prevent a sudden shutdown. The flood will diminish as the tunnels are constricted by

FIGURE 10 Well-defined normally graded-stratified beds (turbidites) formed of redeposited tephra possibly formed from discrete tephra jets during intermittent jetting activity. Kalfstindar, Iceland.

ice deformation concurrent with the falling hydrostatic pressure. Conditions are reestablished in which the vault may refill with meltwater and the eruption can become subaqueous once more. The resulting association of repeated subaqueous and subaerial lithofacies could be very complicated in a prolonged eruptive episode. As far as the author is aware there are no published descriptions of a volcanic succession of this type.

ragged gray pumice mixed with minor angular fragments of obsidian glass, in featureless to poorly bedded units up to 40 m thick. A wide range of grain sizes is present, including submillimeter-sized fine clasts. By contrast, the hyaloclastite breccia is formed of angular fragments of obsidian, flow-banded pumiceous glass and crystalline rhyolite. Clasts are coarse (millimeters to 40 cm) and they form unbedded deposits 20–40 m thick that grade laterally into ellipsoidal and irregular rhyolitic lava lobes and interconnected lobe complexes (Fig. 11). Some lobes are greatly elongated vertically and apparently intrude overlying and adjacent breccia. Lobe size varies considerably; they are commonly 2 to 70 m in diameter, but exceptionally range from 40 cm to 900 m. The lobes are mineralogically and chemically similar to the pumice and obsidian clasts in the adjacent breccias and they normally display alternating textural zones of black obsidian, flow-banded pumiceous glassy rhyolite, and slightly to completely crystalline vesicular rhyolite with well-developed curving columnar joints.

The field relationships clearly indicate that the hyaloclastite breccia formed by the progressive mechanical disintegration of massive flow lobes. The brecciation must have occurred during emplacement and concurrent chilling of the lobes by meltwater, perhaps during effusion beneath ice and/or intrusion into water-saturated pumice breccia. Conversely, the pumiceous deposits were interpreted as products of highly explosive mag-

## VI. FELSIC SUBGLACIAL ERUPTIONS

There are very few published descriptions of subglacial eruptions of felsic magmas (andesite/dacite/rhyolite compositions). There has been no modern volcanological study of these sequences and they were last investigated in the 1970s. Two different types of occurrence are described.

In southwest Iceland, felsic centers are up to 2 km in diameter and 500 m thick. They consist of lava lobes, hyaloclastite, and pumice breccia erupted beneath glaciers <400 m thick. The lithofacies form prominent interlayered sequences comprising alternating pumice breccia and lobe complexes, the latter formed of lobes of lava intimately associated with cogenetic hyaloclastite breccia. The pumice breccia consists of angular and

**FIGURE 11** Closely jointed margin of a rhyolite lobe changing laterally into glassy and crystalline breccia caused by chilling, quenching, and disintegration when the lobe came into contact with water melted from an adjacent glacier. Blahnukur, Iceland.

matic eruptions. The presence of fines and fracture-bounded clasts was attributed to minor water interaction. Comparisons were made with subglacial table mountains and explosive surtseyan eruptions, although this author notes that there are also surprising similarities in scale and lithofacies characteristics to sequences formed by subglacial basaltic eruptions beneath thin glaciers.

An unusual subglacial volcano constructed entirely of andesite lavas within a former ice sheet at least 500 m thick has been described from a locality in British Columbia known as The Table. The volcano forms a pillar-like mass with sheer cliffs 300 m high, rising to a nearly flat summit measuring 300 m long and 225 m wide. It is constructed of horizontal lavas 30–75 m thick in its central part and subvertical lavas on some sides. The lavas show spectacular columnar joints with styles characteristic of rapid cooling, and one of the steep-dipping flows overlies a deposit of glacial boulder clay at the foot of the cliff. The outcrop was interpreted as an original structure little modified by erosion and, with no trace of a preexisting rock mass or ash cone in the vicinity, effusion within a confining cylindrical ice vault drained of meltwater was postulated. The lavas were envisaged spreading laterally until they came in contact with ice walls, which they solidified against. Later lavas poured into the steep gap thawed around the cooling lava pile. Contemporaneous ice flow would have caused the vault to deform and extend downstream of the (pro-

tective and warm) vent and lava masses. Thus, the outcrop elongation, parallel to the local paleo-ice flow direction, was interpreted as an original constructional feature.

#### VII. LARGE SUBGLACIAL VOLCANOES—AN UNTAPPED SOURCE OF PALEOENVIRONMENTAL INFORMATION

Volcanoes can be very sensitive indicators of climatic variations. With their potential for precise isotopic dating, the analysis of long-lived large volcanoes in glaciated regions may permit the reconstruction of temporal and spatial variations of former ice sheets. Thus, the research can contribute to our knowledge of climatic fluctuations. There are very few published descriptions of large subglacially erupted volcanoes. They are common in Antarctica and Iceland but most of the investigations are rather dated now and lack the input from modern volcanological studies. On the basis of geomorphological evidence interpreted from photographs, Olympus Mons, the largest volcano on Mars and far

larger than any volcano on Earth, may also have erupted through an ice sheet in times past.

Mount Murphy is a basalt to trachyte shield volcano about 25 km in diameter with a postulated small ice-covered caldera. It was constructed relatively quickly between 8 and 9 Ma on a prominent basement massif that rises to more than 2000 m above sea level. Younger satellite centers (7–4.5 Ma) on the west side are the remains of several small dissected surtseyan volcanoes with predominantly basaltic compositions; they were probably erupted beneath a gently north-sloping ice sheet whose elevation fluctuated through 200 m during their eruptive period. Interpretations of the Miocene glacial history based on the Mount Murphy shield succession are complicated by the coastal position of the volcano [marginal to the West Antarctic Ice Sheet (WAIS)] and possible influence of the basement topography on the local elevation of the WAIS. Striations and molded surfaces on the basement surface suggest the presence of a thin mountain ice cap prior to activity in the shield.

More than 2000 m of section is exposed at Mount Murphy. The lower half is dominated by subglacially emplaced basaltic pillow lava and hyaloclastite breccia, and is succeeded by subaerial basalt and trachyte lavas. The basal hydrovolcanic section consists of several sequences of water-reworked gravelly sandstone and breccia intercalated with columnar lava lobes and pillow lava-hyaloclastite breccia (Fig. 7). The individual volcanic and volcaniclastic sequences are each a few tens of meters thick. Some contain intercalated tillite formed entirely of locally derived volcanic debris and they are separated by striated and polished glacial unconformities. Striations on the unconformities indicate radial ice flow from the shield summit. There is a remarkable similarity in thickness and lithofacies to sequences of small basaltic volcanoes erupted beneath thin valley-confined glaciers but the Mount Murphy succession differs in the generally much more widespread sequences and presence of subordinate subaerially erupted and emplaced units. The latter include strongly welded strombolian bomb and lapilli fall deposits, which have been interpreted as an indication of reduced ice cover. This could have occurred in the short periods immediately following eruptions when the ice was removed from parts of the volcano flanks. The presence of a capping subaerial lava sequence suggests that the ice cap was very thin or absent once the volcano summit grew above a critical elevation, possibly like some volcanoes in the region today (e.g., Mount Erebus).

The Mount Murphy volcano also underwent postvolcanic overriding by a continental ice sheet. This is indi-

cated by striated surfaces strewn with basement-derived erratics up to 1800 m above sea level on the present-day flanks of the volcano, which show ice transport directions obliquely traversing the volcanic topography. Recycled microfossils suggest a minimum early Pliocene (<3.5 Ma) age for the overriding period. The surface of the present-day WAIS south of the volcano lies about 1000 m below the fossiliferous deposit. Thus, a complicated glacial history is preserved at Mount Murphy, recording an early ice cap and later ice sheet(s). Any ice sheet present at 9 Ma must have been below 400 m above sea level, but, between 7 and 4.5 Ma, the western satellite centers record an ice sheet with a surface elevation fluctuating between about 400–600 m above sea level. The ice sheet surface rose above 1800 m in post-Early Pliocene times, before reducing to its present elevation.

## VIII. SUBGLACIAL VOLCANISM—THE WAY FORWARD

Despite sometimes spectacular recent eruptions (e.g., Iceland 1996) and associated major flooding, research into subglacial eruptions has, until recently, been neglected. We are still largely ignorant about many aspects. The thermodynamics of the eruptions are particularly poorly understood and none of the published studies appears capable of explaining the way in which melting at the base of a glacier is so rapid that several hundred meters of overlying glacier ice can be melted through completely in only a few hours. The magma is often treated as if always emplaced as pillows, although observations of many real sequences suggest that this may not be typical. Each basalt mass contains enough energy to melt at least 10 times its mass of ice, if the basalt is able to cool from 1200° to 0°C. Thus, there is abundant total heat in the magmatic system to melt the ice and create space for the magma. However, it is unlikely that each basalt mass will cool to 0°C before the next extrusion, and the solidification time of basalt pillows is much too slow (by at least an order of magnitude) to account for the observed energy flux per unit area. Observations of real eruptions suggest that magma is apparently emplaced at a much faster rate than space can be created by melting, a presently unsolved enigma. Studies of the rate of meltwater generation, the timing of floods, and effects of water on eruptive events will also strongly influence our assessment of the volcanic

risks associated with subglacial volcanoes and in the formulation of plans for risk mitigation.

Long-lived, large subglacially erupted volcanoes are very poorly described so far. Yet, they could be a prime source of information on paleoenvironments and environmental variations with time. In particular, recent developments in our understanding of the hydraulic controls on subglacial eruptions have yielded the clear potential to map the important characteristics of ice sheets associated with eruptions, including their thickness, thermal state, structure, and age. Concurrent investigations of the pore-filling and coeval glass alteration minerals are also yielding chemical criteria for identifying whether eruptions were into freshwater (therefore possibly glacial) or were submarine and they provide critical additional support for interpreting eruptive palaeoenvironments. Studies of the large subglacial volcanoes in Antarctica, which are associated with a globally important ice sheet, are likely to be particularly significant. With concurrent studies of other large volcanoes associated with lower latitude glaciers (e.g., Andes), the potential exists for investigating the geographical synchronicity (or otherwise) of glaciations.

The fluid dynamic processes of subglacial eruptions are only relatively well known for small-scale basaltic eruptions beneath wet-based or temperate glaciers. We know that hydraulic conditions in temperate glaciers are largely responsible for determining the sequence of events during subglacial eruptions. By contrast, polar or dry-based glaciers are frozen to their bed. Meltwater flow beneath polar ice may be impossible and any subglacial vault will only be able to drain by overflowing, but there is no published modeling of the processes involved. We also lack much information on subglacial felsic eruptions, and it is unclear how they differ from eruptions of basaltic magmas. With the very different magma properties involved, there could be significant differences in styles of eruption and volcano construction.

It has been suggested that there are elevated ground temperatures associated with active subglacial volcanoes beneath the WAIS. The thermal flux regulates the supply of meltwater ultimately responsible for ice streaming, thus forming a control on the dynamics of the ice sheet independent of global climate. Ice streams stabilize the slowly moving inland ice sheet by protecting it from oceanic degradation. Increased basal melting may lubricate the basal sediment layer, thereby increasing ice streaming and leading to rapid ice sheet drawdown. If the WAIS were to melt completely, sea level would rise by about 6 m globally. However, observations of the effects of modern eruptions on basal ice conditions are conflicting. Over the eruptive fissure during the 1996

Icelandic eruption, the glacier showed no obvious tendency to rapid basal sliding, whereas the section between Grimsvötn and the glacier terminus apparently underwent a partial collapse, although the extent of sliding was unclear.

Distinctive bedforms and sequence types in subglacial volcanoes have been linked tentatively to the style of explosive eruption. This work is still in its infancy, but a logical extension would be to conduct detailed studies of grain size populations, clast composition, and morphology in the different bed types. These could provide critical information specific to eruptions from flooded vents, in particular the nature of the postulated vent-filling slurries and extent of the influence of steam cupolas that may partially insulate hot pyroclasts from cold ambient water.

## PART IV

---

# EXPLOSIVE VOLCANISM

Explosive volcanic eruptions are among the most spectacular displays of nature. The nature and products of explosive volcanism are treated in eighteen chapters as Part IV of the *Encyclopedia of Volcanoes*. These chapters follow a pattern that parallels the evolutionary structure of the entire encyclopedia. We discuss first the mechanisms for volcanic explosions and the styles of eruption, which constitute the opening seven chapters of the section, and then we discuss the processes of transport and deposition and their products in the following eight chapters. Finally, these deposits are woven together in the final three chapters of the section to build the framework of the three great classes of explosive volcanoes.

The chapters Magmatic Fragmentation and Phreatomagmatic Fragmentation set the stage, defining and modeling the two mechanisms for producing volcanic explosions. Magmatic Fragmentation describes how the rapid release of dissolved gases from swiftly ascending magma “drives” most volcanic explosions. Magma is transformed from a foam of gas bubbles in silicate liquid into a rapidly accelerating stream of gas carrying “pyroclasts” (liquid and solid particles). The violent interaction of magma and surface water (lakes or seas) or ground water is the focus of Phreatomagmatic Fragmentation. The spectrum of activity from passive quenching of the magma to explosive ejection of pyroclasts reflects the hydrology of the environment in which magma comes into contact with water.

In the five chapters that follow, we describe five classical styles of explosive eruptions. The spectacular pyrotechnics of strombolian and hawaiian lava fountaining are described and modeled in the first of these chapters. These eruptions are the least violent yet best understood and most majestic form of volcanism. Their subdued intensity and power are the consequences of the low viscosity of the erupted magmas, allowing gas to escape with relative ease.

Next is Vulcanian Eruptions, which describes short (seconds to minutes) discrete explosions, capable of ejecting incandescent lava bombs and blocks of fragmented rock to distances greater than 5 km. During the past two decades, understanding of the causes and timing of vulcanian eruptions has improved dramatically.

Following this chapter is Plinian and Subplinian Eruptions, which describes eruptions characterized by the formation of high eruption plumes resulting in atmospheric ash and particle injection and dispersal by winds over huge areas. The name for these eruptions is taken from the 79 A.D. eruption of Vesuvius that provoked the death of Pliny the Elder. The dynamics of these awesome events are modeled in this chapter, drawing from the classical eruptions of Vesuvius and plinian events at Mount St. Helens in 1980 and El Chichon in 1982.

The classical eruption of the Icelandic volcano Surtsey in 1963 gave rise to the term surtseyan volcanism. The chapter Surtseyan and Related Phreatomagmatic Eruptions examines this event and other examples of fluid basaltic magma mingling with external water.

In phreatoplinian eruptions, silicic magma interacts violently with abundant water often residing in caldera lakes. This chapter reexamines the deposits of classical eruptions of this type in Iceland and New Zealand and the role of the water in the formation of clusters and aggregates of ash particles in the eruption plumes.

A volcanic explosion produces a jet of gas and pyroclasts, which may entrain air and atmospheric moisture and continue to rise as a billowing, buoyant eruption plume. Large volcanic plumes that penetrate the tropopause may trigger global environmental effects and produce short-term regional changes of climate. Elegant models for eruption plumes are presented in the chapter Volcanic Plumes.

The authors of Pyroclast Transport and Deposition use four parameters (particle trajectory, particle concentration, the extent to which the concentration fluctuates with time, and presence or absence of cohesion during deposition) to explain the characteristics of the great proportion of subaerial pyroclastic deposits.

Important clues about eruption processes come from a study of the textures and fabrics of pyroclastic fall deposits, as described in the next chapter. These deposits, produced by the rain-out of clasts through the atmosphere, are the simplest of pyroclastic products, and their value is in the ease with which their properties can be used to infer eruption parameters.

The perception of pyroclastic density currents as a highly dangerous and devastating type of explosive volcanic activity was brought about dramatically by the 1902 eruptions of Mount Pelée, Martinique, which killed 30,000 people. Since then, several destructive py-

roclastic-flow eruptions have occurred every decade. Pyroclastic surges and blasts, described in the next chapter, are a class of pyroclastic density currents that have low particle concentrations, are turbulent and often pulsating, and produce deceptively thin, bedded, and cross-bedded massive deposits. Depositing flows of high particle concentration (tens of volume %) produce ignimbrites and block-and-ash flow deposits. The architecture and characteristics of these units are described in the following chapter.

The next chapter, Lahars, covers what occurs when large masses of volcanic sediment, and water, sweep down and off volcano slopes incorporating additional sediment. This chapter describes how both liquid and solid interactions determine the unique behavior of lahars and distinguish them from debris avalanches and floods. The rock fragments carried by the flows make them especially destructive.

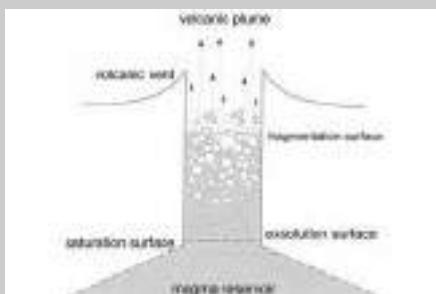

The next chapter describes the architecture and internal fabric of debris avalanche deposits and the models used to describe their emplacement. A debris avalanche is the product of a large-scale collapse of a sector of a volcanic edifice often triggered either by intrusion of new magma or by a phreatic explosion or an earthquake. The 1792 debris avalanche at Unzen volcano killed 15,190 people.

Calderas are described next as large volcanic craters, more or less circular, with diameters many times greater than those of the volcanic vents they enclose. Formation of calderas by roof collapse over an underlying shallow magma reservoir is now recognized as accompanying most eruptions that involve magmatic volumes greater than a few cubic kilometers. Caldera-forming explosive eruptions probably are the most catastrophic geologic events that affect the earth's surface, other than rare large meteorite impacts.

Ask a small child to draw a volcano and chances are that he or she will draw a composite cone. Human populations are attracted to these magnificent landforms by the fertile soils generated on the cones and yet are threatened by the hazards associated with their frequent eruptions. The chapter Composite Volcanoes builds an elegant model for the life spans, geometry, and internal structure of these volcanoes.

Small basaltic volcanoes, scoria cones, tuff rings, tuff cones, and maars are the most common volcano types, on land, yet each center is tiny compared to calderas or composite cones. Scoria Cones and Tuff Rings explains the behavior of these systems in terms of the eruption of small batches of hot fluid magma.

- V. Summary

---

## GLOSSARY

**bubble** A pocket of gas in a melt.

**fragmentation** The transition from a continuous melt with a dispersed gas phase to disconnected parcels of bubbly melt within a continuous gas phase.

**magma** Silicate melt with dissolved gases (volatiles); may also contain crystals and/or bubbles.

**pyroclasts** All solid fragments ejected from volcanoes (from Greek meaning “fire broken”).

**pumice** Solidified fragments of quenched vesicular silicic melt (vesicularity  $>\sim 60\%$ ).

**scoria** Basaltic pumice.

**tephra** All pyroclasts that fall to the ground from eruption columns (from Greek meaning “ashes”).

**vesicle** A hole (bubble remnant) preserved in a solidified pyroclast.

**vesicularity** The volume percent of bubbles in a melt or the volume percent of vesicles in pumice.

**vesiculation** Nucleation and growth of gas bubbles in a magma.

---

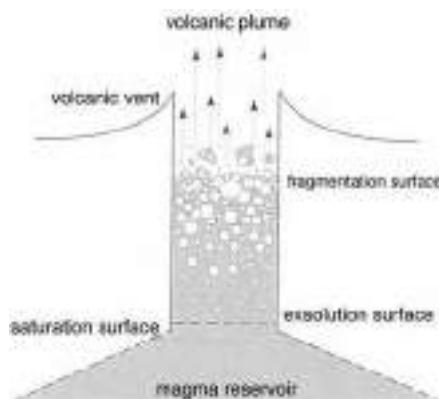

## I. INTRODUCTION

Explosive eruptions are the most powerful and destructive type of volcanic activity. Explosive eruptions produce large quantities of fragmental (pyroclastic) material that are carried upward in convecting columns or transported laterally in energetic pyroclastic flows. Recent eruptions of volcanoes such as Mount St. Helens (United States) and Mount Pinatubo (Phillipines) serve as vivid reminders that this pyroclastic material can have devastating effects on human populations. Tephra falling from convecting columns disrupts daily life in downwind communities and may completely devastate areas close to a volcano. Fine ash and aerosols injected into

the stratosphere during very large eruptions may modify global climate for years after the eruption.

Two different mechanisms can generate explosive eruptions. Magmatic, or “dry,” eruptions are driven solely by gases originally dissolved in the magma, while phreatomagmatic, or “wet,” eruptions result when magma is mixed with external water (see Phreatomagmatic Fragmentation). In this chapter we focus on magmatic eruptions and specifically on the explosive process itself — the process of *fragmentation* — as this process is central to our understanding of how volcanoes work. Fragmentation transforms a magma from a liquid with dispersed gas bubbles to a gas with dispersed liquid drops ( $\pm$  bubbles and solids) or isolated solid particles. The explosive force of magmatic eruptions is generated during fragmentation, where the potential energy of an expanding magma (melt + bubbles) is converted to the kinetic energy of individual fragments and then thermally expanded in volcanic plumes. Magmatic fragmentation occurs when magma ascends rapidly, as in plinian eruptions (see Plinian and Subplinian Eruptions), after rapid decompression caused by volcanic edifices or lava dome collapse, or when hot solid lava blocks fragment on impact during dome collapse (see Domes and Coulees). These different processes can occur individually or sequentially as a single eruption changes style during its initiation and quasi-steady phases.

Direct observations of magmatic fragmentation are not possible, thus models of fragmentation are derived from studies of volcanic deposits, theoretical analysis, and analog experiments. Early models of fragmentation include magma disruption by (1) bubble coalescence, (2) expansion waves traveling through the magma at sound speed, and (3) excess pressure within bubbles in a coherent magma. The latter model has been the most widely accepted, with magma fragmentation viewed as bursting of bubbles at a free surface (the fragmentation surface; Fig. 1) as a consequence of the pressure difference across the interface. In this model, the location of the fragmentation surface within the conduit is controlled by the point at which the vesicularity of the rising and expanding magma reaches  $\sim 70\text{--}80\%$  (representing closest packing of spherical bubbles). Recent years have seen the emergence of several new perspectives on the fragmentation process, perspectives that combine contributions from (1) experimental studies of volatile exsolution and vesiculation, (2) numerical models of magma ascent in volcanic conduits, (3) fragmentation simulations, and (4) studies of pyroclasts. Below we use this new work to describe magma ascent from its source to the point of fragmentation (see Fig. 1) and

**FIGURE 1** Schematic illustration of processes that occur in volcanic conduits. Magma is saturated in volatiles at the top of the reservoir (the saturation surface). Bubbles nucleate at a slightly higher level (the exsolution surface), as magma rises and experiences a decrease in pressure. Between the exsolution and fragmentation surfaces, the magma is a two-phase mixture of silicate melt and gas bubbles. Fragmentation occurs when gas occupies 70–80% of the available volume. At this point, the magma transforms from a liquid with suspended bubbles to a gas with suspended clots of liquid. The abrupt density decrease (expansion) that accompanies this transformation results in acceleration of the gas mixture out of the vent, in the form of a volcanic plume. [Modified from Sparks, 1978.]

to review current models of the fragmentation process itself.

## II. BUBBLE FORMATION — THE EXSOLUTION SURFACE

Explosive magmatic eruptions occur when volatile exsolution (primarily  $\text{H}_2\text{O}$ ) from magma is rapid. What triggers rapid  $\text{H}_2\text{O}$  vesiculation? To answer this question, we must first determine the volatile saturation of magma prior to an eruption plus the ease with which the magma can respond to that saturation by nucleating bubbles. Together, these two processes (volatile saturation and bubble nucleation) will determine the location of the exsolution surface (Fig. 1).

### A. Magma Storage Regions

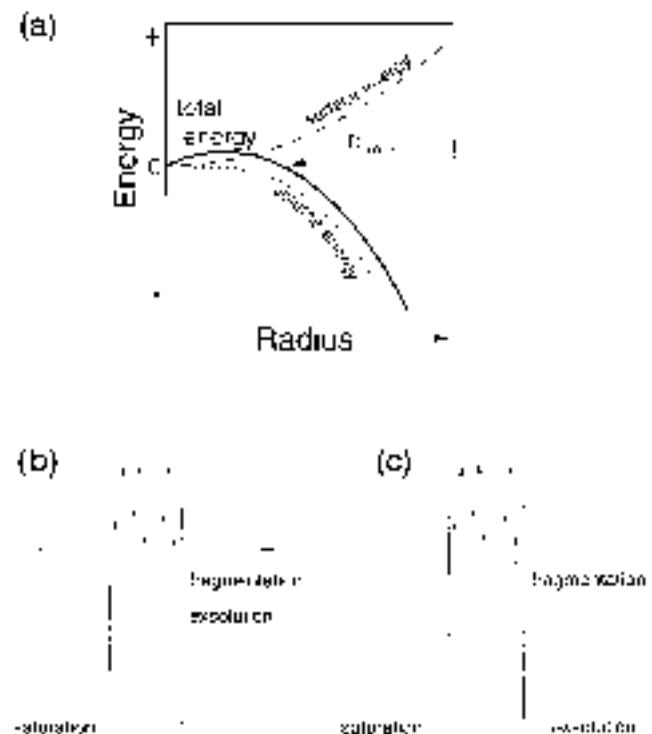

Recent data suggest that the upper parts of many silicic magma chambers are not only volatile-saturated prior

to an eruption, but that magma in these reservoirs contains at least a small volume fraction of gas bubbles. Thus the presence of bubbles is not sufficient, by itself, to cause an explosive eruption. This conclusion is supported by abundant evidence for noneruptive gas emissions from volcanoes, emissions that indicate the “leakiness” of many reservoirs to magmatic gases. However, accumulation of even a small volume fraction of bubbles at the roof of a magma reservoir can increase the pressure exerted by the magma on the surrounding rocks. It is thus possible that vesiculation in magma storage regions could generate sufficient overpressure to cause the rock fracture required for magma ascent and eruption. Other eruptions may require external triggers, such as the injection of a new batch of magma into an existing reservoir. In all cases, however, the rapid vesiculation required for explosive eruptions probably initiates somewhere above the level of magma storage, accompanying magma ascent to the surface.

## B. Bubble Nucleation

Vesiculation (the formation of a separate gas phase) occurs when a magma becomes supersaturated in a volatile phase and starts with bubble nucleation. According to classical homogeneous nucleation theory, there will be a critical size ( $R_{\text{crit}}$ ) above which nuclei are stable and additional growth can occur. Bubble nucleation may thus be described as the initial formation of the smallest possible stable bubble. This critical bubble size is described mathematically as the size at which the energy decrease resulting from creation of a gas phase more than offsets the energy increase required to maintain the gas–liquid interface (Fig. 2a). This theory suggests that homogeneous nucleation of bubbles in a silicate melt should require extremely high supersaturations, and thus that magma would have to rise far above the volatile saturation surface before bubbles could form. However, nucleation may also be heterogeneous. In heterogeneous nucleation, existing impurities provide sites for bubble nucleation, nucleation can proceed at much smaller supersaturations, and vesiculation will not be limited by the kinetics of bubble formation.

On the basis of nucleation behavior alone, two end member models have been used to describe vesiculation in volcanic conduits. At one extreme, bubble nucleation is homogeneous, supersaturations required for bubble nucleation are large, and vesiculation is delayed until the magma is high in the conduit (Fig. 2b). In this case, delayed nucleation results in rapid magma expansion

**FIGURE 2** Bubble nucleation. (a) Energy balance important in generation of stable bubble nuclei. Nucleus formation results in a negative energy contribution from phase formation (volume energy) and a positive energy contribution from interface formation (surface energy). When the nucleus size is larger than  $R_{\text{crit}}$ , the energy decrease from the formation of the gas phase exceeds the positive energy of the interface, and bubble growth can occur. (b) Schematic illustration of the expected locations of the saturation and exsolution surfaces when bubble nucleation is homogeneous (nucleation is delayed). (c) Schematic illustration of the equivalence of the saturation and exsolution surfaces when bubble nucleation is heterogeneous (there is no kinetic barrier to nucleation). Explosive eruptions are expected to be more violent in the scenario shown in (b) than in that shown in (c).

and fragmentation, as seen in many analog (shock-tube) experiments (see below). At the other extreme, nucleation is heterogeneous, the kinetics of nucleation do not hinder volatile exsolution, and volatiles exsolve during magma ascent according to equilibrium models (Fig. 2c). Such an equilibrium model is commonly assumed in numerical descriptions of magma ascent. Is there evidence to support one model over the other? Evidence for supersaturation conditions in volcanic conduits may lie in the vesicles preserved in pumice and scoria. When supersaturations are large, nucleation dominates and the resulting bubble number density (number per volume)

is high. High vesicle number densities typical of silicic pumice ( $\sim 10^{14}$ – $10^{16}/\text{m}^3$ ) may thus indicate nucleation at very high supersaturations, although heterogeneous nucleation of bubbles on submicroscopic crystals cannot be ruled out. In contrast, vesicle number densities preserved in basaltic scoria are substantially lower ( $\sim 10^{10}/\text{m}^3$ ), a possible reflection of nucleation at much lower supersaturations than in silicic systems. However, even in basaltic magmas equilibrium concentrations of volatiles are not completely maintained, so that the actual exsolution history of any particular magma probably lies somewhere between the two end member models for nucleation.

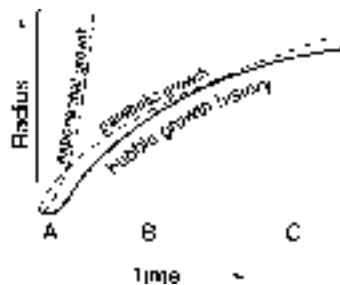

---

### III. CONDUIT PROCESSES — EXSOLUTION TO FRAGMENTATION

Once nucleated, bubbles can grow. Magma expansion resulting from bubble growth accelerates magma up volcanic conduits. If bubbles grow faster than they can rise or escape laterally through conduit walls, the magma ascends rapidly to the fragmentation surface, and erupts explosively. If bubbles can rise through the ascending magma, or if bubble networks are sufficiently interconnected to allow permeable gas escape, the magma may reach the surface without fragmenting (it will erupt effusively; see Effusive Volcanism). Thus the relative rates of bubble growth, magma transport, and gas loss will control the style of eruptive behavior (explosive vs effusive).

#### A. Bubble Growth

Bubble growth is controlled by both diffusion of water molecules toward the bubble–melt interface and expansion against the surrounding viscous melt. Growth of a single bubble at constant pressure occurs in two stages: exponential (viscosity-limited) growth and parabolic (diffusion-limited) growth. *Exponential* growth dominates immediately after nucleation, when diffusion is rapid and the bubble radius increases at a rate limited by the melt viscosity (Fig. 3, segment A). As the bubble grows, equilibrium saturation pressure in the bubble cannot be maintained by diffusive flux of water through

**FIGURE 3** Time-dependent changes in the form of bubble growth. The bubble growth history curve is divided into three segments, as follows. Growth is initially exponential (viscosity-limited) when the bubble is very small (segment A). Growth becomes parabolic when limited by diffusion of volatiles into the bubble (segment B). In real systems at long times, bubble growth will be limited by proximity of neighboring bubbles and will thus drop below the parabolic curve (segment C). Shown for reference are anticipated growth histories for exponential and diffusional growth (dashed lines). [Modified from Navon and Lyakhovsky (1998), in Gilbert and Sparks (1998).]

the interface, and growth is *parabolic* (Fig. 3, segment B), although more rapid growth is possible if the liquid undergoes high strains. The combined growth history of a bubble for these idealized conditions (a single bubble in a stationary liquid at a constant pressure) will be determined by both melt viscosity and volatile abundance. For example, bubble growth in a water-rich (low viscosity) rhyolite would be limited by diffusion after less than 1 s, while bubble growth in a water-poor (high viscosity) rhyolite may be exponential for hours to days.

In real systems, bubbles do not grow singly, nor do they grow at constant pressure; thus bubble growth will be limited by both the proximity of neighboring bubbles and the rate of magma decompression. Bubble proximity is determined by the initial separation distance of bubble nuclei (bubble number density; Section IIB). Separation distance determines the length scale of volatile diffusion and, as a result, the timescale required to achieve equilibrium bubble growth during magma ascent. In hydrous silicic melts, the time to achieve equilibrium is about 30 s for moderate ascent velocities ( $\sim 1 \text{ m/s}$ ) and bubble separations of  $10 \mu\text{m}$  (bubble number densities of  $\sim 10^{14}/\text{m}^3$ ; see above). Larger bubble separation distances increase the time required to achieve equilibrium. The rate of magma decompression affects the relative rates of diffusion-controlled and expansion-controlled bubble growth. Deep in the conduit, bubble growth is limited by the rate of volatile diffusion. High in the

conduit expansion becomes more important, the magma accelerates, and bubble growth may be limited by the viscous resistance of the surrounding magma (Fig. 3, segment C). The result of rapid expansion is the development of excess internal bubble pressures at shallow conduit depths, excess pressures that may lead to fragmentation. Such a departure from equilibrium will be enhanced by rapid decompression and by large increases in melt viscosity that may accompany decompression (anticipated as H<sub>2</sub>O contents drop below 1 wt%, particularly if volatile loss is accompanied by crystallization).

### B. Magma Ascent Dynamics

Flow models of magma ascent through volcanic conduits provide estimates of pressure and velocity changes with transport and allow important constraints to be placed on processes that lead to magma fragmentation. Current models are for steady-state flow in one dimension and simple magma rheologies. The steady state assumption is justified by the steady discharge of fragmented magma (over a period of hours) that characterizes explosive plinian eruptions. The need for models of flows in two dimensions and models that include non-Newtonian rheologies appropriate for bubble-bearing melts provides clear directions for future research in this area.

Early models of magma flow through conduits calculated the velocity of a homogeneous fluid moving steadily up a cylindrical pipe. Velocities were calculated using volatile exsolution and expansion as dictated by solubility models, combined with frictional energy losses dictated by wall shear stresses. Fragmentation was assumed to occur when bubbles occupied 70 to 80 vol% of the erupting mixture. More recent nonhomogeneous models allow thermal and mechanical disequilibrium between the gas and the liquid phases. In these models, the conduit region below the level of fragmentation has large gradients in both flow variables and magma properties (conduit variations in gas volume fraction, magma viscosity, and normalized pressure are shown in Fig. 4 for ascent of a volatile-rich rhyolite). An abrupt drop in viscosity marks the fragmentation surface itself, as the erupting mixture changes from liquid- to gas-dominated. These simulations emphasize the importance of both volatile (H<sub>2</sub>O and CO<sub>2</sub>) content and anhydrous magma composition on the depth of volatile saturation and magma fragmentation. The newest models also allow dynamic controls on fragmentation, with magma disruption occurring not at a set bubble

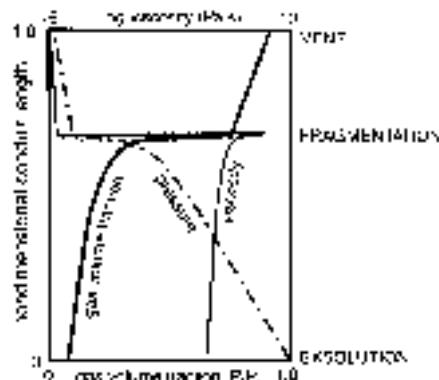

FIGURE 4 Calculated distribution of gas volume fraction and nondimensional pressure (pressure divided by magma chamber pressure; scale shown along the bottom axis) and mixture viscosity (scale shown on the top axis) along a conduit (from exsolution level to the vent). Simulation is shown for a rhyolite magma with 6.5 wt% total water content, conduit length of 7000 m, conduit diameter of 127 m, magma temperature of 827°C, and magma chamber pressure of 192 MPa. Note that all parameters change abruptly just below the level of fragmentation and then again at the point of fragmentation. [Modified from Papale et al., 1998.]

volume fraction, but instead at a strain rate sufficient for liquid rupture (see below).

Further improvements to models of conduit flow will require improved understanding of the effects of crystals and bubbles on magma rheology, evaluation of the strength and stability of magmatic foam flowing in conduits, and incorporation of non-Newtonian rheologies into flow models. It is well known that subliquidus (crystal-bearing) magmas have viscosities that are a function of crystal content and that magmas have non-Newtonian rheologies at crystallinities >~25–30%, when individual crystals start to interact. Crystallinities >60% probably cause flow to cease entirely. Bubbles deform in a shear flow, as illustrated by highly elongated vesicles found in some silicic pumice. Both experimental and numerical results suggest that transient effects related to bubble deformation may decrease the viscosity of bubbly melt below that of the bubble-free melt. Such transient effects may have important consequences for magma flow in conduits. For example, under these conditions, flow gradients prior to fragmentation may not show the abrupt changes illustrated in Fig. 4. Non-Newtonian magma rheologies may also cause the flowing foam to decouple from conduit walls and thus move unimpeded in a slug flow prior to fragmenting.

### C. Volatile Loss from Volcanic Conduits

The models for bubble growth and magma ascent described above assume that magma acts as a closed system with respect to the gas phase until the point of fragmentation. However, there is abundant evidence that magmatic gas can be lost from volcanic systems during magma ascent, evidence that includes long-period seismicity that accompanies volatile loss, the eruption of dense (vesicle-poor) yet degassed magma, and the syn-ascent breakdown of hydrous phases (see Rates of Magma Ascent). As substantial syn-ascent gas loss may prevent explosive eruptions, conditions of volatile loss during magma ascent must be addressed.

Volatile loss from volcanic conduits requires either two-phase flow (relative motion between bubbles and the enclosing melt) or the development of a permeable bubble network within the magma. Relative motion is important in strombolian eruptions (see Hawaiian and Strombolian Eruptions), where magma viscosities and ascent rates are sufficiently low that individual bubbles can rise and coalesce within the conduit. Lateral bubble migration during slow ascent of more viscous melts may allow volatile escape via permeable wall rocks and consequent lava dome effusion. When magma ascent rates are similar to those of bubble rise, bubbles move with the magma and gas loss must be through permeable networks in the magma itself. Conditions required for such permeable foam formation are not well constrained. The porosity at which magmas become permeable, the extent to which interaction with surrounding hydrothermal systems affects eruptive activity, the conduit conditions that permit the entrance of groundwater (see Phreatomagmatic Fragmentation) and the limiting rates of gas escape necessary to prevent fragmentation all remain as questions.

---

## IV. FRAGMENTATION

Prior to an eruption, magma at depth is held at high pressure by the strength of the surrounding rock. The pressure difference that drives an eruption acts when the magma source is connected to a region of lower pressure, such as the atmosphere, across the fragmentation surface. By Newton's laws, the force imbalance, or thrust, causes the magma to accelerate. Two processes have been proposed to drive the expansion that powers explosive eruptions. In the first, vesiculation and bubble growth provide the driving force for expansion, with

fragmentation occurring by the *disintegration* of the resulting foam. Fragmentation may result from instabilities in the fluid or by brittle fracture as the tensile strength of the melt is exceeded, but in either case the fragmentation results from high strain rates in the expanding two-phase mixture. In the second, fragmentation is accomplished in an already-vesiculated magma, which may or may not be moving in a conduit, by the failure of suddenly loaded bubbles in a *fragmentation wave* similar to that which causes rockburst in mines. This fragmentation wave model is applicable to the failure of volcanic domes, and may also be applicable to the explosive disruption of more viscous melts during plinian and subplinian events. Below we discuss these mechanisms in more detail and then use textural analysis of eruptive products to speculate on fragmentation mechanisms operative during different types of explosive eruptions.

### A. Fragmentation Resulting from Rapid Acceleration

Recent laboratory experiments on low viscosity fluids have examined the fragmentation of rapidly flowing vesiculating liquids in conduits. High-speed photography has shown that vesiculation can power large accelerations of the bubbly mixture to high velocities, with fragmentation occurring after acceleration. As bubbles grow, they merge and form a foam moving at high velocity. Eventually the bubble walls get so thin that the foam becomes unstable and breaks up to form relatively large-scale finely vesicular clots. The breakup is associated with violent motions, such as impingement of the flow on conduit walls. Violent motions accompanying fragmentation may induce further breakup via the fragmentation wave mechanism (see below) if vesicles contain pressurized gas when large relative motions lead to impact. The experiments produce a finely dispersed droplet aerosol, and appear directly applicable to fragmentation in basaltic (hawaiian) fire fountains, where pyroclasts are variably vesicular and commonly show fusiform shapes (see Hawaiian and Strombolian Eruptions). These results are also suggestive of processes in a high-velocity heterogeneous multiphase flow that can simultaneously produce pumice and volcanic ash. Large accelerations may lead to fragmentation in high-viscosity silicic liquids, although fragmentation is likely to be brittle as a consequence of rate-limited crossing of the glass transition. Magma flow modeling shows that elongational strain rates may exceed the strength

of silicic melts at gas volume fractions of 0.6–0.85 and that magma vesicularity and mixture viscosity are inversely related at the point of fragmentation.

### B. Fragmentation by Rapid Decompression

Rockburst models have been applied to the flow generated by a volcanic blast after rapid decompression by edifice collapse. The rapid decompression model is a quantitative treatment of the concept illustrated in Fig. 1, by which one or several rows of bubbles at the edge of a body fail by fluid rupture or solid fracture when exposed to low ambient pressure. This rupture exposes adjacent rows of bubbles in the magma interior to low pressure, and, consequently, a sequential inward progression of the fragmentation process. The theory is incomplete, in that it does not treat the conservation of momentum. Instead, an empirical constitutive relation substituted in its place yields fragmentation waves that propagate at several tens of meters per second, and generate dusty-gas flows of 100–200 m/s.

The rapid decompression model was designed to describe volcanic blasts, where the depressurization front is predicted to move downward at speeds from a few to several tens of meters per second. Such conditions may occur when a conduit is sealed by emplacement of a lava dome or conduit plug, and gas pressure beneath the plug increases with time by either anhydrous crystallization or upward volatile migration through permeable networks. However, a rapid decompression model could equally well apply to other types of fragmentation. Small scale comminution of brittle foams during dome collapse and disruption of vanguard magma to initiate eruptions may both involve fragmentation by rapid decompression. Additionally, some component of fragmentation by rapid decompression may be important during plinian eruptions, where the steady character of such eruptions suggests that the depressurization wave is fixed in space over time.

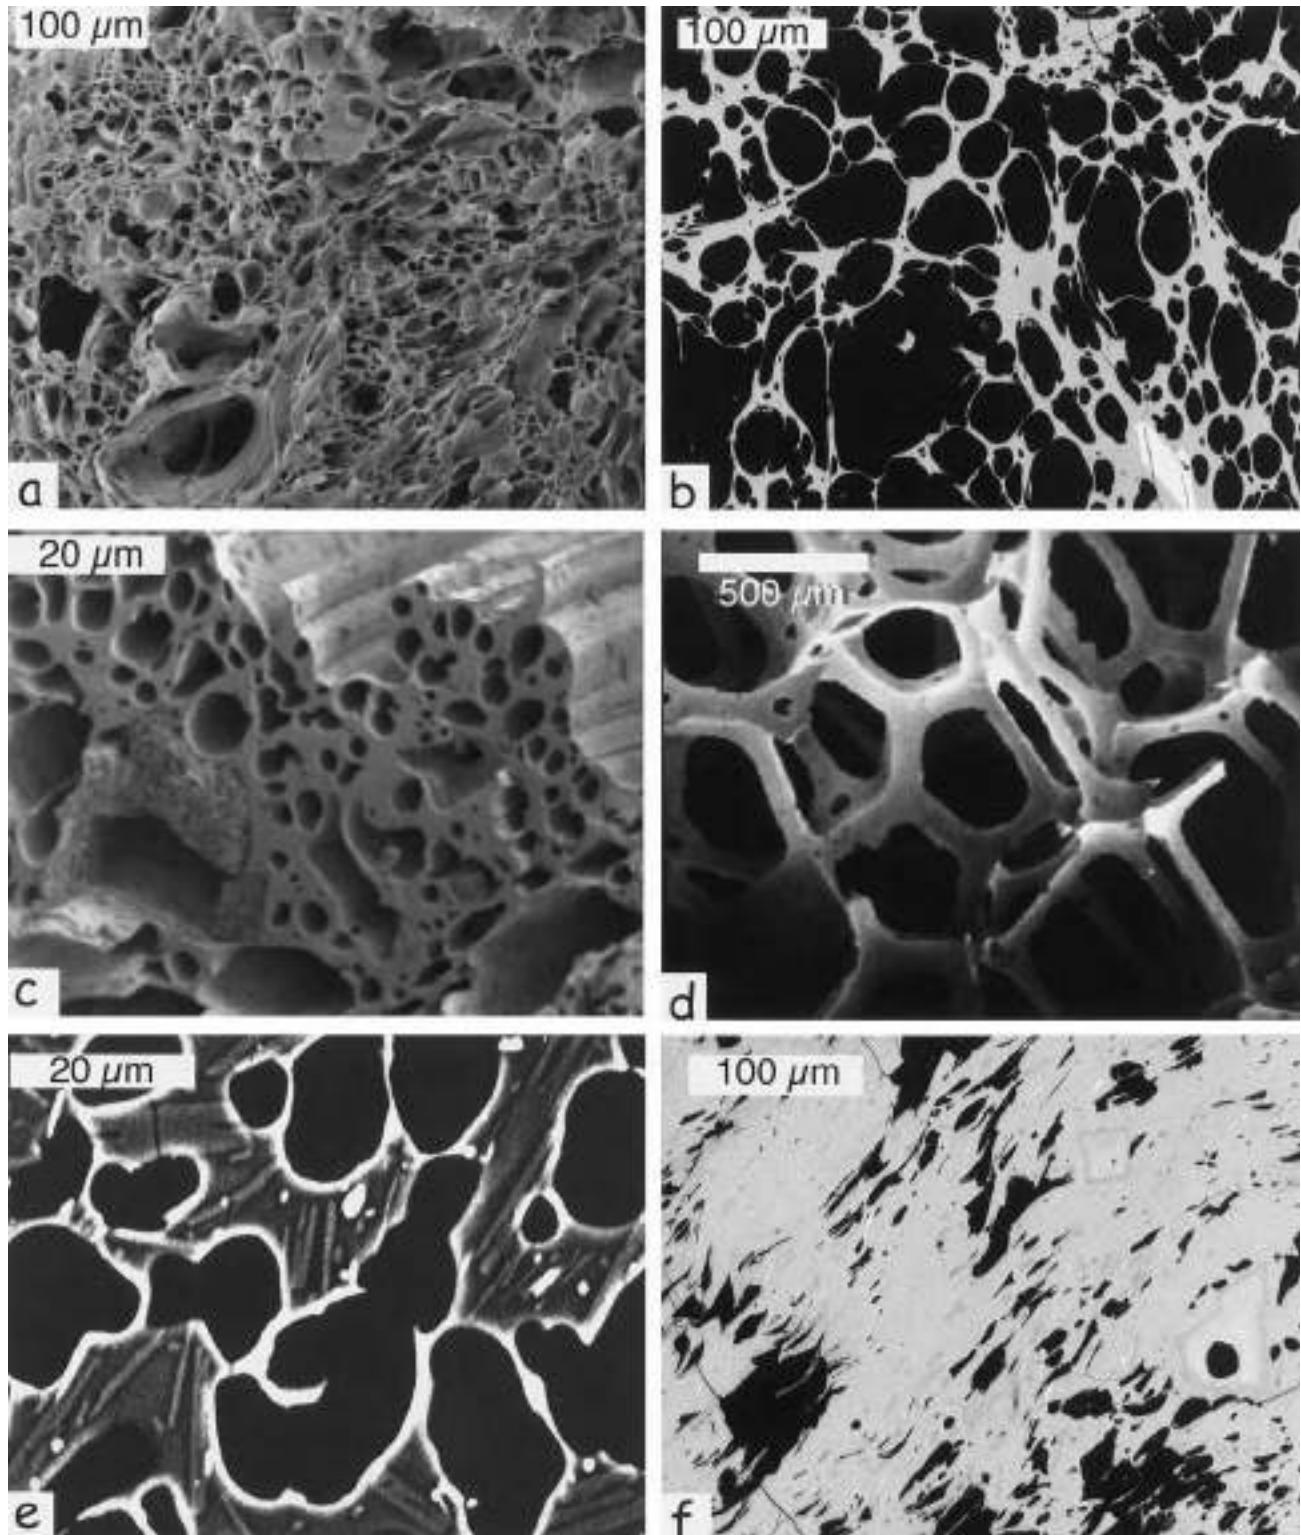

### C. Products of Fragmentation

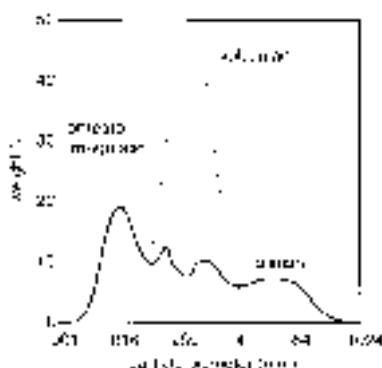

Any model of fragmentation must explain the textural characteristics and the size distribution of particles produced. Clast sizes and shapes, preserved vesicle sizes and shapes, and the relative abundance of different clast size populations, in turn, all provide important insight into the fragmentation process. Most attention has been focused on the interpretation of textures characteristic of

pumice from plinian eruptions. Plinian pumice typically has a narrow range in vesicularity [70–85%; Figs. 5a and 5b]; to what extent does this vesicularity preserve information about the fragmentation surface? One view is that pyroclasts are quenched soon after fragmentation and that pumice textures can be used directly to understand fragmentation. In this model, pumice vesicularities of 70–85% and permeabilities  $\sim 10^{-12} \text{ m}^2$  represent conditions necessary for pumice preservation during the process of fragmentation. An alternative interpretation is that fragmentation occurs at lower vesicularities (~60%), and that final clast vesicularities result from extensive postfragmentation expansion.

Additional insight into fragmentation may be gained by examination of pyroclasts with anomalously high (>90%) or low (<60%) vesicularities. Generation of extremely high vesicularities requires reorganization of bubbles into elongated cylinders (“long-tube” pumice) or polyhedral cells (“reticulite”) and probably requires fragmentation by rapid acceleration. In contrast, low clast vesicularities (<60%) may result from fragmentation by rapid decompression. *Long-tube pumice* (Fig. 5c) is a minor to moderate component of most silicic pyroclastic deposits. The extreme bubble elongation preserved in these clasts is commonly interpreted to result from high elongational strains near conduit margins (thus providing support for some component of strain-induced fragmentation) and requires rapid quenching after fragmentation. *Reticulite* (Fig. 5d), in contrast, results from unconstrained postfragmentation expansion of vesicular liquid clots. Reticulite is unique to high basaltic fire fountains, and forms where clasts initially formed by strain-induced fragmentation of the liquid continue to expand in the thermal core of the fountains. *High density (low vesicularity) juvenile clasts* are common in vulcanian and subplinian eruptions. High clast densities may result when high microlite crystallinities inhibit bubble expansion (Fig. 5e) or when vesicular magma experiences varying degrees of bubble collapse during ascent (Fig. 5f), perhaps along conduit margins. Strain-induced fragmentation of low vesicularity clasts seems unlikely; thus dense clast formation is best explained by interaction of ascending, partially vesiculated magma with a downward-propagating decompressional wave.

Finally, what can the characteristics of pyroclastic deposits tell us about fragmentation? While data are scarce, it appears that the size distribution of pyroclasts may vary with fragmentation style (Fig. 6). The unimodal size distributions typical of vulcanian eruptions may result from fragmentation by rapid decompression of a lava plug. Clast size distributions from these eruptions are similar to those resulting from comminution of sol-

**FIGURE 6** Schematic illustration of whole deposit grain size distributions from plinian and vulcanian eruptions. The vulcanian peak is unimodal and is likely a consequence of the fragmentation wave mechanism acting on a partially solidified plug within the volcanic conduit. The plinian peak is polymodal and suggests that fragmentation in plinian eruptions is complex and possibly the result of more than one fragmentation mechanism. Relative proportion of fine ash ( $<63 \mu\text{m}$ ) increases with the increasing intensity of eruption and may provide a measure of fragmentation efficiency. Distribution from a phreatomagmatic eruption shown for comparison (see Phreatomagmatic Fragmentation).

ids. In contrast, the polymodality of plinian deposits may reflect a complex fragmentation history, with both fragmentation mechanisms (rapid acceleration and rapid decompression) acting simultaneously. Pumice may form through magma disruption during rapid acceleration facilitated by inhomogeneous distribution of elongational strain (particularly along conduit margins), with preservation of large clasts allowed where high permeabilities permit adequate volatile loss. Silicic fine ash (fractured remnants of bubble walls and interstices) may form by rupture of individual bubble walls through interaction of a decompression wave with the bulk of the finely vesicular (low permeability) conduit interior. If so, then the proportion of fine ash in a plinian deposit should correlate with eruption intensity, and could

provide a quantitative measure of fragmentation efficiency.

#### V. SUMMARY

Magmatic fragmentation occurs in a variety of eruptive settings, and the actual process of fragmentation is probably different in magmas of different rheologies. Two end member types of fragmentation are identified. In the first, vesiculation and bubble growth provide the driving force for expansion and acceleration of the two-phase (bubble + melt) flow. Fragmentation results from high strain rates in the expanding mixture, either from instabilities in the fluid or by brittle fracture, as the tensile strength of the melt is exceeded. Fluid instabilities are the likely fragmentation mechanism in low viscosity magmas, such as hawaiian fire fountains and strombolian bubble bursts, and brittle fracture may be important in plinian eruptions. In the second, fragmentation of an already-vesiculated magma occurs by sudden decompression and bubble rupture. This fragmentation model applies to the failure of volcanic domes, and may also describe explosive disruption of viscous melts during vulcanian eruptions. The mechanism(s) of fragmentation in silicic plinian eruptions remains a question, although we speculate that both fragmentation mechanisms (rapid acceleration and rapid decompression) may be acting simultaneously. In this scenario, pumice lapilli may be interpreted as magma disrupted but not fully disintegrated during rapid acceleration, perhaps as a consequence of some limiting permeability. Fine ash formation, in contrast, appears best explained by rupture of individual bubble walls through passage of a decompression wave. The relative proportions of fine ash and pumice record the relative importance of the two fragmentation mechanisms.

As vesiculation is the dominant process responsible

**FIGURE 5** Scanning electron microscope (SEM) and backscattered electron (BSE) images of volcanic pyroclasts. (a) SEM (three-dimensional) image of "normal" plinian pumice (80% vesicles), showing the narrow range in vesicle size and generally spherical shape of the vesicles. (b) BSE (two-dimensional) image of plinian pumice (70% vesicles), showing that vesicles in pumice, in detail, show a range of sizes, shapes, and extent of coalescence (vesicles are black and glass is gray in this image). (c) SEM image of long-tube pumice (88% vesicles); note that vesicles are small ( $<10 \mu\text{m}$  diameter) but extremely elongate ( $>20 : 1$ ). (d) SEM image of basaltic reticulite (98% vesicles) showing the polyhedral cell network developed when expansion of the gas–melt mixture is not constrained by conduit walls. (e) BSE image of microlite-rich pumice clast (55% vesicles) illustrating ways in which microlites (light gray, elongate crystals in dark gray glass; vesicles are black) may inhibit bubble expansion. (f) BSE image of collapsed vesicles (black) in a dense pyroclast ( $<40\%$  vesicles); bubbles in this clast were severely compressed prior to clast quenching. Images a, b, c, and f are of pumice clasts from Crater Lake, OR; image d is of a pyroclast from Kilauea volcano, Hawaii; image e is of a gray pumice clast from Mount St. Helens, WA.

for magma acceleration up volcanic conduits, improved modeling of conduit processes requires a better understanding of vesiculation (particularly bubble nucleation) and the rheology of bubbly melts. For example, large numbers of very small vesicles in silicic pumice may indicate either nucleation at very high supersaturations or heterogeneous nucleation on submicroscopic impurities. Distinguishing between these alternatives is critical for understanding conditions of vesiculation in silicic magmas. Also critical are better descriptions of the changes in material properties that a magma experiences as bubbles grow, deform, and collapse on conduit walls. As changes in rheology will feed back into the dynamics of magma ascent, such changes may ultimately dictate the point at which fragmentation occurs. All of these topics represent fertile areas of research, and improvements in all of these areas will certainly increase our understanding of explosive magmatic eruptions in the future.

## GLOSSARY

**phreatomagmatism** Volcanic activity resulting from the interaction between magma/lava and groundwater or surface water including seawater, meteoric water, hydrothermal water, or lake water.

**FCI** An abbreviation for fuel-coolant interaction, referring to an industrial analog to phreatomagmatic explosion involving a fuel such as molten iron and a coolant such as water. The interaction of the fuel and coolant has resulted in vapor explosions in industrial environments and are a potential hazard associated with nuclear core meltdown.

**superheated liquid** A metastable thermodynamic state of a liquid resulting from rapid heating to a temperature well above the boiling point.

**Kelvin–Helmholtz and Rayleigh–Taylor instabilities** Interfacial fluid instabilities caused by relative motion of two immiscible fluids. Kelvin–Helmholtz instabilities are induced by shear stresses along the interface, whereas Rayleigh–Taylor instabilities develop during acceleration of a denser fluid by a less dense fluid. In both cases fragmentation occurs when surface tension forces are exceeded.

**vapor film** A layer of vapor formed at the interface of water and a hot liquid or solid body (temperature  $\gg$  boiling point).

**wet/dry eruptions** At standard conditions (25°C and 0.1 MPa), water is a two-phase (liquid and vapor) fluid. Depending on the quantity of available heat energy, when water comes into contact with magma it may become a liquid-rich fluid or a vapor-rich fluid, resulting in a dry eruption or a wet eruption, respectively.

*IT WAS FASCINATING to watch the lava crater and glowing rivers and rivulets flowing down the slopes of the lava dome. Still more exciting, however, was the relentless struggle between the advancing lava and the sea. From the very beginning of the lava eruption it was noteworthy how much of the lava became fragmented when it came into contact with the sea.*

—S. Thorarinsson, 1966

The above quote was made by Thorarinsson as he observed the eruption of Surtur volcano and the formation of a new island (Surtsey) off the south central coast of Iceland in 1964. His observations of this eruption led to a new classification of volcanism known as phreatomagmatism and the awareness of fragmentation processes associated with the interaction between magma and nonmagmatic water.

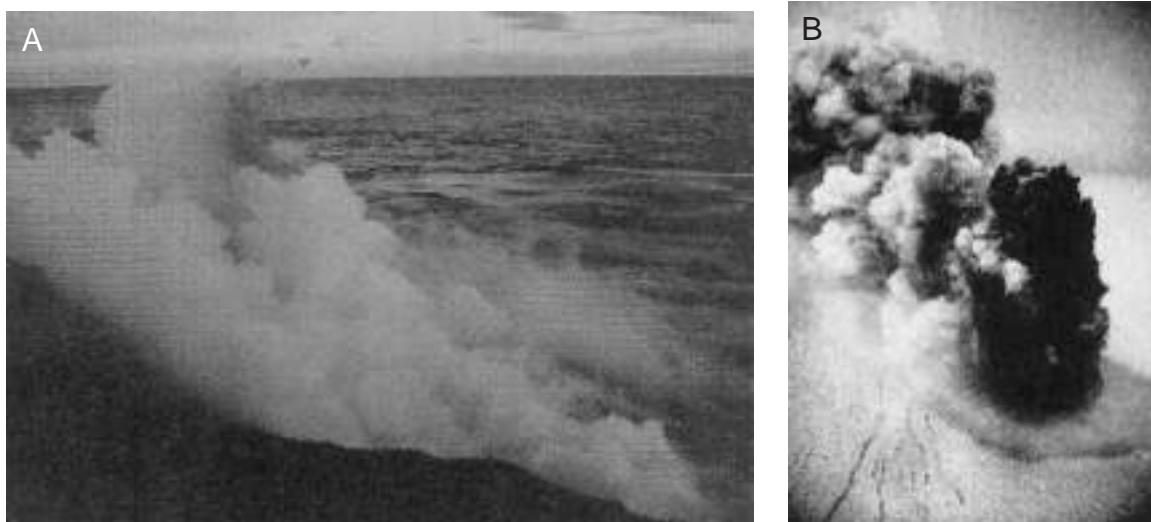

## I. CHARACTERISTICS

### A. Global Occurrence

Phreatomagmatic activity involves the physical interaction of magma or lava with an external source of water either within the Earth or on its surface. A spectrum of activity results when magma contacts water as illustrated by the following examples. (1) Since 1990, lava has been pouring into the sea along the shores near Kalapana, Hawaii, producing a range of activity from the explosive ejection of fragmented lava to a continuous emission of steam and passive quenching of lava (Fig. 1a). (2) The subglacial eruption at Grimsvotn volcano (Iceland) in 1996 caused extensive flooding in south central Iceland and produced explosive jets of ash (Fig. 1b). (3) At Mount Ruapehu (New Zealand) in 1995, a vigorous uprush of water, vapor, and scoria bombs was observed

through the crater lake, producing cock's tail explosive jets of ash. (4) In 1977, the two Ukinrek Maars (Alaska) formed by several hundred periodic blasts which were accompanied by a pervasive production of steam when rising magma surfaced into a shallow lake.

The array of eruption styles associated with phreatomagmatic activity reflects the many environments in which magma or lava may encounter water. Specific environments include deep or shallow submarine, littoral, lacustrine, phreatic, and subglacial. Phreatomagmatism is not restricted to magma type or vent type (monogenetic or polygenetic) and reflects the pervasive occurrence of water in the crust. Volcanoes that build up from repeated eruptions (polygenetic) such as stratovolcanoes and shield volcanoes, often have a phreatomagmatic phase or phases (i.e., vulcanian, phreatoplinian, or surtseyan) during an eruption period. The distinguishing features of a phreatomagmatic eruption phase are that plumes tend to be more steam or water rich and the grain size of the eruptive products tend to be finer than those from the associated magmatic eruptive phases. Explosive phreatomagmatic activity is also characterized by intensive fragmentation and ejection of the wall rocks in the vicinity of the explosion site, which results in the formation of large craters. Volcanoes that build up from a single phreatomagmatic eruption (monogenetic) form either a tuff ring, tuff cone, or a maar volcano when rising magma contacts water. The deposits of such volcanoes may consist of some 10 to more than 1000 single layers and result dominantly from

**FIGURE 1** (A) Photo of the lava from Kilauea volcano entering the coast near Kalapana in 1992 (taken by Thorvaldur Thordarson). (B) Photo of the October 2, 1996, eruption column after it broke through the ice at Grimsvotn volcano (Courtesy of Freysteinn Sigmundsson, Nordic Volcanological Institute).

transport and deposition by pyroclastic surges. These types of volcanoes are found all around the world and include Craters of the Moon, United States; Deception Island, Antarctica; Eifel volcanic field, Germany; Iwo Jima, Japan.

## B. Eruption Styles

A phreatomagmatic eruption is driven primarily by the volumetric expansion of external water after it has been rapidly heated by contact with magma. Exsolving magmatic volatiles may also contribute to expansion and fragmentation during a phreatomagmatic event. When water comes into contact with magma, it will either transform to steam (vapor) or a two-phase (liquid and vapor) fluid depending on the relative masses of water and magma interacting. It may also become superheated to a metastable liquid state which will flash to steam when acted on by an external force. In general, the more water available during the interaction, the wetter (liquid-rich fluid) the eruption will be. There is a wide variety of eruption styles that results from magma/water interaction. The style of activity ranges from passive quenching and granulation of magma or lava to large scale thermohydraulic explosions, representing the most energetic result of magma/water interaction.

The most commonly recognized phreatomagmatic eruption style is that characterized by cypressoidal (cock's tail) explosive jets of ash accompanied by billowing clouds of steam. This style of activity was well described during the emergence of Surtsey volcano off the coast of Iceland in 1964 and appropriately named *surtseyan*. Ejecta are directed vertically and laterally with the laterally directed ejecta producing a base surge. Similar activity has been observed at Capelinhos (Azores), Taal (Philippines), St. Augustine (Alaska), Ruapehu (New Zealand), and Vulcano (Italy) where magma has come into contact with either seawater or lake water filling a crater. Deposits related to this style of activity have been described as wet deposits, indicating that not all of the water was converted to steam during eruption and deposition.

Other phreatomagmatic eruption styles include vulcanian and phreatoplinian. Vulcanian eruptions are discrete, explosive events that last seconds to minutes. These eruptions are thought to be caused by highly pressurized gases derived from the magma or from a phreatomagmatic interaction. Phreatoplinian eruptions are similar in style to plinian eruptions except that deposits are finer-grained. Deposits related to these two

styles of activity are dry relative to *surtseyan* deposits in that most of the water was converted to steam during eruption and deposition.

## C. Tephra Characteristics

The products from a phreatomagmatic eruption are predominantly a mixture of glass, crystals, and foreign or wall rock lithics (fragmented material from the conduit and vent). In many cases, the lithic fragments represent by far the dominant part of the ejecta with grains ranging in size from fine ash to blocks. Their shapes may indicate fragmentation by fracturing (i.e., angular edges) and not by abrasion (i.e., rounded edges). In terms of grain size, phreatomagmatic tephra generally are finer grained than magmatic tephra (Fig. 2a), particularly for high water/magma ratios.

Under optical and electron microscopes, the juvenile (glass) component of phreatomagmatic tephra contains distinct grain shapes. These shapes include blocky, fusiform, mosslike, platey, and spherical or droplike as shown in Fig. 2b. Other distinguishing textural features are particles adhering to glass surfaces, grooves or scratches, chipped edges, and rounded edges. Also, the glass constituents may be more hydrothermally altered than magmatic tephras of equivalent age, especially in samples from wet tephra deposits in which hot water was captured. Basaltic glasses alter to palagonite, whereas rhyolitic glasses alter to a fine-grained mosaic of quartz, potassium feldspar, and clays.

## D. Phenomenology

The physical dynamics of phreatomagmatic fragmentation parallel a well-studied process called fuel-coolant interaction (FCI). FCI refers to a heat transfer process which can occur in any environment, converting thermal energy into kinetic energy on a short time scale (<1 ms) during the interaction of a cold volatile fluid (coolant) and a hot fluid (fuel) with a solidus temperature well above the homogeneous nucleation temperature of the coolant. In volcanological terms, the fuel is the magma and the coolant is water. Water at atmospheric conditions has a homogeneous nucleation temperature exceeding 300°C. Magmas have temperatures well above this temperature, therefore, in principle, phreatomagmatic explosive eruptions can occur in any volcanic environment.

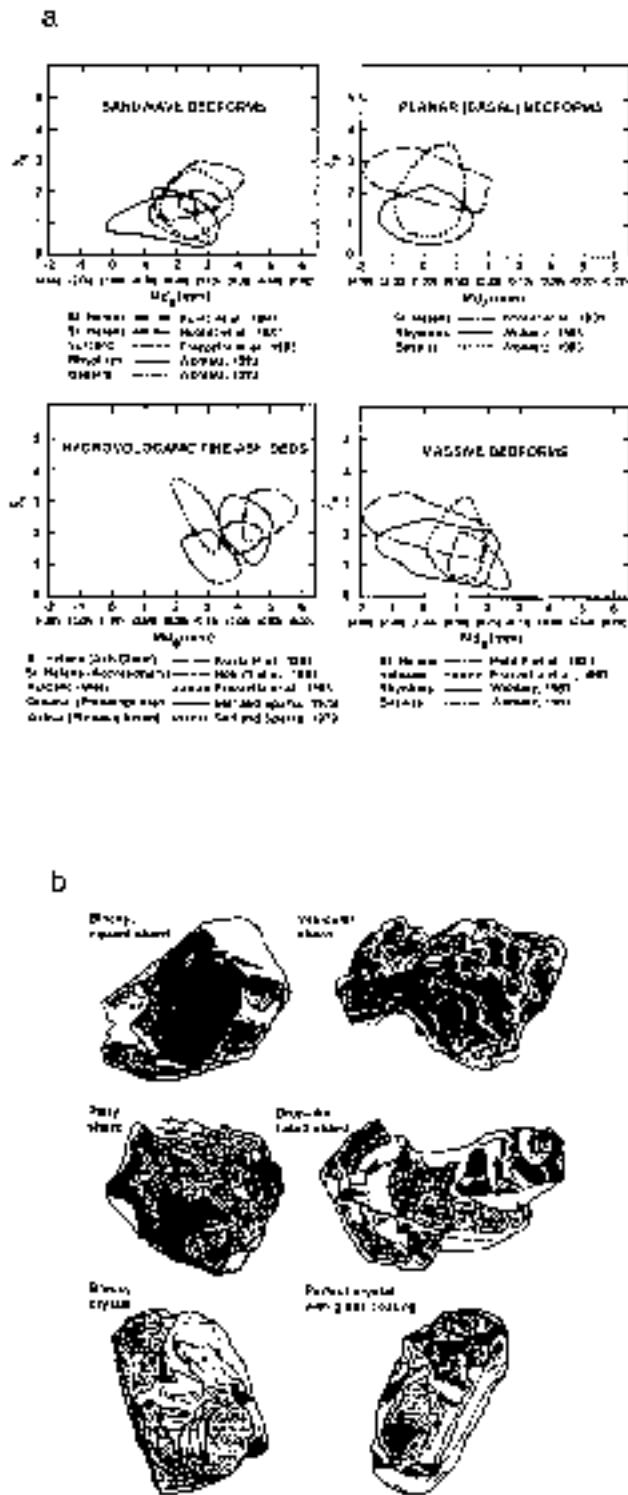

FIGURE 2 (a) Grain size distributions for phreatomagmatic tephra. (b) Clasts shapes characteristic of phreatomagmatic fragmentation.

FCI may be explosive or nonexplosive depending on the rate of heat transfer between the fuel and coolant and the subsequent pressurization rate of the coolant. The rate of heat transfer is a function of the surface area of the fuel which, in an explosive FCI, increases by a cascading fragmentation process. The fragmentation process is enhanced by thermal expansion of the coolant that creates new contact surfaces.

The physical dynamics of an explosive FCI are represented by the following stages:

1. Initial contact and coarse mixing of fuel and coolant under stable vapor film boiling conditions (Leidenfrost phenomenon).

2. Complete vapor film collapse caused either by the passage of a pressure pulse which may be of external origin (e.g., seismicity) or by a local implosion (i.e., water hammer) due to rapid condensation of coolant vapor. Once the coolant vapor is completely condensed, the fuel and coolant are thermally and mechanically coupled.

3. Episodic increase of heat transfer from fuel to coolant and fine fragmentation leading to superheated and pressurized water. As the coolant is heated, it expands at a rate of  $<1$  ms, leading to rapid increase in load stress on the melt. Relaxation of load stress in the brittle mode (elastic rebound) causes the explosive release of seismic energy. Up to 90% of the total kinetic explosion energy is released in this phase.

4. Volumetric expansion of the fuel-coolant mixture from the transformation of the superheated water to superheated steam. At this stage, the fuel and coolant are thermally and mechanically decoupled.

All FCIs, explosive or nonexplosive, are initiated by Stage 1. A nonexplosive FCI terminates at Stage 1 or Stage 2. The wetness of an explosive FCI reflects the degree of fragmentation and the rate of heat transfer (or the efficiency of the feedback mechanism) during Stages 2 and 3.

## II. THEORETICAL AND EXPERIMENTAL RESULTS

### A. History

Theoretical and experimental studies at Sandia National Laboratory (New Mexico) in the 1970s and 1980s provided a strong basis for understanding FCIs and a framework for the study of phreatomagmatic activity. These

experiments were designed to investigate the occurrence of steam explosions during core meltdown at nuclear reactors and others industrial environments such as metal smelters. The primary goal of the experiments was to constrain models for the conditions for a steam explosion when a coolant comes into contact with a fuel. Fuel (melt) used in the experiments ranged from molten salts to thermite-generated melts. Results from these studies include the four steps describing the physical dynamics of a FCI.

Phreatomagmatic explosions are complex interactions of four phases which are often internally heterogeneous (magma, magmatic volatiles, external water, and wall rock). Experimental studies of simple systems offer powerful tools for understanding the eruption dynamics.

## B. Thermite: Water Experiments

Experiments conducted at Los Alamos National Laboratory were designed to simulate phreatomagmatic activity using an Fe-Al thermite melt and water. The objectives were to monitor dynamic events and to determine what controls the rapid conversion of the melt's thermal energy into mechanical energy when it interacts with water. The melt, simulating basaltic magma, resulted from an exothermic reaction of fine-grained aluminum (~24 wt%) with magnetite (~76 wt%). In general, this thermite composition yields about 1130 kJ excess heat per mole of iron oxide at 1800 K. The physical and thermal properties of Fe-Al thermite melt are compared with those of a typical tholeiitic basaltic melt in Table I.

Four designs, shown and described in Figs. 3a–3d, were employed to evaluate the effects of contact geometry, the mass ratio of water to melt, and the confining strength (or pressure) on the explosivity of the experi-

mental phreatomagmatic eruption. High speed cameras were used in all experiments and samples of ejected thermite were collected from some of the experiments.

More than one style of melt ejection, each resembling a type of natural volcanic activity, resulted from these experiments:

1. Continuous fountaining of centimeter-sized liquid fragments of thermitic melt, which resembled a hawaiian eruption
2. Pulsating ballistic ejections of partially quenched and vesicular (scoriaceous) fragments, which resembled a strombolian eruption
3. Dry vapor-rich explosions ejecting micrometer-sized fragments in expanding jets of superheated steam, which resembled a surtseyan eruption
4. Wet vapor explosions ejecting millimeter-sized fragments in ballistic plumes of condensing steam
5. Passive chilling of the thermitic melt into centimeter-sized fragments with quenched surfaces, which was analogous to the formation of pillow lavas or peperites

A fifth experiment was designed to resemble a propulsion rocket (Fig. 3e) in order to quantify the water-to-melt mass ratio and confining pressure controls on the mechanical energy of an interaction. In this design, ejection of high pressure steam and fragmented thermite passing through the vent caused the vessel to lift off the ground. Measurements of the internal pressure history and ejecta characteristics were recorded, as was the maximum height reached by the vessel. Three confining pressures were used, 6.8, 16.3, and 35.7 MPa; the last exceeds the critical pressure of water (22.0 MPa). The water-to-melt mass ratio investigated ranged from 0.38 (1.82 kg of water and 4.73 kg of melt) to 2.00 (4.00 kg of water and 2.00 kg of melt).

The results from these experiments include three distinct pressurization histories or groups which were found to correspond to three specific ranges of lift-off heights (LOH) and produced clasts with distinct morphologies. The three pressurization histories are characterized by (1) exponential pressure-time curves; (2) an initial linear pressure rise and after approximately 0.3 to 0.8 s, a parabolic pressure increase to a value near the confining pressure; and (3) an initial linear pressure increase followed by an event that pressurized the chamber to a maximum value within 5 to 20 s.

Although the number of experimental samples is limited, an interesting correlation was observed between the six distinct grain shapes (Fig. 4a) identified in recovered samples and the three pressure groups: Group 1 experiments produced predominantly mosslike grains; Group 2 produced mainly spherical or droplike and aggregate

TABLE I Physical and Thermal Properties of Fe-Al Thermite and Basaltic Melt

Properties	Fe-Al melt	Basaltic melt
Liquidus T	1000–2000 K	1370–1520 K
Enthalpy	3700 kJ/kg	1150 kJ/kg

Thermal conductivity	2.4 J/(m s K)	2.1 J/(m s K)

grains; Group 3 experiments produced mainly blocky and irregularly shaped grains. Platelike grains were found in the fine-grain fraction of most samples. The correlation between grain shapes and the three pressure groups suggests that the grains are a consequence of the dynamic behavior of water as it is being heated by the melt during preburst interaction. Although sampling did not adequately represent the fraction of the sample finer than 62 mm (4  $\phi$ ), the distributions shown in Fig. 4b are very similar to some phreatomagmatic tephra size distributions (Fig. 2a).

In order to facilitate the use of these experiments as analogs of hydrovolcanic eruptions of much larger scale,

the explosive energy is expressed as the ratio of the measured and calculated mechanical energy to the initial internal (thermal) energy of the melt. This ratio is called the conversion ratio (MCR) and was calculated from the conservation of momentum.

As shown in Fig. 5, a positive correlation was found between MCR and the water-to-melt mass ratio ( $R_m$ ) within the three pressure groups. This plot shows that the observed pressurization mode is strongly linked to the resulting conversion ratio for each experiment. The pressure-time histories associated with each pressure group reflects the degree to which the water-thermite melt interaction approached thermal equilibrium. Thus,

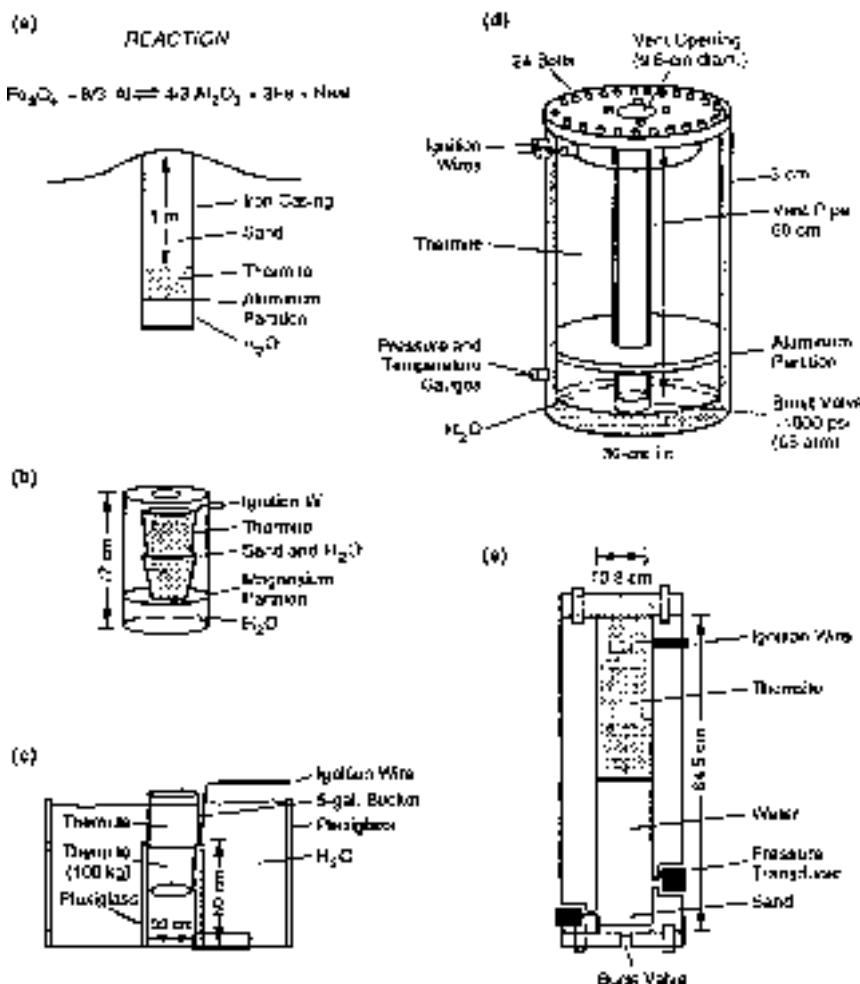

FIGURE 3 Schematic drawings of the five thermite–water interaction experiments conducted at Los Alamos National Laboratory. (a) Emplacement of 10 kg of thermite in an iron pipe above a second pipe filled with water; (b) immersion of a Plexiglas tube in a large Plexiglas box filled with >1 cubic meter of water; (c) emplacement of 90 kg of thermite held above water by an aluminum disk in a sealed steel cylinder with a vent at the top that burst open when the internal pressure exceeded 7 MPa; and (d) same as design (c) except the vent pipe extended down through the thermite into the water compartment. (e) The lift-off experiment designed similarly to (d) except the burst valve is located at the base of the vessel.

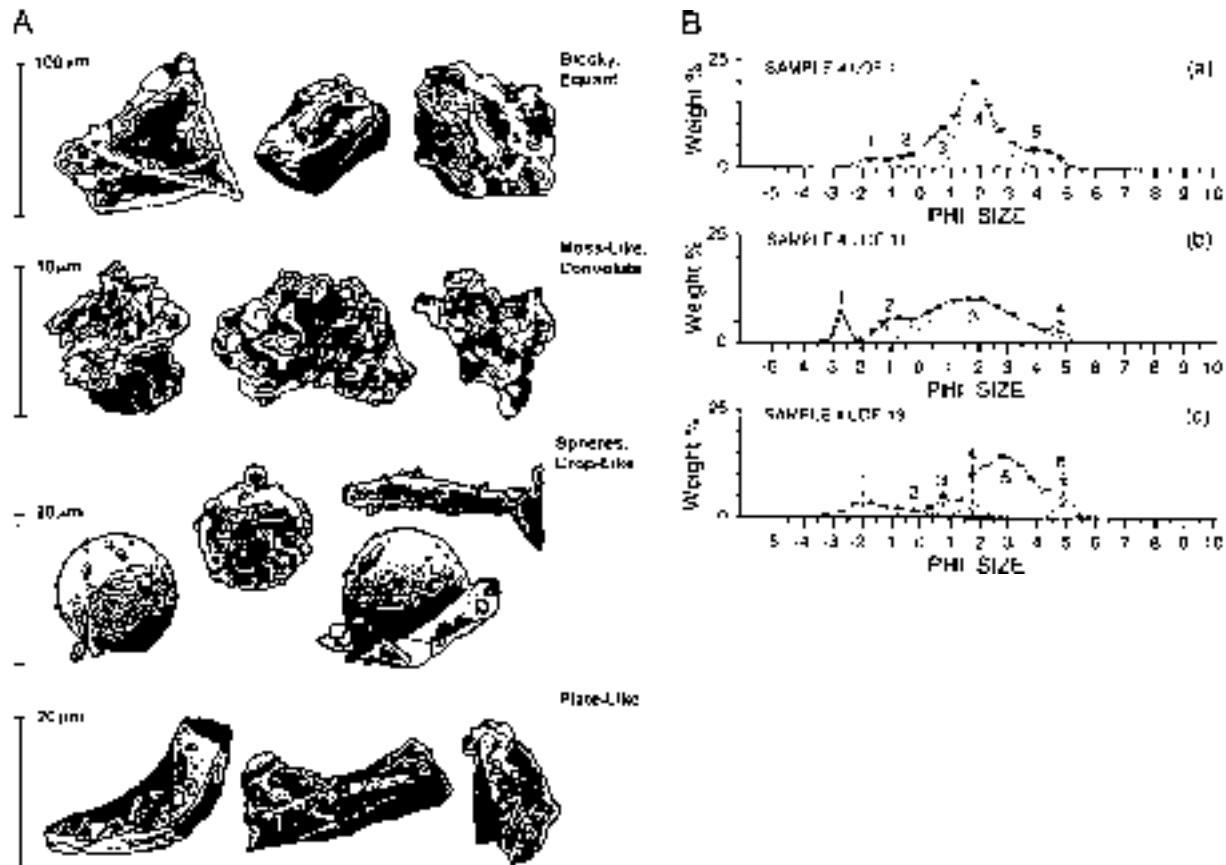

FIGURE 4 (A) Sketches of the four grain shapes observed in samples collected from the LANL experiments: (1) blocky; (2) mosslike convoluted surfaces; (3) spherical and droplet-like; and (4) curvy, plate-like. (B) Results of sieve analysis of three samples of experimental debris. Sample characterization where  $\phi = -\log_2$  (diameter in mm) includes: (a) LOF-I with mean  $\phi = 1.74$  and standard deviation ( $\sigma$ ) = 1.45; (b) LOF-II with mean  $\phi = 1.25$  and  $\sigma = 1.99$ ; and (c) LOF-13 with mean  $\phi = 2.19$  and  $\sigma = 1.90$ .

water–melt interactions involved with Group 1 experiments were the most efficient and explosive, and came closest to thermal equilibrium. These equate to “dry” phreatomagmatic events. Water–melt interactions involved with Group 3 experiments were the least efficient and explosive and did not approach thermal equilibrium. These experiments were considered analogs to submarine phreatomagmatic events. Group 2 experiments fell between Groups 1 and 3 and were considered analogs to “wet” phreatomagmatic events.

### C. Experiments Utilizing Rock Samples

A series of thermal explosion experiments (TEE) at University of Wuerzburg were designed to study phreatomagmatic fragmentation using remelted volcanic rock samples with compositions ranging from ultrabasic to

andesitic. The experiments evaluated the effect of the mode of contact between water and melt, the mixing conditions, the fragmentation processes during an explosive FCI which is also termed a thermohydraulic explosion, and the expansion phase of an explosive FCI. All experiments involved high resolution measurements of physical processes and properties associated with an explosive FCI and the evaluation of fragmented melt.

These experiments included two configurations: (1) water entrapment achieved by injection of a water volume into a melt volume and (2) melt entrapment achieved by the stratification of water and melt on an experimental scale of 5–20 cm (Fig. 6). The latter produced only very weak FCI with low reproducibility and thus were not useful analogs to phreatomagmatic explosions. The former were useful as these produced energetic explosions very effectively. For timing purposes, an explosion in each experiment was initiated by a projectile

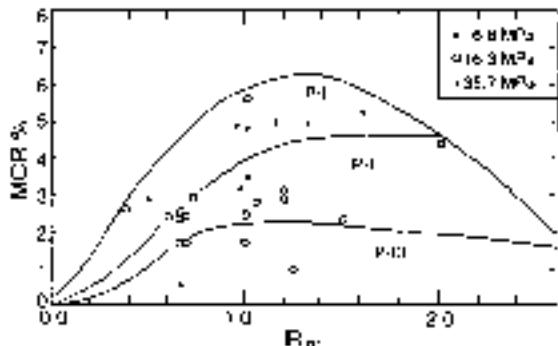

FIGURE 5 Trend of mechanical conversion ratio (MCR) with the water/melt mass ratio ( $R_m$ ) for experiments with different  $p_{conf}$ . The delineated field shows the range of data for the experiments exhibiting pressure records of a given group. P-I experiments showed MCR values greater than those of P-II, and P-III experiments showed the lowest MCR values. This relationship strongly indicates that the mode of pressurization is linked to the mechanism of fragmentation and heat exchange for these experiments.

that was fired at the melt surfaces to breakdown insulating vapor films.

A third experiment was designed to identify and quantify fragment populations generated by processes associated with the expansion of superheated steam (Stage 4 of a FCI). These experiments involved a sudden release of a compressed inert gas (argon) in the melt filled crucible (Fig. 6).

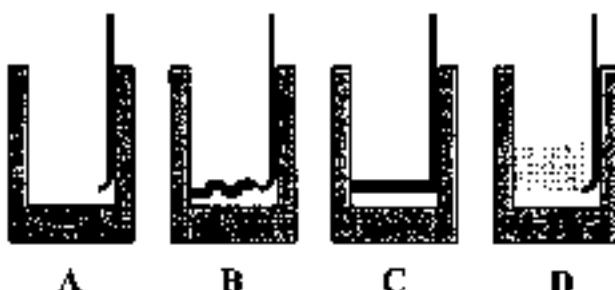

FIGURE 6 Entrapment of water in melt. Schematic cross sections of crucible used in the experiments: (A) A thin walled steel tube is inserted into the melt to the desired depth. (B) Water is injected into the melt; thus a local water/melt premix is produced. (C) After triggering, the escalating process of thermohydraulic explosion takes place in this premixed zone, during which water is superheated. Once the superheat reaches a critical value the phase transition to superheated steam is enforced, resulting in very rapid volume expansion. (D) The superheated steam finally expands to ambient pressure in an adiabatic way, thus accelerating the overlying melt strata out of the crucible.

Results from the first two experimental designs suggested that heat loss from the melt during the initial contact and premixing phase is critical for the generation of an explosion. Two contact modes were investigated, hot melt surrounded by excess water or water surrounded by excess melt. When the melt was dispersed in excess water, the heat transfer, even under stable vapor film boiling conditions, was very effective such that melt particles with diameters  $<1$  cm completely solidified or a thick crust formed around larger melt particles within  $<1$  s. In this case explosive FCI did not occur. In the case of water entrapment by excess melt, an explosive FCI was found to be highly probable. Here, the intensity of a resulting thermohydraulic explosion is proportional to the initial contact areas.

The mixing phase was found to be the primary control on the intensity of an explosive FCI. The available interfacial area between the two liquids is governed by (a) the differential flow speed (hydrodynamic energy) between the two fluids and (b) by the material properties of the fluids. Efficient mixing (i.e., creation of a large interfacial area in a short time), was achieved when the flow speed is high, and the densities and viscosities of the liquids are similar and low. Silicate magmas have densities between  $2500$  and  $3000 \text{ kg m}^{-3}$  and viscosities ranging from few  $\text{Pa s}$  to  $>10^6 \text{ Pa s}$ . In contrast, water has a density near  $1000 \text{ kg m}^{-3}$  and a viscosity of  $10^{-3} \text{ Pa s}$ . In Figs. 7 and 8, the optimum mixing conditions for low viscosity, ultrabasic melts are the maximum values for the water-to-melt volume ratios and the differential flow speeds which correspond to 11 vol% water and

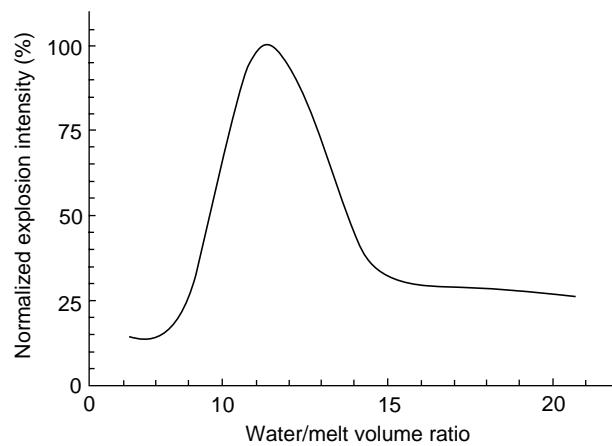

FIGURE 7 Water/melt volume ratios of mixing in entrapment configuration. The melt used in this experiments was a remelted olivine–melilitite at  $1350^\circ\text{C}$  and a viscosity of about  $1 \text{ Pa s}$ .

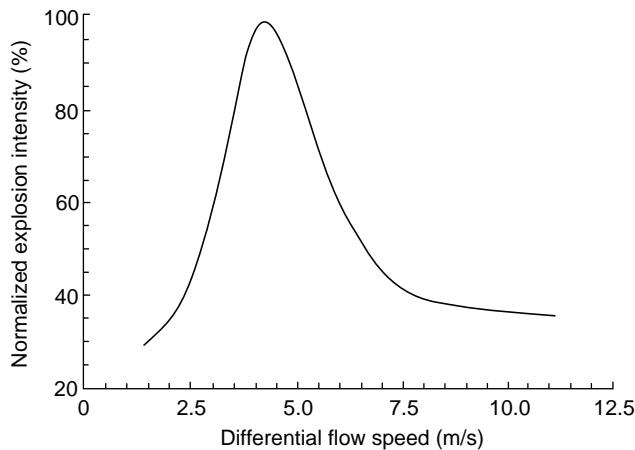

FIGURE 8 Differential flow speeds of mixing at a water/melt volume ratio of 11% in entrapment configuration. The melt also was remelted olivine–melilitite at 1350°C and a viscosity of about 1 Pa s.

~4.5 m/s, respectively. These values are thought to be valid for all basic magmas for cases in which water intrudes on the magma. Although these maxima are well defined, explosions occurred in a wide hydrodynamic mixing range.

Three fragmentation regimes were distinguished:

1. Fragmentation of the melt inside the crucible without measurable expansion of the mixture during fine-fragmentation and heat transfer (Stage 3 of a FCI)
2. Fragmentation of melt strata during acceleration of the melt by expansion of superheated steam inside the crucible
3. Fragmentation of the melt during high speed ballistic trajectory outside the crucible

Particles produced by the fine-fragmentation, regime 1, resembled the ash-sized particles generated by the LANL experiments. The fine-fragmentation phase was found to be the crucial phase for an explosive FCI, during which the maximum kinetic energy (explosion energy) is released. This phase produced angular shaped particles with diameters between 30 and 130  $\mu\text{m}$ . Fragmentation during melt acceleration in a confined geometry produced spherical fragments with diameters between 90 and 180  $\mu\text{m}$ . Fragmentation during decelerated movement of melt on ballistic trajectories in free air produced elongated shapes to hairlike shapes similar to Pelé's hair, depending on the ejection velocity.

An experimental explosive FCI is a highly energetic, short-time process occurring on a timescale of <1 ms. Within this time frame, new surfaces were created by a brittle type of fine fragmentation. The particles

exclusively produced during this event were identified and quantified. The total of new surface area was found to correlate linearly with the respective explosion intensity.

### III. FRAGMENTATION MECHANISMS

#### A. Types of Fragmentation

A fragmentation mechanism associated with each phreatomagmatic grain type (i.e., blocky, fusiform, moss-like, platey, and spherical or drop-like) can be inferred from results of the phreatomagmatic analog experiments and FCI theory. The blocky grains found in tephra deposits and produced in lab experiments resemble shattered glass or glass that has been partially twisted and deformed while still plastic. These fragments form when stress waves propagate through a melt and produce deformation rates that exceed its bulk modulus (Fig. 9). Also it is envisioned that the local temperature of the melt is near solidus and brittle fractures develop in response to thermal contraction or tensional stress waves produced by vapor film collapse. Because stress waves typically propagate faster than thermal waves, it is likely that thermal contraction affects only melt surfaces while

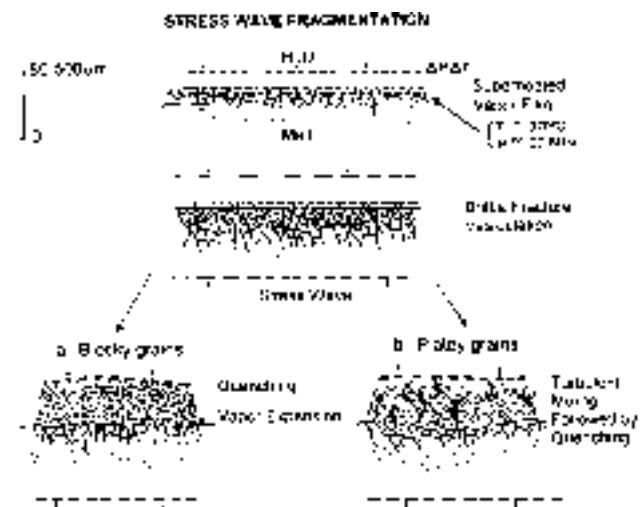

FIGURE 9 The collapse of a superheated vapor film or the explosive expansion of the film will produce stress waves in the melt. If these exceed the bulk modulus of the melt and it fractures in a brittle fashion, (a) blocky Type 1 or (b) Type 2 pyroclasts will form. [Reprinted with permission from Wohletz, 1983.]

the bulk of the melt is rapidly subjected to mechanical stresses.

In quenched portions of the melt, fractures tend to propagate at angles less than  $45^\circ$  to the melt surface, forming block-shaped clasts with planar to curviplanar surfaces. Vapor film oscillation may produce turbulence that tends to spall quenched melt fragments from the surface of the molten body and expose unquenched surfaces (Fig. 9). For portions of the melt that fragment prior to quenching, vapor turbulence can cause deformation of unquenched shards with melt surface tension promoting formation of fluidal surface textures.

Moss-like grains develop by viscous deformation under tensional stress conditions created during rapid vapor formation. These conditions are predicted by the development of Rayleigh-Taylor and Kelvin-Helmholtz instabilities. These instabilities are caused by the relative motion of the vapor along the melt surface (Fig. 10). They perturb the melt surface and introduce additional morphological characteristics. Tiny plumes of melt rise from the surface when surface tension forces are exceeded by Rayleigh-Taylor instabilities (Fig. 11). Kelvin-Helmholtz instabilities are induced by shear stresses that further stretch and disperse the melt surface. Because these instabilities form with a range of

wavelengths and orientations, melt surfaces can become very convoluted, resulting in tortuous, high surface area fragments.

Spherical or droplike grains develop from the effect of surface tension when magma is still hot enough to behave like a fluid. As with moss-shaped grains, melt surface instabilities both grow and detach to form spherical or elongated ribbon-like structures in response to the force of locally collapsing vapor films (Fig. 12). The most rapid mechanism contributing to production of these grains occurs when compression waves associated with vapor film collapse become large enough to shatter the surface undulations produced by instabilities; this results in the production of a multitude of fine-grained fragments. When axisymmetric collapse of vapor films produces accelerations sufficient to overcome surface tension forces of fluid melt, water jets can penetrate into the melt and become partially or completely entrapped beneath the surface. The trapped water becomes superheated and expands, thus causing additional fragmentation of melt.

Platey grains have been interpreted as pieces of quenched crust stripped off the surface of the magma (Fig. 9b). The stripping process can be attributed to the turbulence of vapor film oscillation, vaporization wave

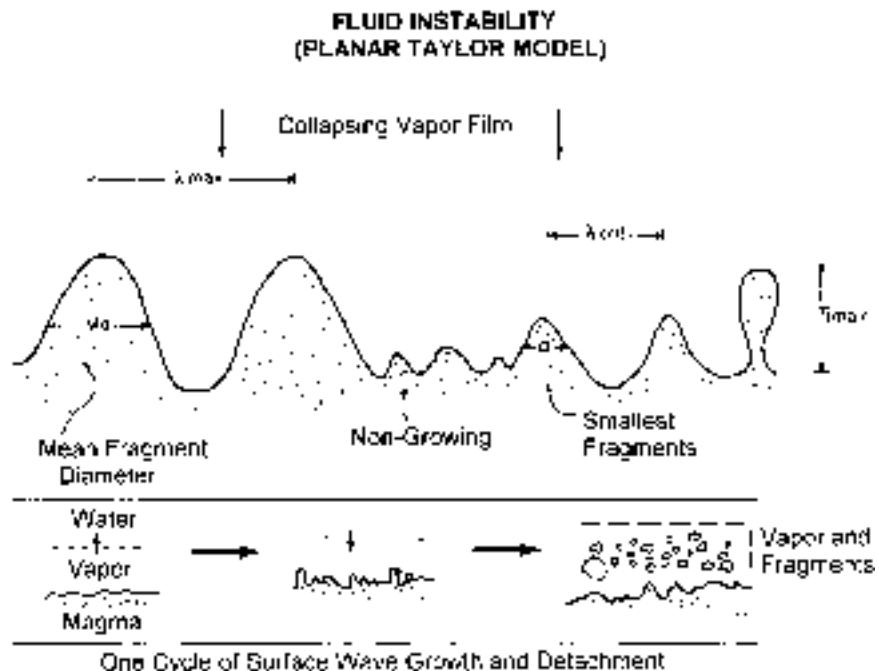

FIGURE 10 (Top) Sketch of a planar Taylor instability at the interface between magma and a collapsing vapor film. (Bottom) Diagram of a complete cycle of instability growth. The oscillation of the vapor film transmits sufficient momentum to the magma surface so that it becomes distorted into waves. [Reprinted with permission from Wohletz, 1986.]

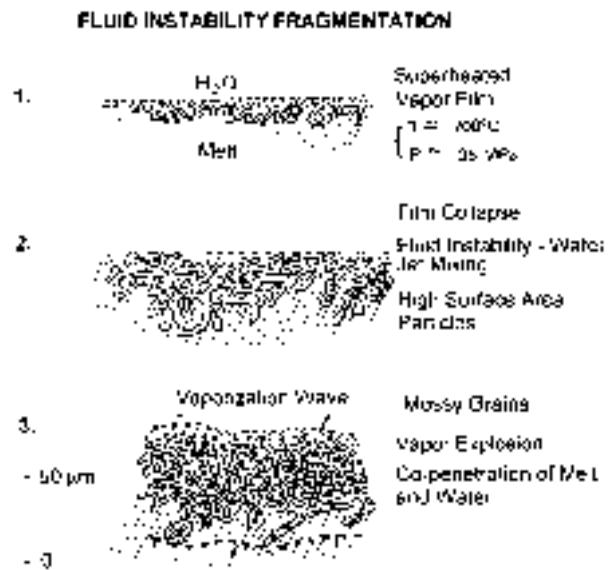

FIGURE 11 Fluid instabilities can form at the contact of water with melt. These instabilities are of a Rayleigh–Taylor or Kelvin–Helmholtz type, both of which may cause axisymmetric film collapse that causes water jets to penetrate the melt. The result is high surface-area fragmentation, rapid heat exchange, followed by vapor explosion. The explosion then generates new contact areas and/or a shock wave that fragments more melt and acts as a detonation wave. This process requires abundant water to be present. [Reprinted with permission from Wohletz, 1983.]

propagation, or Kelvin–Helmholtz instability. High velocity ejection of liquid melt leads to the formation of rock wool.

### B. Growth and Evolution of Fragmentation Events

Phreatomagmatic fragmentation evolves in a number of different manners depending upon the primary controlling parameters of viscosity, temperature, confining pressure, and water/magma contact mode (i.e., mixing conditions and mass ratio). These parameters are largely determined by the environmental setting of the volcano and its magma characteristics, discussed below, and they determine the rate of heat transfer from the melt to water. Fragmentation events follow a complex growth history that includes premixing, pressure growth, triggering, failure, and ejection. These stages are similar to those associated with an FCI.

Premixing is an increased intermingling of water with the melt, which leads to a large increase in surface area,

and hence in heat transfer. The intermingling is driven by diffusional and kinetic mechanisms, including hydraulic fracturing, stress corrosion, capillarity, vapor-film collapse and water jetting, molecular diffusion, and Taylor and Helmholtz instability. It is important to note that this intermingling occurs over a wide range of scales from submicrometers to meters, and that it occurs without significant heat transfer to the water, because of vapor-film insulation.

After premixing, thermal energy is transferred to the water over a large effective surface area, and with this transfer, pressure builds, in many cases making the water a supercritical fluid or a metastable superheated fluid. From experiments this phase of pressure growth may show several different temporal patterns, including exponential, parabolic, and cyclic growth with time. For exponential growth pressure increases with surface area during premixing, which requires that premixing produces melt fragments that decrease in size linearly with time. This produces an exponential rise in surface area, hence in heat transfer with time, and an accompanying exponential rise in water pressure. On the other hand, a parabolic pressure rise probably reflects simple thermal diffusion in which heat transfer is initially rapid and slows with time as diffusional distances increase. Cyclic pressure increases best reflect cyclic growth and collapse of vapor films as premixing progresses. Rapid heat transfer at a water–melt interface causes a vapor film to pressurize and rapidly expand past its stable size, leading to overcooling of the film and its immediate condensation and collapse, which may produce water jets that

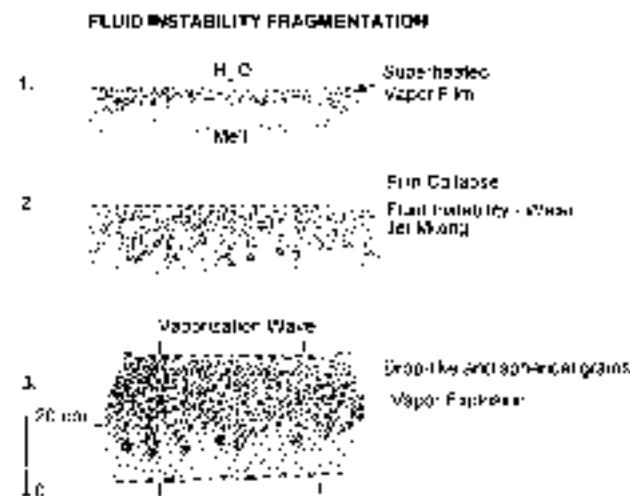

FIGURE 12 Fluid instabilities will form spherical or drop-like shapes of melt if viscosity is low and surface tension effects are strong. [Reprinted with permission from Wohletz, 1983.]

impinge the surface of the melt. The initial film pressure then becomes the force exerted on the melt surface by the film's collapse, which leads to the eventual breakup of the melt into smaller particles and an increase in heat transfer surface area. As the surface area grows, the pressure of each cycle of film growth also increases.

Premixing and pressure growth may continue or may decline with time, the latter case resulting in a highly metastable situation that can exist only in high confining pressures ( $>16$  MPa). However, for the former case, water will gradually increase in temperature until it spontaneously vaporizes in whole or part. If a small portion of the water reaches this point first, its vaporization produces a pressure pulse that triggers the vaporization of the rest of the water and may cause an explosion.

An explosive vapor expansion drives a shock wave by which the melt is rapidly accelerated. This acceleration produces stresses that can exceed the bulk modulus of the melt, leading to its whole-scale failure and production of fragments; fragments formed during premixing are further comminuted and intact melt is torn apart. The mode of failure is largely determined by the properties of the melt, and it ranges from brittle to ductile in behavior.

The final stage of fragmentation is the ejection phase where fragments are moving at high speeds. If the explosion originates away from a free surface, then as the shock wave emerges through the free surface it will create a rarefaction wave that propagates in the opposite direction. This rarefaction wave allows immediate vapor expansion as it propagates into the conduit. It is at this stage when the wall rock (nonjuvenile lithics) becomes fragmented and incorporated into the erupting mass. With vapor expansion, fragments are accelerated and ejected out of the system. During this ejection, the speed of the fragment is proportional to its size because of inertial effects, such that fragments will move at different speeds and collide with one another, leading to further fragmentation.

Melt fragment shapes and size distributions are controlled by the types of premixing, triggering, failure modes, and ejection. Although growth and evolution cannot be directly observed, the overall pattern of phreatomagmatic fragmentation is portrayed by eruption phenomena. In this light, fragmentation evolution can be classified as: (1) escalating, (2) declining, (3) cyclic, or (4) delayed. Escalating fragmentation during eruption results in larger and larger volumes of tephra produced in each successive burst. Such behavior requires the mass of magma fragmented to increase by an increase in the water flux and/or magma flux. As discussed above, the water/melt mass ratio ( $R_m$ ) determines in part the energy

of fragmentation with higher fragmentation energy leading to more magma fragmentation. Conversely, decreasing fluxes or a change in  $R_m$  away from high energy fragmentation leads to a declining fragmentation evolution. Cyclic evolutions are common where fragmentation repeatedly grows and then declines. This situation is most common where water supply is depleted after large fragmentation events, resulting in less energetic ones until the water supply is reestablished. Delayed fragmentation refers to a situation where a fragmentation event occurs after a prolonged period after premixing. Prior to fragmentation, the system is metastable, requiring a trigger. This type of fragmentation, although well-observed in experiments, is difficult to sustain in volcanic situations. Such situations might include an upper-crust magma chamber that interacts with water saturated rocks for a long time prior to eruption.

### C. Fragmentation Controls

Through the experiments and theory described above and observations at numerous volcanoes around the world, it has become clear that phreatomagmatic fragmentation is largely controlled by three key parameters: magma viscosity, temperature/pressure, and water/magma contact mode. The third is a function of the supply rate of magma and external water which is determined by the hydrology of and around the vent and conduit.

During phreatomagmatic fragmentation part of the thermal energy of the magma is converted to mechanical energy, including seismic and acoustic energy, fragmentation energy, and kinetic energy of fragment motion. With an increasing *efficiency* or conversion ratio, more mechanical energy is released and fragmentation increases. In field observations at volcanoes, the relative efficiency of phreatomagmatic fragmentation is reflected by fragment size distribution and mode of fragment dispersal.

In general, (1) higher temperature melts have greater thermal energy available for conversion to mechanical energy, (2) viscosity retards the mixing of magma and water in a manner that generally predicts that fragmentation will be greater in lower viscosity magmas, and (3) the amount of water relative to that of magma involved in fragmentation determines the intermediate and final thermodynamic states of water for phreatomagmatic eruptions. Magma and water temperatures prior to interaction influence the heat transfer rates and equilibrium temperature approached during mixing. In a simple way, the higher the equilibrium temperature,

the more energy is available for mechanical work, but the rate of heat transfer is complexly linked to water temperature, rising rapidly with temperature until the onset of vapor-film boiling. Thermal equilibrium is probably never reached during fragmentation because instability and vapor expansion occurs before this point is reached. For the instantaneous heating case, the temperature of the interface,  $T_i$ , is theoretically constrained by

$$T_i = \frac{T_m(\alpha_m/\sqrt{\kappa_m}) + T_w(\alpha_w/\sqrt{\kappa_w})}{(\alpha_m/\sqrt{\kappa_m}) + (\alpha_w/\sqrt{\kappa_w})},$$

where  $\alpha$  and  $\kappa$  are thermal conductivity and diffusivity, respectively, of the respective phases water,  $w$ , and melt,  $m$ . If  $T_i$  is greater than the spontaneous nucleation temperature of water, then a spontaneous superheat vaporization would occur.

The effect of ambient (or confining) pressure is less understood. Pressure is thermodynamically linked to temperature, and, as such, the pressure-volume work of a fragmentation should increase with pressure, but there are some experimental indications that pressure also acts to subdue interaction because it limits vapor-film growth and the amount of premixing. However, the most violent experimental fragmentations have occurred where confining pressure is in excess of the critical pressure of water.

The viscosity of magmas ranges from few Pa s in the case of basaltic composition to millions of Pa s in the case of silicic magmas. Viscosity is additionally coupled to temperature in magmas (higher temperature magmas have generally lower viscosities). While temperature may vary several hundreds of degrees, viscosity varies over many orders of magnitude. Viscosity (and surface tension) is an important parameter for growth and propagation of fluid instabilities at the interface between magma and water. Such instabilities have been cited as likely mechanisms.

The combined effect of viscosity and temperature on the efficiency of fragmentation is markedly less than that of water/magma ratio, which varies over two orders of magnitude. This observation reflects the major control of water expansion during fragmentation, a control determined by intermediate and final thermodynamic states of water. If very little water is available, it can be heated to high temperatures and pressures, but fragments only a relatively small volume of magma. At the other extreme, abundant water may never get enough thermal energy for fragmentation. At intermediate mass ratios, there is enough thermal energy to take all the water to high states of internal energy, thus resulting in rather complete magma fragmentation.

Water involved in the interaction may not always be a pure liquid, it may contain particles (sediment or tephra) or other impurities such as dissolved compounds (seawater or hydrothermal fluids). The effects of these impurities on the fragmentation process are related to the changes in the physical properties of the impure water. Depending on the concentration of impurities in the water, its viscosity may increase up to an order of magnitude, the density may double and the heat capacity may decrease by one-fourth.

#### IV. FIELD OBSERVATIONS

Hydrologic settings for phreatomagmatic fragmentation vary from deep ocean (marine) to near shore (littoral) to lake (lacustrine) to surface drainages (fluvial) and groundwater (phreatic) settings. The hydrological settings affect the abundance and supply rate of water and the ambient pressure at which interaction occurs. Accordingly, the character of phreatomagmatic fragmentation varies in a systematic manner with setting.

For marine settings, deep water explosive fragmentations are not generally observable. In fact, many researchers propose that for depths where hydrostatic pressure is greater than the critical pressure of water, explosive fragmentation does not occur. These researchers explain deep ocean hydroclasts to have resulted from simple quench fragmentation of extruded lava, because most hydroclasts are blocky shaped and coarse to medium in size. On the other hand, experimental and theoretical evidence shows that the critical pressure of water is not the maximum pressure at which explosive fragmentation may occur. In fact, for most substances that undergo such rapid vaporization (leading to explosive expansion), the phase change may occur well above the critical pressure. Future research involving actual observation of deep water eruption or documentation of explosive effects in deep water tephra deposits may resolve this debate.

Littoral fragmentations have been well documented in Hawaii where lava flows enter the sea. A large variation in fragmentation dynamics is observed from passive steam and quench-fragmentation to violent bursts that form high-speed sprays of fine-grained hydroclasts. One control is thought to be whether or not lava contacts water within the confined space of a lava tube or not. The fragmentation starting in a lava tube is observed to be very violent, suggesting that such confinement allowed buildup of high pressure during the event. Con-

sequently, fragments from littoral fragmentation show a wide range of shapes and sizes from centimeter-sized fluid-shaped clasts to micrometer-sized blocky shards. Cones that form in the littoral zone are similar to tuff cones that grow in lacustrine environments. These eruptions are observed to produce large amounts of saturated steam and are called “wet” eruptions. The associated cones are referred to as littoral cones or rootless craters for those that form where lava has traveled over a marsh or a bog.

Phreatomagmatic fragmentation in fluvial or phreatic hydrogeological environments is governed by a limited supply of water. Such fragmentations, though, can be the most violent because water/magma ratios are in the range of optimal interaction and the contact modes under confined conditions (i.e., in hydraulically active fault systems) are optimal for the generation of thermo-hydraulic explosion. Tuff rings (e.g., Crater Elegante, Mexico; Panum crater, United States) in these settings show wide-area, high energy dispersal with superheated vapor that does not produce such wet deposits; hence palagonitization is limited. Such fragmentation is called *dry* and in many places occurs with scoria deposits that result from little or no water interaction. Typically the fragments are fine-grained ash, showing a range of shapes from blocky to mossy aggregates to micrometer-sized spheres. Tuff cones (e.g., Cerro Colorado, Mexico; Koko crater, United States) show low energy dispersal with saturated steam that produce palagonitized deposits. Such fragmentation is called *wet* and in many places produce basal surge deposits that result from a progressively water-rich interaction. Typically the fragments are fine- to medium-grained ash, showing a range of shapes from blocky and platey with dust-sized fragments adhering to surfaces, forming accretionary type grains.

The depth of fragmentation is likely determined by the depth of the aquifer. During eruption, an aquifer may be drawn down such that fragmentation level gets deeper while the hydrostatic pressure onto the system is more or less constant. Explosions propagating downward will fragment and erupt wall rock at deeper and deeper levels, thus enlarging the conduit (e.g., a dia-treme) to the depth of the aquifer. The amount of lithic ejecta also reflects the stability of the walls. Very little fragmented wall rock is erupted when the walls are stable and the eruption is fairly continuous and weak. If the walls are unstable, then the walls may be eroded during a weak eruption, thus producing a significant amount of fragmented wall rock. The collapse of eroded wall rock can trigger a strong, discrete explosive phreatomagmatic eruption that erupts mostly lithic material.

## V. SUMMARY AND FUTURE RESEARCH

1. Phreatomagmatic fragmentation is quite distinct from magmatic fragmentation in both the eruptive phenomena and the driving mechanisms as well as in the types of fragments produced. Phreatomagmatism produces unique juvenile grain populations that reflect the relative amount of water and magma involved in the interaction. The quantity of nonjuvenile (fragmented wall rock) material found in deposits reflect the stability of the conduit walls and the explosivity of the eruption.

2. Phreatomagmatic fragmentation results in a spectrum of eruptive activity ranging from passive quenching of magma/lava to explosive ejections of ash. The style of eruption primarily reflects the hydrologic environment in which magma/lava come into contact with water.

3. Much of our understanding of phreatomagmatic fragmentation stems from laboratory experiments related to fuel-coolant interactions (FCIs) as well as field observations and laboratory analysis of the fragments. It is future experimental studies that may best improve our current knowledge of the controls of phreatomagmatism. For example, experiments have thus far only covered a rather narrow range of melt compositions, including thermitic melts and some remelted volcanic rocks. Detailed experiments may reveal how fragmentation is affected by compositions ranging from mafic to silicic and with different proportions of dissolved volatiles. Similarly, experimental coolants have been pure or nearly pure water, so very little is known about how impurities in the coolant effect the fragmentation process. These areas for future research are just a few that could further the relevance of experimental analogs to phreatomagmatic volcanism.

## GLOSSARY

- annular flow** Two-phase flow (gas and liquid) in a tube. Central gas jet surrounded by an annulus of magma. Volcanic equivalent: hawaiian fire fountains.
- gas–piston activity** A rhythmic rise and fall of the magma level within a volcanic conduit due to ascent and escape of large pockets of magmatic gas.
- Hawaiian eruptions** Basaltic eruptions with very low viscosity magma (10–100 Pa s). Fire fountains and lava flows. Examples: Kilauea Iki (United States), Piton de la Fournaise (France), Heimaey (1973, Iceland).
- lava fountain** A pillar-like jet of gas and molten pyroclasts that towers tens to hundreds of meters above a central vent.
- lava pond** An accumulation of coalesced molten pyroclasts that are trapped at the vent by the walls of a developing spatter or cinder cone.
- pyroclast** A general term for any fragment of lava ejected during an explosive volcanic eruption.

**reticulite** A delicate scoria containing 95–99% void space within a honeycomb-like network of thin glass struts.

**scoria** A porous, glassy pyroclast containing 70–85% void space.

**slug flow** Two-phase flow (gas and liquid) in a tube. Large gas pocket rising in a liquid and filling up the entire width of the conduit. Characteristic of strombolian explosions and gas–piston events during hawaiian eruptions.

**spatter bombs** A glassy pyroclast >64 mm across that develops a fluidal shape by the force of ejection.

**Strombolian eruptions** Basaltic eruptions with a low viscosity magma (100–1000 Pa s). Series of explosions. Examples: Pacaya (Guatemala), Paricutin (Mexico), Sakura-jima (Japan), Stromboli (Italy), Tolbachik (Russia), Yasur (Vanuatu).

**tremor** A continuous vibration of the ground around active volcanoes.

**H**AWAIIAN AND STROMBOLIAN eruptions are the least violent, and perhaps the most majestic, form of volcanism. Their subdued intensity, magnitude, and dispersive power are the consequence of the low viscosity of the magma erupted, typically basalt or basaltic andesite, which allows gas to segregate and escape with relative ease. During strombolian eruptions,

gas is released in discrete, often rhythmic, bursts, each of which disrupts the top of the magma column and ejects a shower of incandescent lava fragments, or pyroclasts (e.g., long-standing eruptions of Stromboli, Aeolian Islands or Mount Etna, Sicily; 1943–1954 Paricutin, Mexico; 1993–1995 Mount Veniaminof, Alaska; 1995–1996 Pacaya, Guatemala; 1996 Rabaul, Papua New Guinea; 1996–1998 Villarrica, Chile). During hawaiian eruptions, gas is also released in discrete rhythmic bursts and each burst in gas flux gives rise to a sustained lava fountain (e.g., 1959, 1969, 1983–1986 Kilauea and 1950, 1975, 1984 Mauna Loa eruptions in Hawaii; 1992, 1998 Piton de la Fournaise, Reunion Island).

In actuality, a continuum exists between the two styles of volcanism, and it is not uncommon for one type of activity to give way to the other (e.g., 1961 Askja and 1973 Heimaey, Iceland; 1975 Tolbachik, Kamchatka; 1987 Izu-Oshima, Japan; 1996 Mount Etna, Sicily; 1996–1997 Pavlof and 1997 Okmok, Aleutian Islands). In this chapter, we first describe the end member characteristics of strombolian and hawaiian eruptions and then integrate these observations with two-phase flow models (e.g., analog gas–liquid systems) to infer the dynamics of hawaiian and strombolian eruptions and the transition between them.

sustained gas jet carrying a dispersed load of centimeter-to meter-sized, molten clots. Gas emission and lava volume measurements made during the 1983–1986 eruption of Kilauea volcano give average effusion rates of  $4.7 \times 10^5 \text{ kg s}^{-1}$  lava (dense rock equivalent) and  $2.5 \times 10^3 \text{ kg s}^{-1}$  gas (0.42 wt% combined  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{SO}_2$ ). The gas to clot ratio averaged for the eruption is 70:1 by volume, assuming lava and gas densities of 2700 and  $0.2 \text{ kg m}^{-3}$ , respectively. The clots exit at near vertical angles at speeds  $v$ , determined from the ballistic approximation  $v^2 = 2gb$ , of  $\approx 100 \text{ m s}^{-1}$ . Eruption temperatures are highest in the center of the fountain, creating an incandescent yellow-white axis that extends almost to the top of the fountain. Eruption temperatures ranging between  $1150^\circ\text{C}$  (1986–1987 Izu-Oshima eruption) and  $1216^\circ\text{C}$  (1959 Kilauea eruption) have been reported. The hot, thermal core of the fountain passes outward into a fiery orange-red region of slightly cooler temperature and lower clot density, and then to a sparse, black halo of chilled pyroclasts. Although the jetting is continuous, brightly glowing fronts pulse upward through the core of the fountain at 1- to 5-s intervals.

A central vent (i.e., a point source, Fig. 1B) may experience many fountaining episodes. The 4-week-long eruption of Kilauea volcano in 1959, for example, underwent 16 2- to 32-hour fountaining phases after the initial outburst. Typically, the fountaining ends with magma draining to deep levels in conduit amid sporadic bursts of molten ejecta and gas, and then gradually, over periods of several hours to days, it rises in preparation for the next event. As it nears the surface, the level of magma in the conduit may begin to rise and fall rhythmically (gas–piston activity) due to the ascension and release of large gas pockets (e.g., 1969–1971 and 1983–1986 eruptions of Kilauea; Fig. 2). The top of the column begins to churn and a low, commonly dome-shaped, lava fountain spawns as the new episode commences. Usually within several tens of minutes to a few hours the incipient fountain builds to a maximum height, which may hold constant through a significant part of the episode. The end of each episode is often abrupt compared to the period of buildup. In the first 17 fountaining cycles of the 1983–1986 eruption of Kilauea volcano, for example, 100- to 300-m fountains built up over several tens of minutes to 2 hours time, whereas the height usually dropped to zero in 3–10 minutes at the end of the episode.

It is not unusual for a long span of successive fountaining episodes to yield to an era of continuous, quiescent lava effusion before the eruption finally comes to an end (e.g., the 1969–1971 and 1983 to present eruptions of Kilauea). The long-standing eruption of Kilauea vol-

## I. DEFINING CHARACTERISTICS

### A. Eruptive Style

Hawaiian-style eruptions begin with a swarm of propagating earthquakes and ground fissures. Vents spawn along a fissure as it lengthens, creating a wall of lava, or “curtain of fire,” that may extend for kilometers (Fig. 1A; see also color insert). Gradually, over a period of hours to days, differential cooling due to irregularities in the width of the feeder dike causes wall solidification at narrow points. Parts of the fissure seal off, and the original line-source (Fig. 1A) becomes a point-source (Fig. 1B). The curtain of fire collapses back into a single, pillar-like fountain towering above a central vent (Fig. 1B). During a fountaining episode, the vent expels approximately  $50\text{--}1000 \text{ m}^3 \text{ s}^{-1}$  of lava, which rises to heights  $h$  of 100–500 m and occasionally higher. Unusually high fountains reaching upward of 1600 m were observed during the 1986–1987 eruption of Izu-Oshima volcano (Japan).

The structure of the fountain is essentially that of a

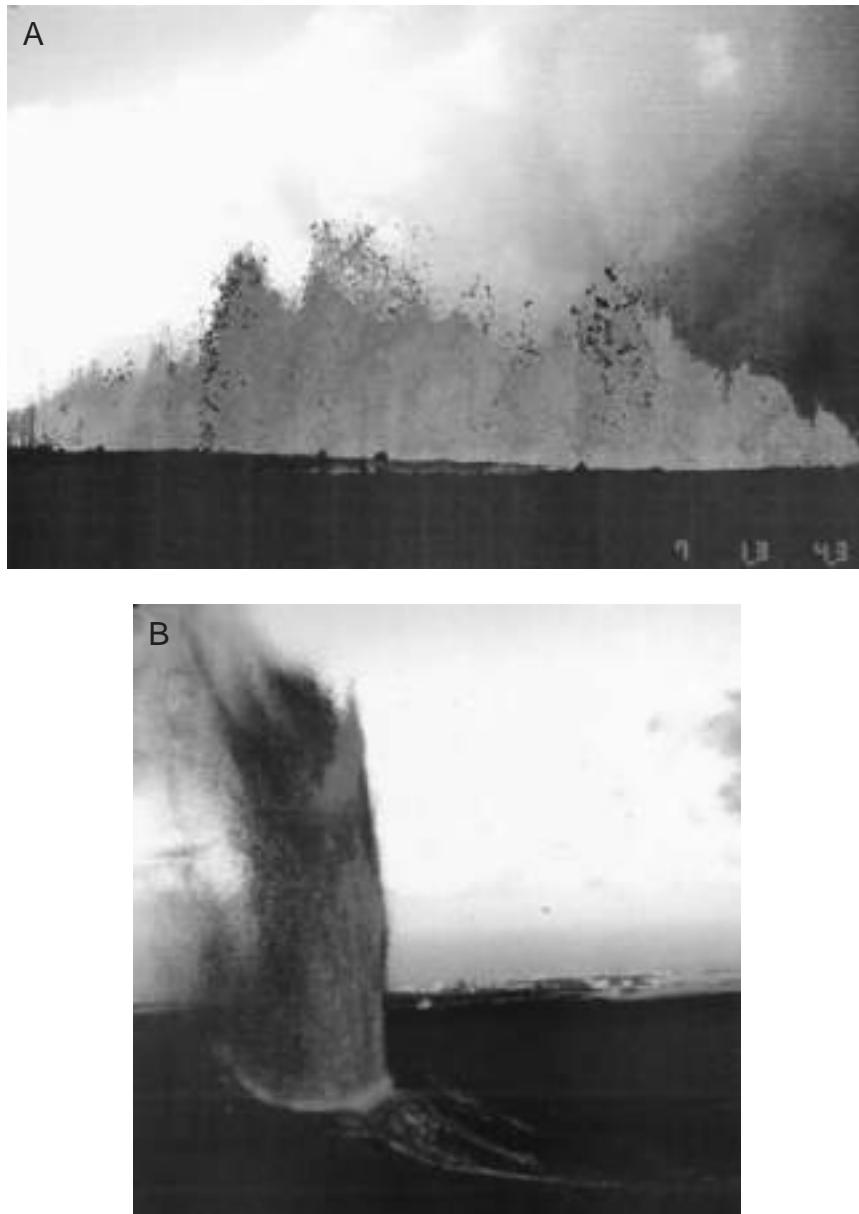

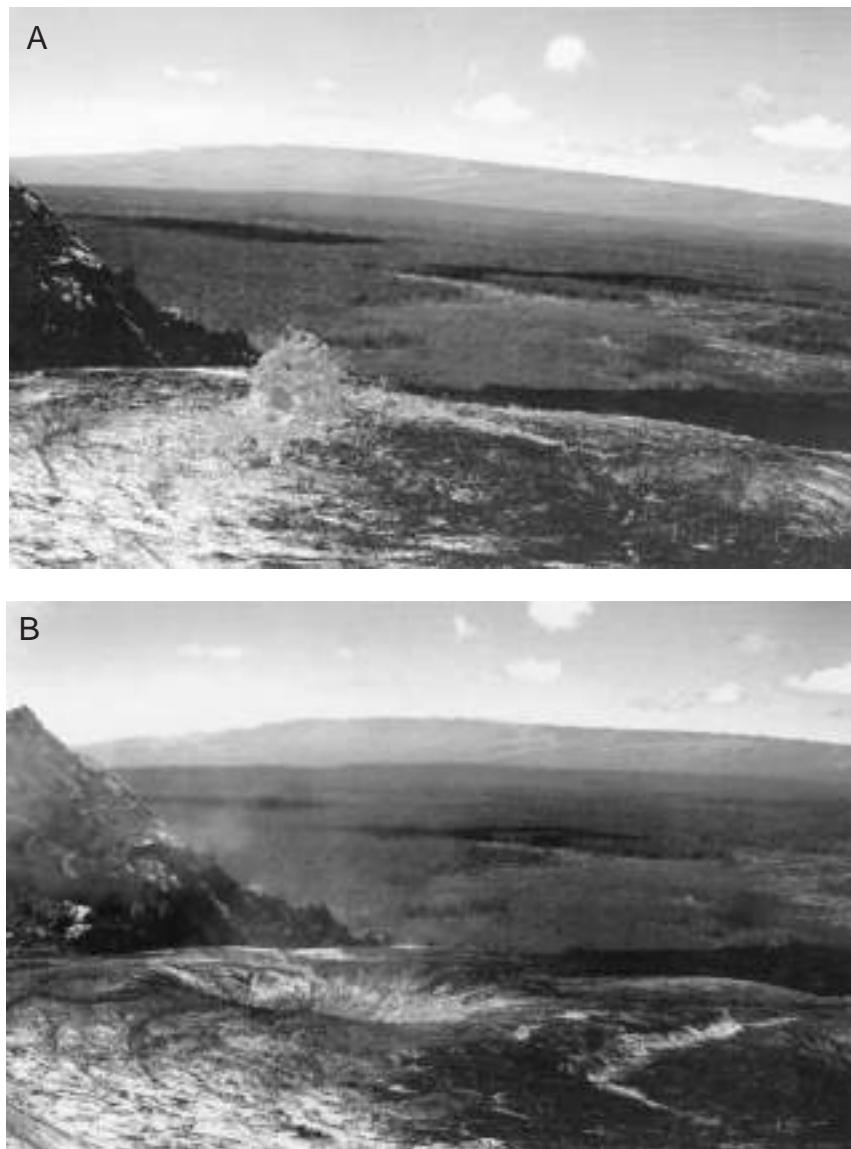

FIGURE 1 (A) A 60- to 100-m-high curtain of fire from the opening stages of the 1983 to present eruption of Kilauea volcano, Hawaii. The photograph shows a 500-m-long segment of an eruptive fissure that extended for 1 km. (Photograph by J. Griggs, U.S. Geological Survey.) (B) A 395-m-high lava fountain from the 1983–1986 fountaining episodes of Kilauea volcano, Hawaii. The photograph was taken 8 minutes before fountaining ceased. (Photograph by G. Ulrich, U.S. Geological Survey.)

cano at the Pu'u'O'o and adjacent Kupaianaha vents, which started in 1983 and continues at the time of this writing, is a prime example of the explosive to effusive transition common to basaltic eruptions. In this instance, the initial fissure opening was followed by 3 years of high lava fountains occurring on a predictable schedule of one fountaining episode every 25 days, on

average. These spectacular events gave way in 1986 to near-continuous, low-level lava effusion, which persists after nearly 13 years of activity.

Strombolian eruptions start with a hawaiian-style fissure eruption, or, alternatively, a vent-clearing vulcanian explosion of rock and ash. The magma involved is often of higher viscosity, because of both cooler eruption tem-

**FIGURE 2** (A) Bursting of a large gas bubble in repose-period gas–pistoning during the 1983–1986 fountaining episodes at Kilauea volcano, Hawaii. peratures (e.g., 1080°C is common at Mount Etna) and the involvement of slightly more siliceous magmas, typically in the basaltic andesite range. Gas release is episodic, leading to larger overpressures, more intense eruptions, and higher degrees of magma breaking (i.e., smaller ejecta sizes) relative to hawaiian-style activity. Prior to each explosion, gas accumulates in the conduit in a large bubble that rises and lifts the lid of overlying

magma to form a gas-filled blister several meters in diameter. The blister swells and eventually explodes with a resounding roar, perhaps ≈1–10 s in duration, expelling a spray of gas loaded with centimeter- to meter-sized fragments of the disrupted lid (Fig. 3; see also color insert).

Overall, the flux of gas relative to lava in strombolian eruptions is considerably larger than in hawaiian eru-

FIGURE 3 April 1992 strombolian explosion at Stromboli volcano, Aeolian Islands. (Reprinted with permission from G. Brandeis, O.M.P., France.) (See also color insert.)

tions (cf. Fig 1 and Fig 3), mainly because the lava column involved in strombolian activity is confined to the volcanic conduit. Ballistic analysis of ejecta and modeling of jet dynamics for eruptions at Stromboli, Etna, Paricutin, and Tolbachik volcanoes suggest typical gas:lava volume ratios of  $\approx 10^5 : 1$ , with lava volume between  $10^{-3}$  and  $10^2 \text{ m}^3$  per explosion (dense rock equivalent) and gas volume of  $10^3 \text{ m}^3$  per explosion. Photobalistic analysis of ejecta trajectories at Stromboli (1971) and Heimaey (1973), show that fragments exit the vent at angles of  $45^\circ$  to over  $75^\circ$  from the horizontal at speeds of  $40\text{--}100 \text{ m s}^{-1}$ , reaching heights greater than 100 m. The tracking of the smallest particles on a series of photographs suggests that gas velocities are roughly double that of most magma fragments. Recent measurements based on the Doppler effect show similar results. The high ratio of gas to lava on ejection allows heat to dissipate relatively rapidly so that most fragments solidify in the air during flight.

Strombolian explosions characteristically occur at quasi-regular intervals. Ongoing activity at Stromboli volcano, for example, averages 3–5 explosions/hour. Violent but rare episodes at Stromboli exhibit cycles of 100 to 1000 explosions/hour.

## B. Eruptive Products

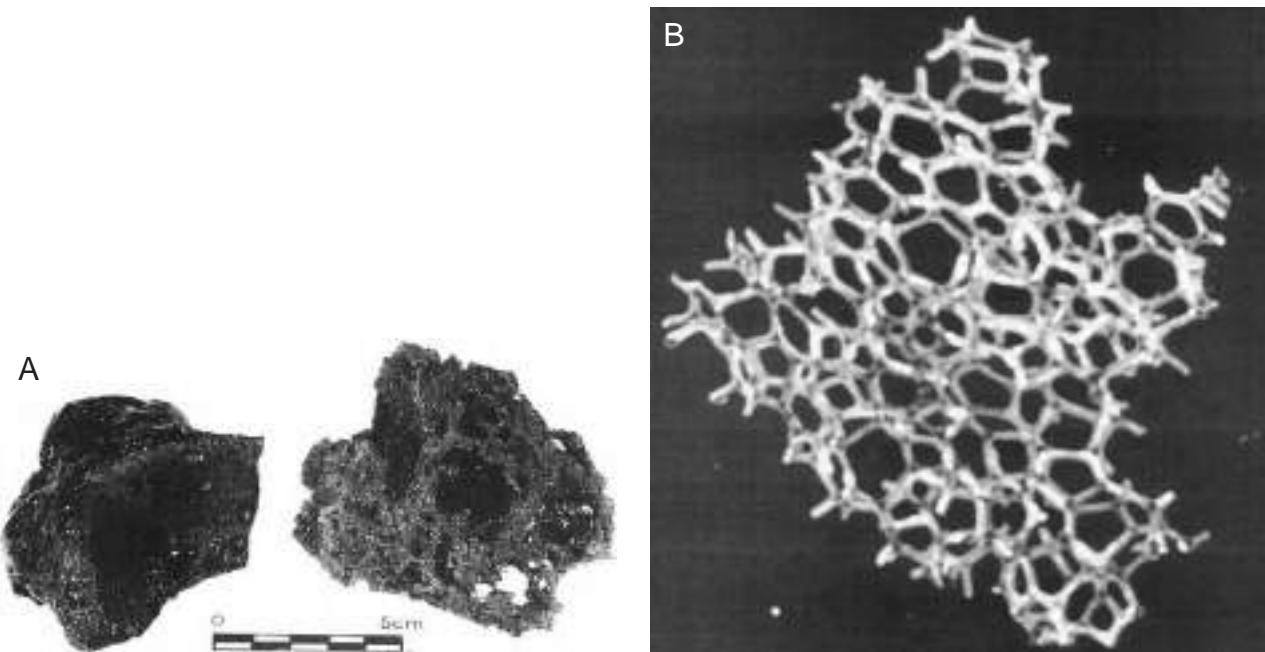

During hawaiian fire fountains and strombolian explosions, magma fragments into bubbly, molten clots. Gas

bubbles within the melt undergo decompressional expansion in the conduit and in the eruption column, causing the bubbly melt to expand as it rises (see Magmatic Fragmentation). The largest clots and those rising in the core of the fountain remain sufficiently fluid through transport and deposition to coalesce at the vent into rootless lava flows or lava ponds (Fig. 1B). Others cool rapidly as they mix with entrained air, or quench, and are deposited as discrete, glassy clasts. In many instances the deformation that the molten droplet has experienced in response to aerodynamic forces and surface tension is preserved in the clot by quenching. The timing of quenching, the magnitude and rate of decompression during magma ascent, and the temperature, composition, and viscosity of the melt control the crystallinity (volume percent crystals relative to glass) and vesicularity (volume percent gas bubbles relative to crystals plus glass) of the quenched clast. Strombolian eruptions often produce clasts that are of lower vesicularity and marginally higher crystallinity (due to cooling at the top of the magma column) relative to hawaiian eruptions.

Spatter bombs are centimeter- to decimeter-sized clots that undergo limited cooling prior to deposition (Fig. 4A; see also color insert). A thin skin of congealed lava forms on the exterior of the bomb during flight, but the clot as a whole remains sufficiently fluid to flatten upon landing and anneal, or weld, to an existing surface. Slow postdeposition cooling and degassing creates a finely crystalline interior interspersed with irregularly shaped relict gas bubbles, or vesicles.

Pele's tears are small droplets of shiny black glass molded and quenched during flight into spherical, dumbbell, or tadpole shapes (Fig. 5A). These droplets range from a few millimeters to a few centimeters in size and can be quite vesicular (up to 70%), although they are more commonly dense. Pele's hair are long, golden threads of glass that have been drawn out, or spun, from molten droplets flung from the vent (Fig. 5B; also see color insert). The strands are cylindrical, with diameters of 1–500 micrometers and can be up to 1 m in length. The thickest strands ( $>50$  micrometers) contain stretched vesicles parallel to the long axis. These clasts are readily carried by wind and can be found tens of kilometers from the vent.

Scoria are thoroughly quenched, frothy clasts centimeters in size that are sufficiently porous and brittle to break when they hit the ground (Fig. 4A). Vesicularities between 70 and 85% and crystallinities of 2–50% are commonly observed (e.g., Kilauea, Etna, Mount Lassen, Paricutin, Izu-Oshima, Stromboli). Scoria with extremely high vesicularities of 95 to 99% are produced

**FIGURE 4** (A) Scoria (right) and spatter bomb (left) from the 1983–1986 fountaining events at Kilauea volcano, Hawaii. The frothy scoria clast has a vesicularity of 85% and a bulk density of  $400 \text{ kg m}^{-3}$ , and the spatter bomb 65% and  $900 \text{ kg m}^{-3}$ , respectively. (Photograph by J. Griggs, U.S. Geological Survey.) (B) Reticulite from a 1983–1986 fountaining episode at Kilauea volcano. The 1-cm clast has a vesicularity of 98%, and a bulk density of  $50 \text{ kg m}^{-3}$ . (Photograph by M. Mangan, U.S. Geological Survey.) (See also color inserts.)

in high lava fountains and have been quenched while expanding. These fragile clasts, known as reticulite, have the appearance of a delicate, golden-brown honeycomb (Fig. 4B) in which close packing has deformed bubbles into 12- to 14-sided polygons. Relict bubble walls,  $\leq 1 \mu\text{m}$  thick, are mostly shattered, and virtually no closed space exists in the clast.

### C. Deposition Features

The low eruption column and coarseness of the ejecta produced in hawaiian and strombolian eruptions limit their dispersal potential. More than half of the ejecta falls within approximately 500 m of the vent in spatter cones or cinder cones (see Scoria Cones and Tuff Rings). These conical deposits, which may reach heights of 100 m or more, are in stark contrast to the massive sheet-like deposits produced in more explosive types of volcanism (e.g., plinian).

Spatter cones form when partially molten clots fall to the base of a lava fountain and enclose the vent in a ring of welded clasts. Very fluid clots may become trapped and coalesce within the developing ring, creat-

ing a molten pond that gradually deepens as the ring grows taller and more cone-like. A cinder cone formed in strombolian eruptions, in contrast, is composed of loose, nonwelded clasts because most of the ejecta are rigid at the time of deposition. Rates of cone building in hawaiian and strombolian eruptions may exceed  $5 \text{ m hour}^{-1}$ .

Typically, a small volume (<1–20%) of millimeter-to centimeter-sized clasts (scoria, reticulite, Pele's tears, and hair) blanket areas surrounding the vent, especially on the downwind side (Fig. 1B). The sheet-like deposit thins abruptly outward from the spatter (or cinder) cone, generally diminishing to 10% of the maximum near-vent thickness over dispersal areas of  $<10 \text{ km}^2$  (e.g., Kilauea, Hawaii; Serra Gorda, Azores; Teneguia, Canary Islands, Heimaey, Iceland; Mount Etna, Sicily). In plinian deposits a 10% diminution in thickness is likely to occur over an area of  $>1000 \text{ km}^2$ .

Of less importance in terms of ejecta dispersal and deposition is the dilute convective plume of volcanic gas, aerosols, and ash that forms above the eruption column during hawaiian and strombolian events. These plumes contain <0.17% of the total mass fraction of lava erupted and rarely penetrate the tropopause.

## II. DYNAMIC PROCESSES

### A. Degassing

Basaltic volcanoes display varied and complex behavior due to the existence of a separate and evolving gas phase. Gas emission measurements at Kilauea, Etna, Strom-

boli, and Pacaya have shown that hawaiian and strombolian eruptions involve the evolution and release of  $\approx 10^5$  metric tons/day of H<sub>2</sub>O-, CO<sub>2</sub>-, and S-rich gas during peak activity. Further, evidence for the importance of the gas phase in eruption processes comes from the fragmentation of magma into discrete, highly vesiculated ejecta, the existence of a volcanic plume above the eruption column, and the deep draw-down of magma

at the end of the eruption. Furthermore, Pele's hair, deposited during fire fountaining, is very likely formed by the drag exerted on the magma droplets by a strong gas jet by analogy with methods used in producing glass fibers.

In a broad sense, degassing is a two-stage process. Basaltic magma begins to exsolve CO<sub>2</sub>-rich gas when it ascends to within a few tens of kilometers of the surface (e.g., 30 km at Kilauea). The second stage is initiated once the magma is within a few hundred meters of the vent (e.g., 150 m at Kilauea) at which time H<sub>2</sub>O and S begin to exsolve in significant amounts.

During both stages, volatile exsolution during ascent leads to the nucleation of bubbles and their growth both by chemical diffusion and decompressional expansion. Bubble growth is initially dominated by diffusion, with decompressional growth becoming increasingly important as the magma approaches the vent. There may be differential movement of melt and gas resulting from the size-dependent buoyancy of individual bubbles relative to the rise velocity of the magma. In general, the larger CO<sub>2</sub>-rich bubbles generated at depth are likely to be sufficiently buoyant to rise up through the ascending magma whereas the smaller H<sub>2</sub>O-rich bubbles generated near the surface are quasi-stationary in relation to the melt.

## B. Two-Phase Flow

A useful way of examining the behavior of a melt-bubble mixture is provided by the separated two-phase flow models developed in chemical engineering applications. In this context, specific regimes are classified on the basis of gas volume fraction, which determines the geometry and partitioning of gas "elements" in the melt rising in the conduit. For a gas content of less than 30%, the melt contains small, discrete bubbles in suspension and is classified as bubbly flow (Fig. 6). Effusive eruptions are the consequence of bubbly flow in the conduit.

At gas contents of about 70%, small bubbles may coalesce, either in the magma reservoir or in the transport system, to produce large gas pockets that fill the entire width of the volcanic conduit (Fig. 6). These gas pockets are separated by smaller regions of bubbly magma and this regime is called slug flow. Strombolian explosions and the gas-piston events observed between some eruptive episodes are the surface expression of slug flow. Both phenomena are due to the bursting of a large slug of gas at the top of the magma column.

Slug flow makes a transition to annular flow at gas volume fractions above 70%. In this regime, gas forms

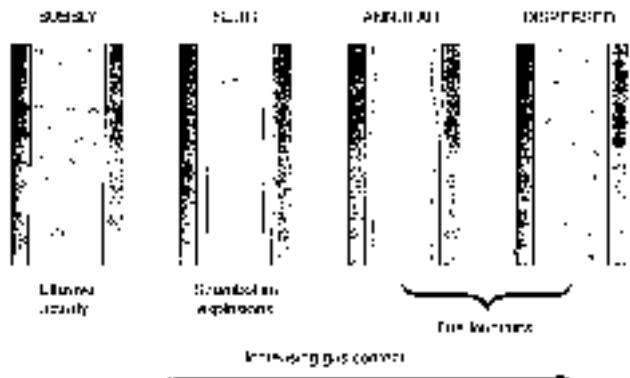

FIGURE 6 Classification of two-phase flow regimes and their volcanic counterparts. Gas fraction increases from the left to the right.

a central jet surrounded by an annular sheet of magma along the conduit walls (Fig. 6). Two types of annular flow exist: at gas volume fractions close to 70%, the melt falls downward under its own weight while the gas phase moves upward in the conduit. At somewhat higher gas fractions, the annulus of melt is driven upward along the conduit walls by the gas jet. If the gas volume fraction is substantially larger than 70%, the regime becomes a dispersed flow in which the magma around the central gas core is fragmented into upward-moving droplets (Fig. 6).

Lava fountains can be described as the surface expression of an annular to dispersed flow regime in the conduit. Although it is often difficult to deduce conditions in the conduit from observations made at the surface, an observation made during the 1959 summit eruption of Kilauea supports the annular flow model. In the most energetic fountaining episode of the eruption (episode 15; maximum height: 570 m), lava was seen draining back into the vent during the final minute of high fountaining (height drop: from 180 m to below the vent). The simultaneous motion of liquid upward in the fountain and downward in the conduit is suggestive of a transition between the two types of annular flow described above.

However, some numerical models suggest that a fire fountain corresponds to a dispersed flow. There are only two primary mechanisms by which a dispersed flow can be produced in the conduit: in the first process, the gas volume fraction is slowly increased from bubbly to slug and annular flows (Fig. 6), whereas in the second one the coalescence of a foam trapped in the shallowest part of the magma conduit causes fragmentation, a mechanism very similar to that involved in the formation of plinian eruption columns. However, the coalescence of

a shallow foam produces fragments of magma which are initially disconnected and distributed homogeneously across the jet. Unless an extra, yet unknown, mechanism concentrates the fragments close to the walls into a continuous layer of liquid, characteristic of an annular flow, fire fountains such as that during episode 15 during the Kilauea Iki eruption (involving annular flow, see above) are more likely to be formed either by increasing progressively the gas volume fraction (Fig. 6) in the conduit or directly at the roof of the magma chamber. However, the first mechanism, very standard in chemical engineering, is not favored because measurements of lava vesicularity during effusive activity suggest that there is no significant coalescence of bubbles during rise in the conduit.

### C. Magma Reservoirs and Conduits

Volcano-tectonic earthquakes and ground deformation patterns crudely define the magmatic plumbing systems underlying basaltic volcanoes. The general view that emerges is that of a large reservoir at a few kilometers depth that is connected to the surface by a narrow conduit a few tens of meters wide (Fig. 7). At Kilauea, for example, earthquake locations define an aseismic, melt-rich zone 2–6 km below the summit caldera that is approximately 2 km in diameter.

Most basaltic volcanoes display cycles of inflation and deflation that correlate with eruptive events. Before an eruption, the ground surface gradually inflates due to an increase in reservoir pressure by injection of magma from below and/or degassing. As the eruption commences, the volcano deflates abruptly and continues to deflate, often at somewhat lower rates, as the eruption proceeds. The deformation pattern at Kilauea volcano, which has been extensively monitored for the past 30 years, offers a classic example of these patterns (Fig. 8). The center of deformation at Kilauea shifts within the summit region over time, suggesting that the reservoir may actually consist of several, smaller, interconnected chambers. Deformation and seismicity also show steeply dipping tabular bodies of magma along the volcano's two rift zones radiating outward to the southwest and to the east of the summit. A rift zone reservoir is located  $\approx 2.5$  km beneath the currently active Pu'u'O'o vent, for example, which is continuously fed magma from Kilauea's summit reservoir more than 15 km away. At the time of its emplacement it was estimated to be 2.5 km high, 11.0–15.0 km long, and 3.5 km wide. Similar deformation patterns have been observed on some strombolian volcanoes.

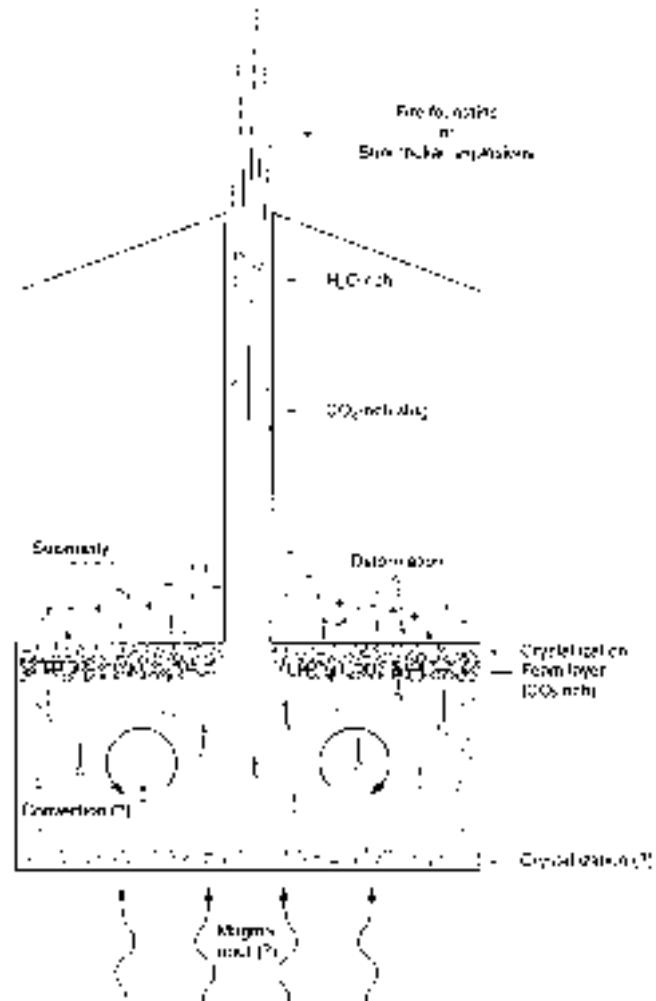

FIGURE 7 Sketch of a basalt volcano and phenomena related to magma storage and eruption.

The large difference between the cross-sectional area of the roof of the magma reservoir, which at Kilauea is  $\approx 30 \text{ km}^2$ , and that of the connecting conduit, which is likely to be  $\leq 0.001 \text{ km}^2$ , imposes a strong constraint on the velocity of magma ascent. Because mass flux must be conserved between the magma chamber and the vent, the drastic reduction in cross-sectional area requires a very large increase in velocity. For example, a small upward velocity of  $10^{-5} \text{ m s}^{-1}$  in the magma chamber produces a velocity of  $1 \text{ m s}^{-1}$  at the vent. In addition, the large difference in density between a slightly bubbly liquid and a gassy lava fountain can lead to a 100-fold increase in the velocity between the bottom and the top of the volcanic conduit.

Eruptions may be triggered by crystallization and ve-

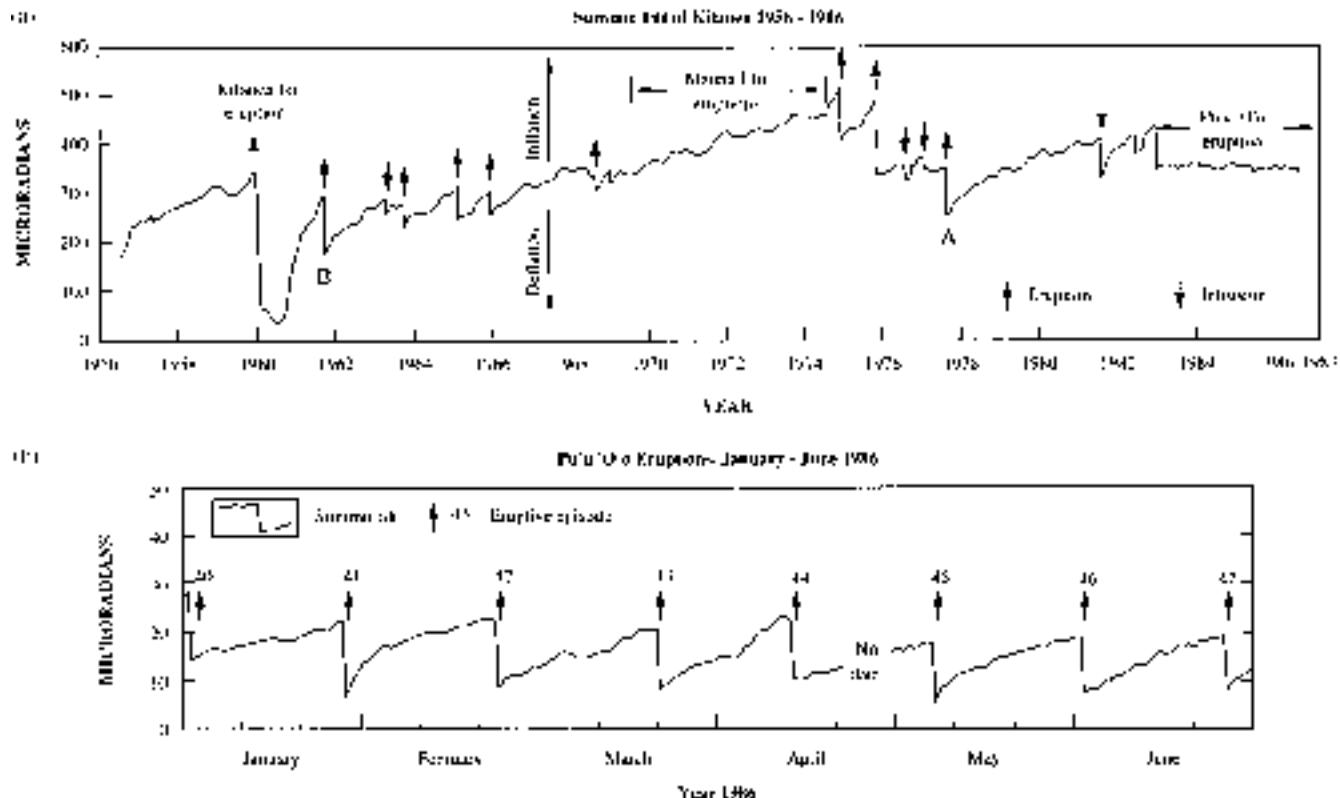

FIGURE 8. Summit tilt deformation (East-West component) at Kilauea volcano, Hawaii (from Tilling et al., 1987; see text): (a) for the past 30 years; (b) during fire fountains.

siculation in the magma chamber. Cooling of reservoirs leads to the formation of crystals, thus enriching the remaining melt in volatiles. When the solubility limit is reached, gas exsolution occurs and the magma chamber increases in both volume and pressure as vesiculation proceeds. Ultimately, the internal pressure may exceed the strength of the surrounding rocks to trigger an eruption. Alternatively, replenishment from a deep magma source may be the triggering mechanism. The input of an additional volume of a bubbly magma combined with the volume increase due to decompressional expansion of tiny bubbles that enter and rise toward the roof of the chamber, may sufficiently pressurize the system to trigger an eruption. The presence of gas bubbles in basaltic magma chambers also has consequences for the development and duration of an eruption as shown at Kilauea Iki (Hawaii), where bubble diameters in the reservoir are  $\approx 0.4$  mm.

#### D. Sources of Vibration

Other constraints on the dynamics of transport emerge from the analysis of volcanic tremor, which is a continu-

ous vibration of the ground around active volcanoes. Volcanic tremor is usually characterized by a sharply peaked spectrum with one dominant and several sub-dominant peaks (Figs. 9, 10a, and 10b). The tremor recorded during lava fountain episodes at Kilauea has several peaks between 3 and 10 Hz (Fig. 9) and is produced at a depth of  $< 1$  km. Tremor recorded during the repose periods, as well as during gas-piston events, shows only two dominant peaks between 2 and 4 Hz. Resonators of various geometries have been called upon to explain volcanic tremor, from the vibration of a crack filled by liquid, to the vibration of a spherical magma chamber. The role of gas as a trigger was suggested at Kilauea because of the similarity between tremor and the seismicity induced by gas-piston events. Gas-pistoning generates a unique signature consisting of a spindle-shape amplitude envelope persisting for a duration of 80 s. Visual observations confirm that each "spindle" correlates with the bursting of large gas bubbles at the top of the magma column.

At Stromboli, the main peak in the tremor is approximately 2 Hz with a secondary peak slightly above 4 Hz. The depth at which the tremor is produced is, for the most part, less than 200 m and results from continuous

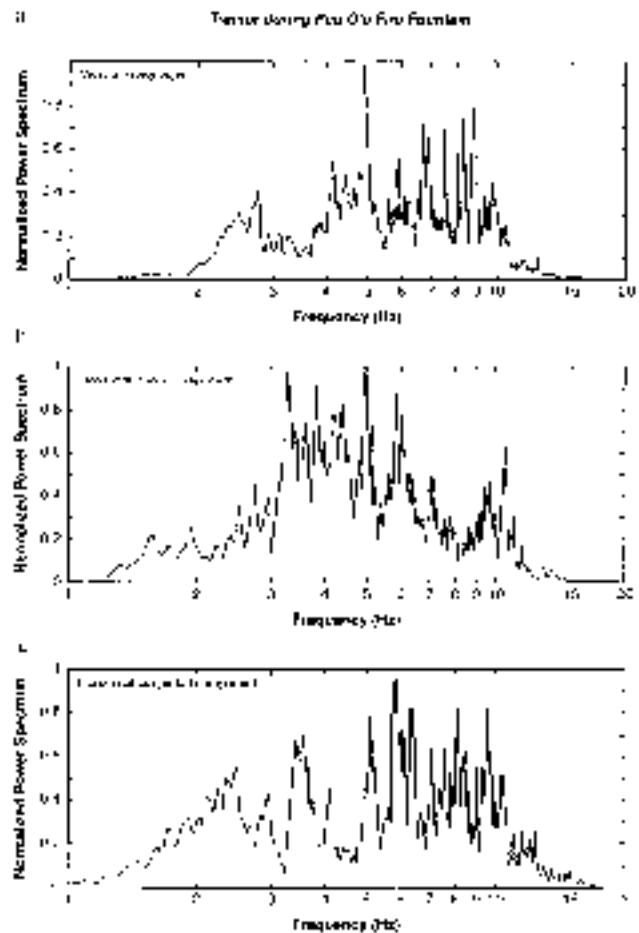

FIGURE 9 Tremor recorded during the Pu'u 'O'o fire fountain, Hawaii (from Koyanagi et al., 1987; see text): (a) vertical component; (b) horizontal radial component; (c) horizontal tangential component.

bursting of small gas bubbles. However, its frequency of  $\approx 2$  Hz can also be interpreted as oscillations of a bubble cloud 50 m in length, with 1% gas volume fraction. Both are reasonable values for the height of the shallow magma column and the gas content at Stromboli. With the development of broad band seismometers, more is to be learned in the future from tremor at periods less than 1 s because it offers constraints on pressure fluctuations resulting from unsteady magma transport.

The pressure waves induced by explosions have been measured at Stromboli volcano and provide additional constraints on conduit transport (acoustic measurements). Although the audible sound radiated by an explosion is very striking, most of the acoustic energy is infrasonic, i.e., below 20 Hz (Fig. 10c). The power spectrum of acoustic pressure before an explosion is very

similar to the seismic recording (Fig. 10b and 10c) with a powerful peak at  $\approx 2$  Hz. However, during explosions the acoustic frequency shifts toward a higher frequency of  $\approx 10$  Hz. The strong acoustic pressure recorded during explosions (Fig. 11) has been associated with the breaking of a gas bubble with a radius of a few meters that is still overpressurized (by  $0.3 \times 10^5$  Pa) at the top of the magma column. Because the vibration of the bubble in air does not have direct interactions with the solid walls of the conduit (part 2; Fig. 11) no seismic waves at  $\approx 10$  Hz are produced in the volcanic edifice (Fig. 10b). Sound waves, albeit of very low intensity, can also be generated by oscillations of the magma column induced by a rising bubble (Fig. 11, part 1), or by oscillations of the bubble bottom after the gas pocket breaks

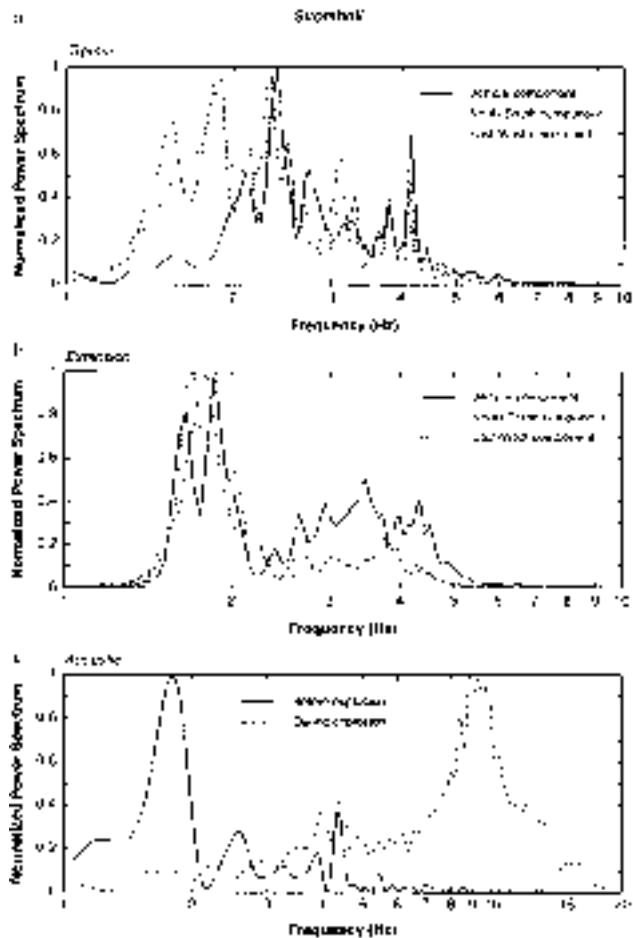

FIGURE 10 Stromboli. (a) Seismicity during tremor (reprinted with permission from Chouet et al., 1997); (b) seismicity during an explosion (reprinted used with permission from Chouet et al., 1997); and (c) acoustic pressure before and during an explosion (reprinted with permission from Vergniolle et al., 1996). Note the similarity in power spectra.

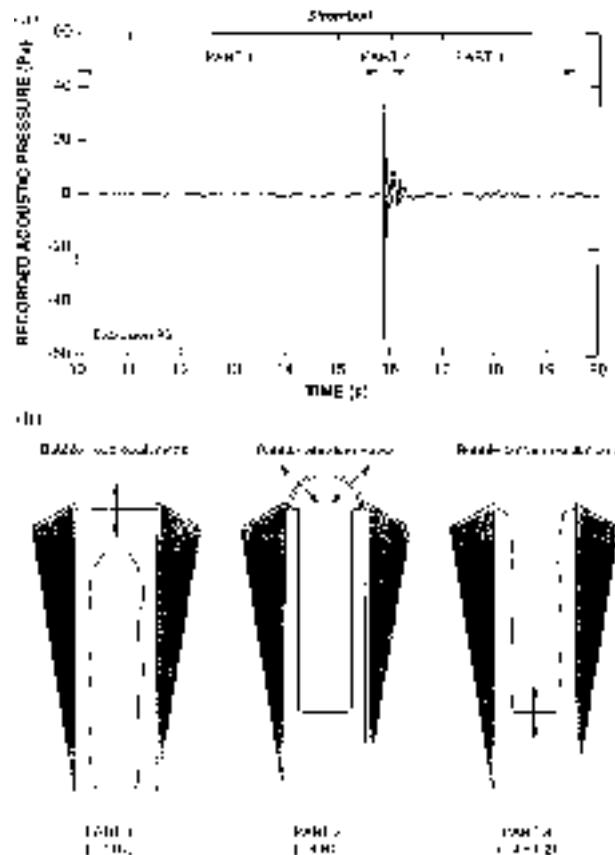

FIGURE 11 (a) Measurements of acoustic pressure at Stromboli. (b) Sketch of the three stages of bubble rise corresponding to the three parts in acoustic pressure. (Reprinted with permission from Vergniolle et al., 1996).

(Fig. 11 part 3). By combining these oscillations, the magma viscosity is estimated at  $\approx 300$  Pa s. In very quiet conditions, bubble rise can be followed on acoustic records (the  $\approx 2$ -Hz mode) in the uppermost 30 m of the magma column. An alternate explanation for the sound waves at Stromboli is that the acoustic sources of the explosions lie at depth and the resonant modes of a magma column can be calculated from them.

### III. ERUPTION MODELS

The evolution and release of a separate gas phase induces complex, time-dependent behavior, and two general approaches have been taken to examine and explain these complexities. Both models recognize that variations in eruptive behavior are the consequence of the volume of

gas present and how this volume is partitioned in the melt: small gas volumes lead to effusive eruptions and lava flows (bubbly flow), whereas large gas volumes cause either strombolian explosions as large gas pockets reach the surface (slug flow) or continuous gas jetting as in hawaiian lava fountains (annular or dispersed flow). The models differ in how and where gas separates from the melt.

The first of the two models uses numerical methods to investigate the rise and expansion of an initially bubbly mixture in the conduit. The decompression of a bubbly magma during rise leads to nucleation and growth of new gas bubbles as well as continued growth of the original bubbles. The model suggests that it is the extent of bubble coalescence (mechanism by which numerous small bubbles are transformed into a smaller number of larger bubbles) that occurs in the conduit during magma ascent that distinguishes hawaiian from strombolian eruptions. Coalescence, in turn, is controlled by the ascent rate of the magma. Slow magma rise may facilitate coalescence because transit times are long and bubbles have ample opportunity to overtake, collide, and coalesce with one another. An initially homogeneous population of small gas bubbles rising in the conduit could thus form large gas slugs that rise through the melt column and burst at the surface in classic strombolian style.

Higher magma rise rates may limit coalescence because the distance bubbles travel relative to the melt is small and the transit time is short, making bubble collisions less likely. The mixture remains essentially homogeneous until the volume fraction of exsolved gas reaches a critical point where bubbles become so closely packed that they deform and burst ( $\approx 75\%$  by volume), causing the magma to fragment. Subsequent rise of the disrupted mixture of gas and clots (dispersed flow) leads to considerable expansion in the conduit, resulting in the formation of lava fountains. The flow conditions in the fountain, such as the emitted mass flux and the exit velocity and pressure, are strongly dependent on the geometry of the conduit and vent. The episodic fountaining pattern exhibited by many hawaiian eruptions is modeled by nonuniform magma cooling that creates a temporary “plug” at narrow sections of the plumbing system of sufficient yield strength to stop the flow of magma between two successive fire fountains.

In the 1990s, two-phase flow concepts and laboratory experiments have been combined and they offer an alternative view. In this model variations in eruptive style are the consequences of the differential motion of bubbles compared to magma inside a large magma reservoir (Fig. 7). A laboratory volcano has been built with a large reservoir filled with viscous oils topped by a narrow conduit. During the experiment, small gas bubbles

formed at the bottom of the chamber rise and accumulate in a foam layer at the roof of the chamber (Figs. 12 and 13). Bubbles in the foam deform as the layer builds and eventually collapse on masse. Sudden coalescence of bubbles in the layer creates a large gas pocket that rises in the conduit and bursts at the surface. Foam accumulation then resumes and a new cycle begins.

This pattern of foam buildup and coalescence is very regular for a given melt viscosity, which dictates the volume of gas in the gas pocket and the timing between the creation and ascent of successive gas pockets. Hawaiian-style lava fountains were qualitatively reproduced using a liquid of relatively low viscosity ( $0.1 \text{ Pa s}$ ). These experiments generated a foam layer that gave rise to a large, single gas pocket upon collapse. The ensuing “eruption” is that of a central gas vent surrounded by a film of liquid along the walls of the conduit (annular

flow; Fig. 12). Minor and frequent coalescence events occurred at the top of the reservoir between successive total collapses, the former being reminiscent of the gas-piston activity often observed between fountaining episodes in hawaiian eruptions. Strombolian activity is reproduced by experiments using more viscous oils ( $1 \text{ Pa s}$ ). Here, collapse involves only parts of the foam and a number of intermediate size gas pockets are produced. The pockets rise and burst intermittently at the top of the conduit (slug flow; Fig. 13). This regime corresponds to a quasi-stagnant liquid column (Fig. 13), analogous to most strombolian eruptions in contrast to the previous regime (Fig. 12) in which huge variations in liquid levels exist, similar to the difference in height between a fire fountain and effusive activity.

In all experiments a critical gas flux to the roof is required for the foam to thicken and ultimately collapse.

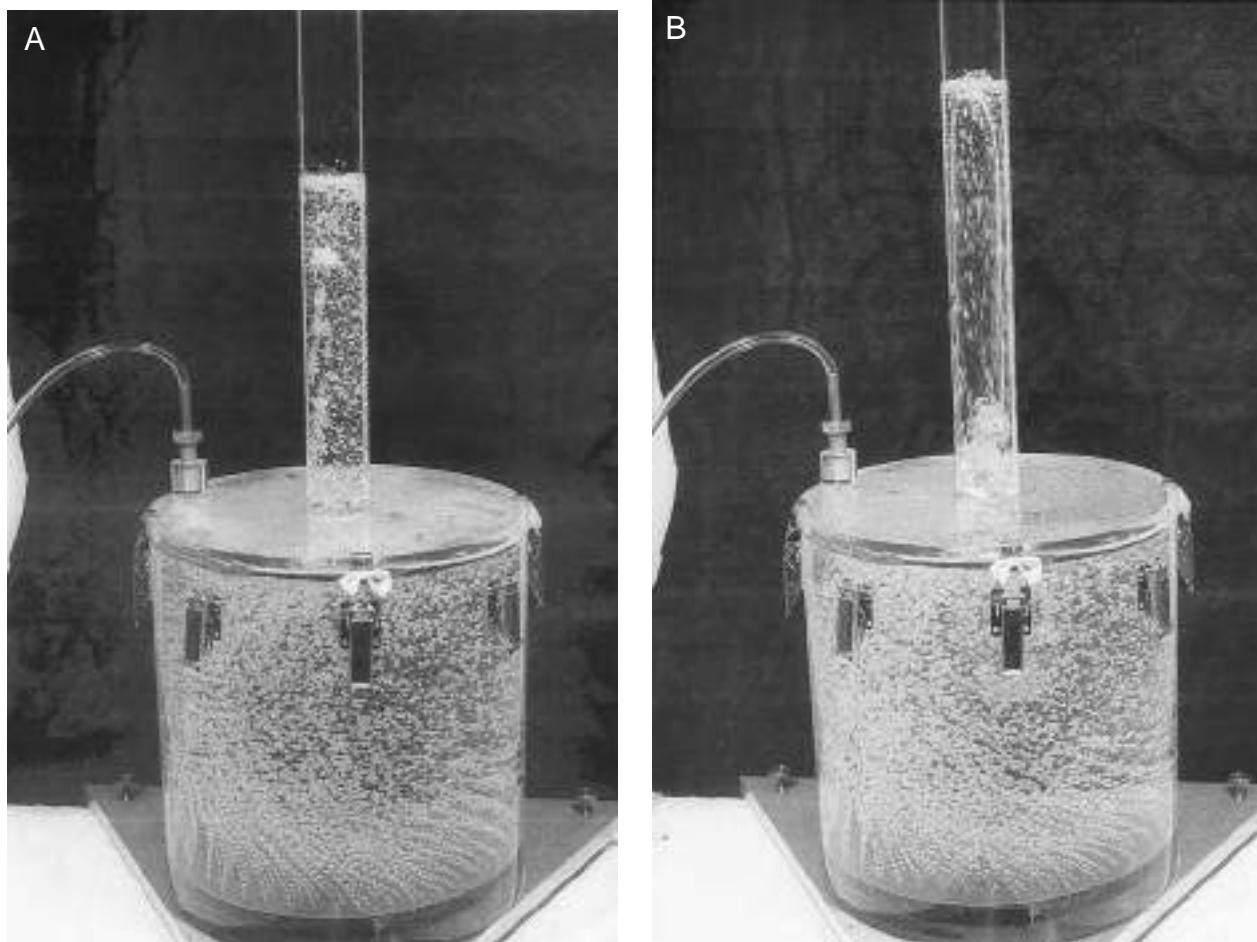

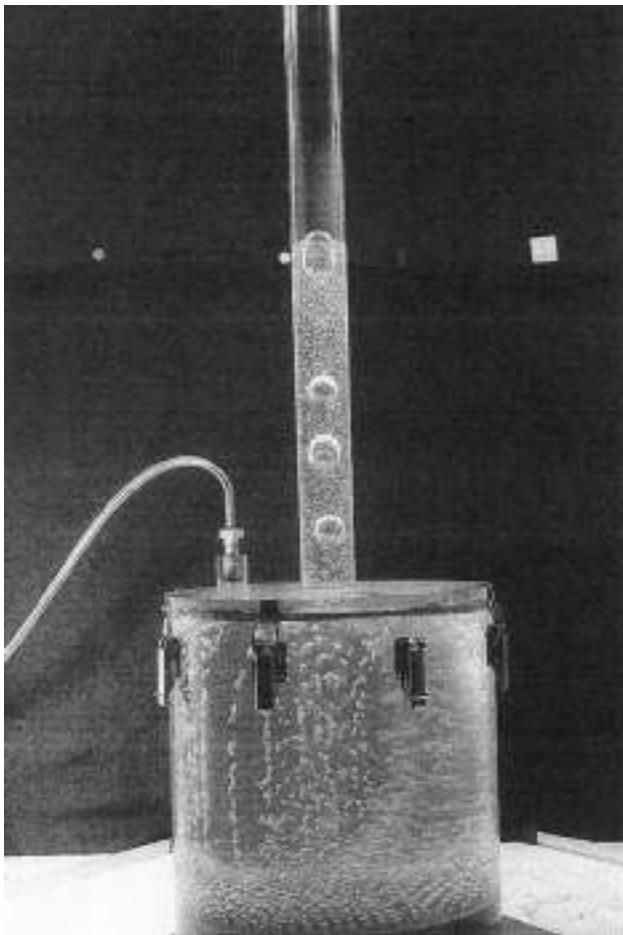

FIGURE 12 Laboratory volcano model using the low viscosity oil ( $0.1 \text{ Pa s}$ ), analogous to a hawaiian eruption. (Reprinted with permission from Vergniolle and Jaupart, 1990.) (A) Buildup of the foam at the top of the reservoir. Regime analogous to effusive activity. (B) Foam collapse and gas pocket rise in the conduit. Regime is analogous to fire fountain.

**FIGURE 13** Laboratory volcano with a more viscous viscosity oil ( $1 \text{ Pa s}$ ), analogous to a strombolian eruption. (Reprinted with permission from Vergniolle and Jaupart, 1990.)

The threshold is dependent on the size and proportion of rising bubbles and the viscosity and surface tension of the melt. At less than critical gas fluxes there is a steady stream of foam rising in the conduit (bubbly flow), and the “eruption” is effusive. The transition between cyclic fountaining episodes to quiescent effusion that is often observed in hawaiian eruptions may thus be a reflection of a waning gas flux to the reservoir roof.

#### IV. CONCLUSION

Although more quantitative field measurements of variables such as pressure, velocity, and gas content will be

useful for constraining models more tightly, a general pattern for basaltic eruptions is starting to emerge, showing, in particular, the importance of the role of the gas phase. Bubbles trigger eruptions and explain many of the features of hawaiian and strombolian eruptions. Lava flows are the consequence of the effusion at the vent of a bubbly flow in the conduit, whereas the most dramatic events in basaltic eruptions are related to very large gas pockets breaking at the vent and ejecting fragments of magma. Furthermore, there are rare situations in which basalts can erupt explosively in plinian basaltic eruptions, typical of a dispersed flow (Fig. 6). The continuum existing between hawaiian and strombolian activity is a direct consequence of the patterns of two-phase flow and the entire spectrum of flow regimes exist in basaltic eruptions.

## GLOSSARY

**andesite** The second most abundant volcanic rock type, containing mainly phenocrysts of zoned plagioclase, pyroxene, or hornblende and a glassy or fine-grained groundmass.

**blocks/bombs** Blocks and bombs are fragments of solid rock and semimolten lava, respectively, with diameters >64 mm.

**explosive earthquakes** Isolated, large amplitude earthquakes lasting 10–20 s with peak frequencies between 1 and 5 Hz.

**juvenile clasts** Fragments of solidified magma involved with the eruption.

**lava dome** Solidified lava, roughly circular in plan view with small surface area that occupies the vent.

**shock waves** A pressure wave that travels at a velocity greater than the sound speed of the medium through which it propagates.

**V**ULCANIAN ERUPTIONS are small to moderate-sized volcanic outbursts that eject material to heights <20 km and last on the order of seconds to minutes. These eruptions are characterized by discrete, violent explosions, by ballistic ejection of blocks and bombs, by atmospheric shock waves, by emission of tephra and by deposits that range widely in the percentage of juvenile versus nonjuvenile components. The juvenile components are composed of fragmented intermediate magma that ranges in composition from andesitic basalt to dacite. Eruptions described as vulcanian generally occur in the summit craters of stratovolcanoes, in some cases through summit crater lakes or lava domes. They have taken place as precursors to subplinian or plinian eruptions, during the waning stages of such eruptions, or with no accompanying larger magmatic eruptions. Moreover, a vulcanian eruption may be a single discrete event or occur as a pulsatory series of explosive events.

---

## I. INTRODUCTION

In 1907, Mercalli coined the term vulcanian to describe eruptions of the sort that took place on the island of Vulcano (Aeolian Islands) between August 3, 1888, and May 17, 1890. Lacroix later incorporated the term into

a classification scheme that ranked eruption types qualitatively in order of increasing explosivity: hawaiian, strombolian, vulcanian, and peléan. Modern textbooks cite not only the eruptions of Vulcano, but more recent ones at Ngauruhoe, New Zealand (1975), Irazu, Costa Rica (1963–1966), and Sakurajima, Japan (since 1955), among others, as examples of the vulcanian eruptive style.

Discrete, violent explosions lasting seconds to minutes in duration are perhaps the most distinctive characteristic of vulcanian activity. During the 1888–1890 eruptions at Vulcano, shock waves from some explosions broke windows in the town of Lipari, 7 km from the vent. Eruptions bearing vulcanian characteristics have produced higher ejection velocities (200–400 m/s) and ejected blocks and bombs to greater distances (<5 km from the vent) than any other eruption type. Blocks ejected in vulcanian eruptions have killed visitors at summit craters several times during recent decades. Vulcanian eruptions through summit crater lakes have also generated lahars that have killed many thousands of people during historical time.

The explosive nature of vulcanian events has been attributed to several mechanisms. One is the brittle failure of a strong, impermeable cap rock beneath which magmatic gas has accumulated. Another mechanism involves interaction of rising magma with external water such as eruptions through crater lakes. The involvement of external water was proposed, in part, based on the similarity between eruptive deposits at Vulcano and at phreatomagmatic maars.

## II. FIELD EXAMPLES

### A. Vulcano, Aeolian Islands

The island of Vulcano, home of the Roman god Vulcan, has erupted numerous times since the dawn of recorded history. The eruptions of 1888–1890 at Vulcano were among the best-documented eruptions anywhere in the world during the 19th century. They took place at a time when volcanologists were recording and classifying different kinds of eruptions. A commission appointed by the Italian government and led by Prof. O. Silvestri documented the events.

The first explosions at Vulcano, on August 3–5, 1888, expelled purely nonjuvenile ejecta from the upper edifice of the central cone (Fossa Cone). Juvenile phases of the eruption began on August 18, 1888, and continued until

March 22, with especially violent events on December 26, 1889, and March 15, 1890. The eruptions were characterized by discrete explosions with repose intervals that varied from minutes to hours or greater. The largest explosions followed the longest repose intervals. They expelled juvenile blocks that were solid enough to resist deformation upon landing, though many vesiculated into breadcrust structures (the term *breadcrust structure* was coined by Johnston-Lavis in 1888 in describing ejecta from this eruption). In 1907, Mercalli described black clouds (“finger jets” in today’s terminology) shooting up from the crater at hundreds of meters per second, spiked by lightning and containing, at the head of the cloud, arrow-like projections whose apices contained large ballistic fragments. Tephra plumes emanating from smaller explosions lacked large ballistic fragments and assumed cauliflower or mushroom shapes.

In 1891, Mercalli and others noted that “just as we have the “*plinian*” or “*vesuvian*” eruptions of Vesuvius accompanied by violent outbursts of “ashes” and welling out of lava, and the incessant milder “*strombolian*” type of eruption, so we may distinguish a “*vulcanian*” type. These distinctions in eruptive style became the basis for the eruption classifications proposed by Mercalli in 1907 and modified by Lacroix in 1908.

Contemporary reports surmised that explosions at Vulcano were caused by accumulation of gas below a plug of solidified magma. In 1977, Schmincke noted similarities in eruptive and deposit characteristics at Vulcano with those at Surtsey (a volcano that erupted through seawater near Iceland) in 1963–1967. He therefore suggested that the 1888–1890 eruption of Vulcano involved mixing of groundwater with magma. Frazetta and others reached similar conclusions for pre-1888 deposits at Vulcano. Barberi and others, however, argued that evidence for external water interaction in the deposits of 1888–1890 is less clear than that in pre-1888 deposits. The earlier eruptive sequences generally contain wet surge deposits, which are lacking in the 1888–1890 deposits. The 1888–1890 deposits, on the other hand, contain abundant breadcrust bombs and pumice fall, which are not generally present in older layers. To date, no consensus has been reached regarding the involvement of external water in the 1888–1890 eruptions.

### B. Ngauruhoe, New Zealand

The 1975 eruption of Ngauruhoe volcano, located on the North Island of New Zealand, was one of the first

well-documented vulcanian eruptions. The 11-month-long eruption commenced on February 12 with a series of intermittent ash eruptions from the summit crater. After a 1.5-hour gas-steaming subplinian event on February 19, nine cannon-like explosions occurred from the summit crater. The subplinian phase was accompanied by a volcano-tectonic earthquake that was followed by 2-hours of volcanic tremor. Seismic activity declined once the series of explosive events commenced.

Each cannon-like explosion generated a visible atmospheric shock wave which preceded the ejection of the pyroclastic slug. Figures 1a–1c show a time series of photographs of one of the cannon-like explosions. Each of these photographs was taken by a different observer attempting to photograph the shock front. None were quick enough to capture the shock front, but its passage is manifested by the appearance of a short-lived white condensation cloud (recorded in Fig. 1b). The condensation cloud forms immediately behind the shock front in the trailing rarefaction wave. The eruption cloud developed from a dense mixture of ash, high-pressure

gases, and massive blocks of andesite from the magma column cap and conduit walls. These blocks were transported as projectiles and then fell back to the ground as the ash and gas continued to rise to 4–5 km (Fig. 1d). The center of the eruption cloud was observed to collapse, forming a pyroclastic avalanche.

The pyroclastic avalanches followed channels down the flanks of the volcano and formed deposits with lobate fronts and 0.5- to 0.8-m-high levees. The deposits are up to 10 m thick,  $1-1.5 \times 10^6 \text{ m}^3$  in total volume and are composed of large, rounded blocks in a matrix of pulverized scoria and lithic fragments. Ballistic blocks ~0.8 m in diameter of massive andesite and scoriaceous breadcrust bombs were also found in ash fall deposits up to 2.8 km from the crater. The largest ballistically ejected block was 27 m long, 15 m wide, and weighed roughly 3000 tons. The fall deposits are up to 1 mm thick at 21 km from the crater and are well sorted. Near (<2 km from) the eruptive vent, the deposit is 3–4 cm thick and has a bimodal grain-size distribution. Scoria 20–30 mm in diameter are present within the fine

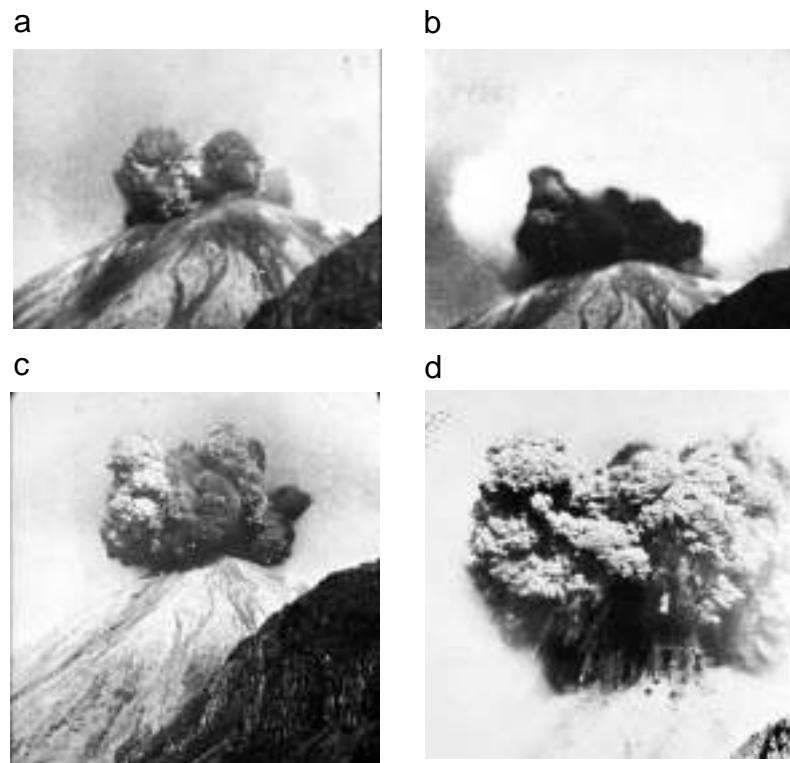

FIGURE 1 Snapshots of a vulcanian eruption at Ngauruhoe in 1975 taken approximately (a) 0.5 s, (b) 1 s and (c) 2 s after initiation. Notice the white halo (condensation cloud) above the ash cloud in (b) that forms after the passage of a shock wave. (d) Eruptive event displaying the characteristic ballistic blocks and ash cloud of vulcanian eruption occurring 11 s after (a).

ash layer (1–3 mm median grain diameter). The total volume of the fall deposits is roughly  $2.4 \times 10^6 \text{ m}^3$ . Ngauruhoe produced similar eruptions in 1954 and 1974 that were not as well documented as the 1975 eruption.

### C. Sakurajima, Japan

Sakurajima volcano is one of the most active volcanoes in the world. Its recent eruption phase, which began in 1955, is characterized by an annual eruption rate of up to 400 explosive events per year. This andesitic stratovolcano is situated on the southern rim of Aira caldera which is located in the northern part of Kagoshima Bay on Kyushu, Japan. All recent eruptions have been concentrated at the summit crater (Minamidake crater), with earlier activity occurring predominantly along the flanks. Typical summit eruption clouds reach heights above the crater between 0.8 and  $>4 \text{ km}$  and eject blocks 40–180 cm in diameter to distances of 0.8 to 3.3 km from the crater.

Due to the proximity ( $<5 \text{ km}$ ) of the volcano to the city of Kagoshima, activity at Minamidake crater has been monitored with geodetic, seismic, and video equipment since 1964 by the Sakurajima Volcanological Observatory of Kyoto University. Summit eruptions are typically vulcanian (Fig. 2a; see also color insert), yet nonexplosive or effusive eruptions and continuous ash eruptions (e.g., plinian) do occur. Nonexplosive eruptions are usually accompanied by volcano-tectonic earthquakes (a.k.a. A-type earthquakes) and plinian eruptions are accompanied by swarms of microearthquakes or volcanic tremor. Vulcanian eruptions are characterized by precursory or accompanying explosive earthquakes (large amplitude, isolated events lasting 10–20 s), volcanic tremor, and sometimes long-period earthquakes (a.k.a. B-type earthquakes). For example, in Fig. 2b, the ejection of ash and blocks from the vent is defined by the emission of an atmospheric shock wave which is preceded (10 s) by an explosive earthquake.

Explosive and nonexplosive eruptions are also accompanied by two respective patterns of ground deformation based on tilt- and strainmeter recordings made below the summit crater. Prior to nonexplosive eruptions, the ground slowly inflates until the eruption and thereafter gradually deflates. Likewise, gradual ground inflation precedes explosive eruptions, followed abruptly by deflation at the onset of the eruption. The amount of inflation associated with a typical vulcanian eruption is estimated at  $10^3$  to  $10^5 \text{ m}^3$  at a depth between 2 and 6 km. Volume

changes associated with deflation at the onset of an explosive eruption are estimated at  $10^3$  to  $10^4 \text{ m}^3$ . The mass of ejected material is equal to two-thirds of the magma mass equivalent to the deflation volume.

The source of vulcanian eruptions at Sakurajima has been interpreted from the relationship between seismicity and geodetic data and the onset of an eruption by several researchers. It has been proposed that as the volcano inflates without an eruption, magma is transported to shallower depths ( $<2\text{--}6 \text{ km}$ ) beneath the Minamidake crater. As magma ascends, volatiles are exsolved and accumulate at the top of the shallow magma body. When a critical pressure is reached which corresponds to the strength of the surrounding rock, the accumulated gas is released into a conduit that is connected to the summit crater. The release of gas is thought to be the source of the precursory explosive earthquakes. At the vent, high pressure gas is released into the atmosphere creating air shock waves that mark the onset of an eruption. The shock waves are immediately followed by the ejection of ash and fragmented magma forming pyroclastic clouds. From photographic analysis, the emitted shock waves travel at speeds of 441–500 m/s from the vent, and block ejecta travel at velocities of 110–160 m/s.

### D. Galeras Volcano, Colombia

Galeras is among the most active volcanoes in Colombia and among the most dangerous in South America. Located near Colombia's western border, Galeras lies about 8 km west of the town of Pasto (pop. 350,000). Because of the danger it poses to surrounding communities, its activity has been the subject of intense research and has been monitored continuously since 1989.

Following a 50-year period of quiescence, seismic activity increased at Galeras in June 1988. A series of small, explosive, mostly nonjuvenile eruptions began in February, 1989, which increased in frequency and became semicontinuous from May 4 to May 9 within the secondary crater *El Pinta*. Between May 1989 and the end of 1990, seismicity and SO<sub>2</sub> emissions remained at a relatively high level (1400 long-period earthquakes/month and 2000–5000 tonnes/day, respectively). During the first half of 1991, a series of minor ash emissions was accompanied by long-period earthquakes, tremor, and inflation of the summit area and by a decrease in SO<sub>2</sub> flux to  $<1000$  tons/day. These trends continued until a dome of  $400,000 \text{ m}^3$  volume was emplaced in the crater between October and December of that year.

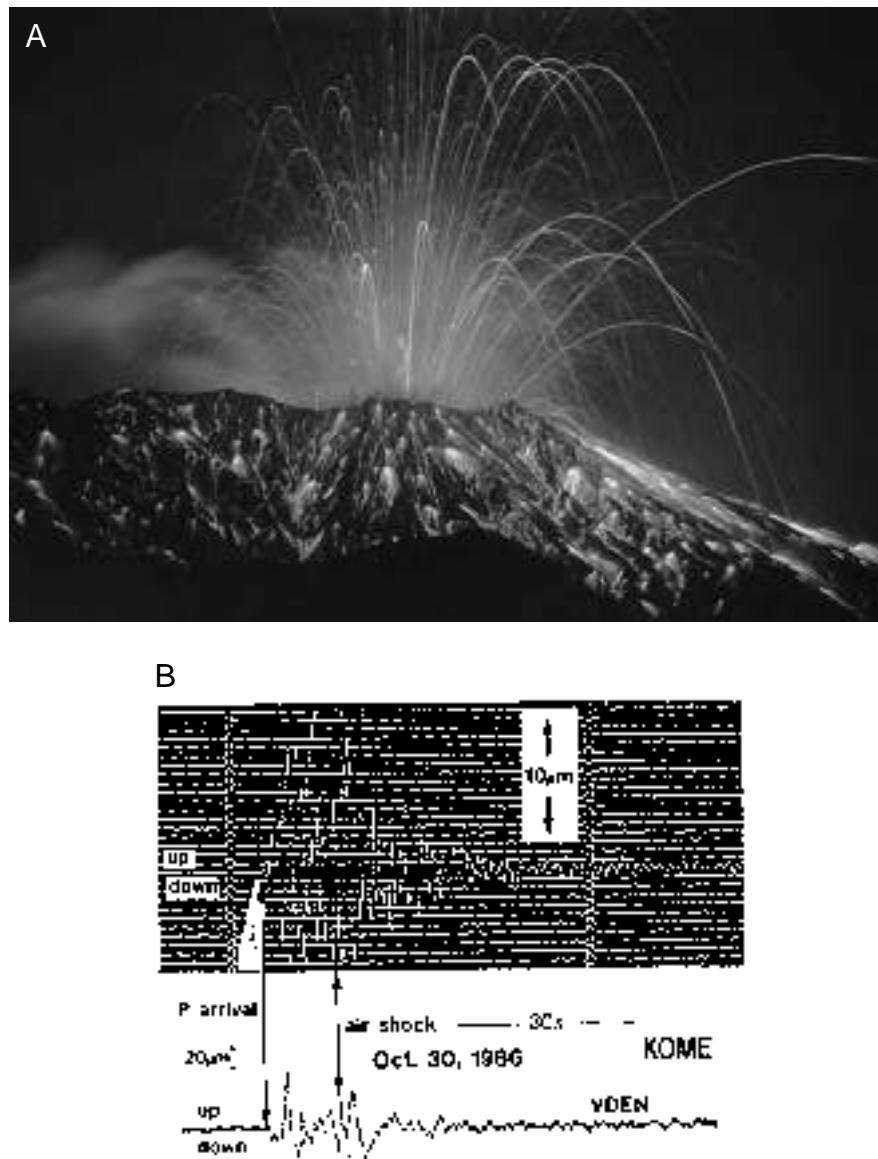

FIGURE 2 (A) Vulcanian eruption that occurred at Sakurajima at 22:53 JST on February 6, 1990. Incandescent arcs define the trajectory paths of ejected blocks. Photo taken at the Sakurajima Volcano Observatory by Tetsuro Takayama with an exposure time of 30 s. (See also color insert.) (B) An example of a short-period (top) and long-period (bottom) seismogram of vertical ground motion. The P-wave arrival of an explosion earthquake is followed within 10 s by an air shock which marks the onset of the October 30, 1986, eruption. [Reprinted with permission from Uhira and Takeo, (1994) *J. Geophys. Res.* **99**, 17,775–17,789, American Geophysical Union.]

From July 16, 1992, until June 7, 1993, Galeras produced six small but explosive vulcanian eruptions, followed by small gas emissions in September 1994 and January 1995. The first vulcanian explosion, on July 16, 1992, destroyed 90% of the lava dome, produced a plume about 4 km high, generated shock waves that broke windows 9 km from the volcano, ejected blocks

40 cm in diameter up to 2.3 km from the vent, and produced at least 277,000 m<sup>3</sup> of tephra. The second, on January 13, 1993, killed six volcanologists and three tourists who were at the summit of the volcano. The eruption lasted about 15 minutes, produced ash plumes 2.5–4 km in height, distributed incandescent blocks and lapilli throughout the 1-km-diameter caldera, and was

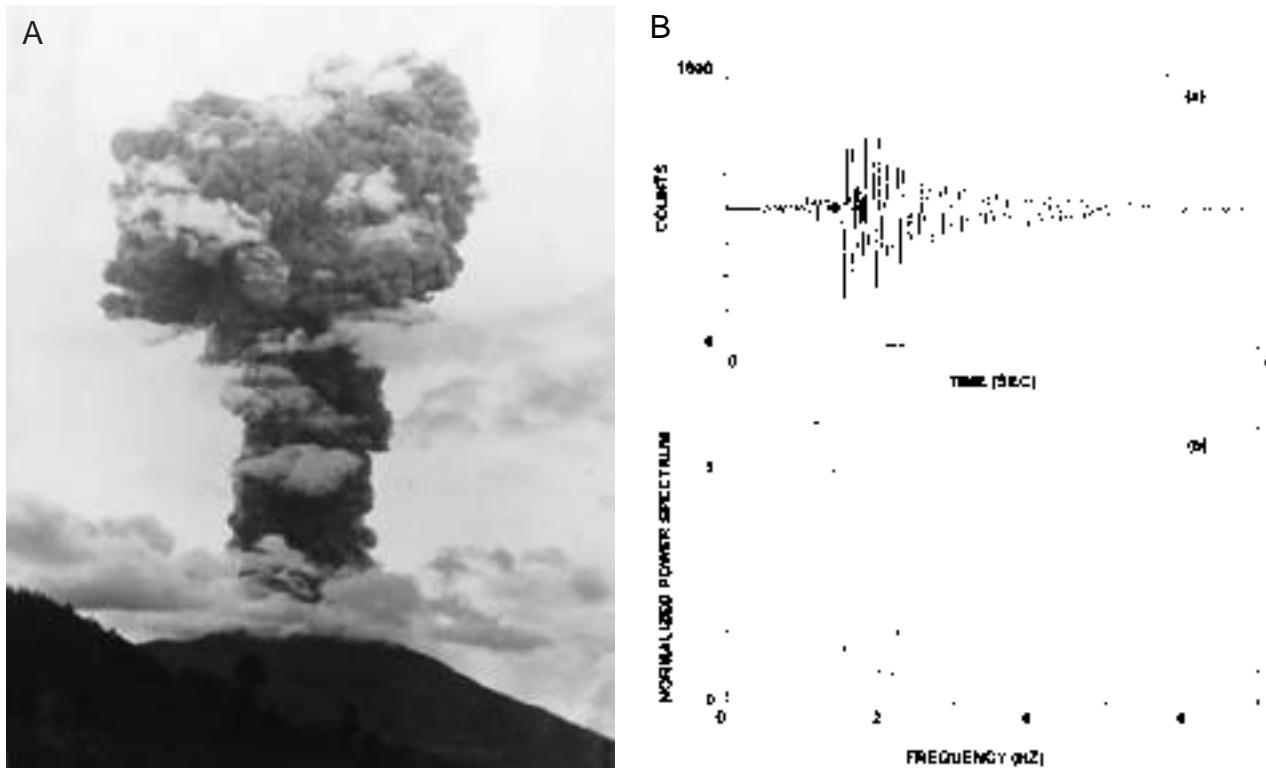

FIGURE 3 (A) Vulcanian eruptive plume from the April 4, 1993, eruption of Galeras. (Photo taken by Luis Esparza of INGEOMINAS, Colombia.) (B) Examples of the vertical ground motion and spectral peaks for a *tornillo* or long-period seismic event at Galeras. [Reprinted from Cruz, G., and Chouet, B. (1977) *J. Volcanol. Geotherm. Res.* **77**, with permission from Elsevier Science.]

followed for several hours by vigorous jetting of gas from the vent. Later eruptions in the sequence (e.g., on April 4, Fig. 3a) were similar in character but decreased progressively in size and increased in frequency through the end of 1993. During the entire 2-year eruptive sequence,  $\text{SO}_2$  flux remained low except for dramatic increases for a few days following each vulcanian eruption.

None of the vulcanian explosions was preceded by any significant increase in seismicity, gas flux, or deformation. However, following the deadly January 1993 eruption, seismologists recognized that each event was preceded by small numbers (a few per day) of distinctive, monochromatic long-period seismic events of a few minutes duration with long codas of constantly decreasing amplitude (Fig. 3b). These events were termed *tornillos* (screw, in Spanish) after their screwlike appearance on helicorder records. The number and duration of the *tornillo* signals tended to increase over a period of weeks, then decrease in the days prior to the eruptions. The appearance of *tornillos* in May 1993 allowed seismologists to warn local authorities of an eruption that occurred on June 7. The warning was attributed to the fact that long-period seismic events are thought to be related to a pressurizing fluid flow at shallow depth.

From gas-flux data and considerations of magmatic cooling rates, it has been argued that vulcanian eruptions at Galeras were caused by generation of gas as the magma cooled and crystallized in the shallow conduit. After late 1991, gas escape through the conduit was impeded by the emplacement of magma, causing gas pressures to build up and vent explosively during vulcanian events. The decrease in eruption size and in the time interval between eruptions were inferred to be related to some combination of two factors: (1) a temporal decrease in tensile strength of the magmatic cap, allowing it to breach under progressively smaller loads, and (2) a deepening of the source of gas from each eruption to the next.

This interpretation was supported by analysis of the seismicity that accompanied the emplacement and extrusion of the lava dome in October 1991. The accompanying seismicity was characterized by a mix of repetitive, long-period events and tremor. Waveform analysis of the long-period events (*tornillos*) in October and November showed that the dominant periods range from 0.2 to 1.0 s. These events correlated with observed intermittent emissions of gas venting through a crack in the lava dome. Using a fluid-driven crack model to interpret the

seismicity, it was inferred that the sources of the long-period events were two resonating cracks within the lava dome. A crack resonated when a gas slug was released from the magma column and dilated the preexisting crack, allowing the gases to escape to the surface. As the gases moved through the crack, progressive mineralization occurred along the crack walls and eventually sealed the crack. The July 16, 1992, eruption occurred when sufficient pressure built up to cause dome failure.

mates gave initial pressures more than an order of magnitude too high (hundreds of megapascals) (Figure 4A). Contemporary pressure–velocity relations, introduced in the early 1980s, assume that block masses are accelerated by an adiabatically decompressing volume of gas in the upper conduit. They show that vulcanian-eruption velocities can be produced by a gas–solid mixtures containing several weight-percent gas or less at magmatic temperatures and at pressure usually less than 10 MPa (Figure 4B).

### III. ERUPTION PROCESSES

#### A. Ballistic Ejection

Among the first features to be studied at vulcanian eruption sites were the trajectories and velocities of erupted blocks. The most energetic vulcanian eruptions have ejected blocks to distances of 5 km (at Arenal volcano, Costa Rica in 1968). Prior to the 1990s, estimates of the velocity required to produce the observed ejection distances have generally assumed that blocks were ejected through still air. Those estimates yielded velocities significantly greater than more recent calculations which consider decreased air drag near the vent. Accordingly, the highest velocities estimated prior to the 1990s, ~600 m/s for the 1968 eruption at Arenal volcano and 400 m/s for the 1975 eruption at Ngauruhoe, have been revised down to roughly 300–400 and 220–260 m/s, respectively. Much higher velocities are likely to be produced within gas jets following the vulcanian outburst, but these velocities have not been successfully measured. The most reliable velocity measurements have been obtained from photographs and videos of explosions, albeit of smaller eruptions than those at Arenal and Ngauruhoe.

#### B. Estimates of Eruption Velocity and Pressure

The great distance over which large blocks are ejected in some eruptions suggests intuitively that the pressure required to accelerate them was very high. Beginning in the 1940s, investigators attempted to estimate pre-eruption pressure using either relations derived for projectiles within gunbarrels (the “gun barrel equation”) or a modified form of the Bernoulli equation (MBE) that did not consider the compressibility of the erupting mixture and inappropriately used the density of the solid phase rather than of the solid–gas mixture. These esti-

#### C. Deposit Characteristics

Brief, violent explosions are the hallmark feature of vulcanian eruptions, and consequently the most salient deposits from such eruptions are produced by ballistic block ejection, pyroclastic avalanches, or nuées ardentes and pyroclastic flows. Block fields at volcanoes such as Galeras, Vulcano, Arenal, Asama, and Sakurajima cover areas ranging up to several square kilometers and contain blocks up to several meters in diameter. When masses of ejected blocks and ash fall to the ground with significant horizontal momentum, or land on steep slopes, they develop into moving pyroclastic avalanches or flows. Pyroclastic avalanches cut undersea cables during the 1888–1890 eruptions at Vulcano and were spectacularly photographed on the flanks of Ngauruhoe in 1975. The deposits are composed of lithics and poorly vesiculated pyroclastic flow or block-and-ash flow materials.

Vulcanian eruptions have also produced widely dispersed, fine-grained fall deposits with volumes up to 1 km<sup>3</sup> reflecting whether the eruption was a discrete or a pulsatory event or a discrete event preceding a sustained eruption phase (e.g., plinian eruption). Fine-grained tephra fall deposits develop by at least two mechanisms: (1) upward convection of fine ash clouds following discrete ash explosions (e.g., Ngauruhoe, 1975) and (2) development of a sustained subplinian or plinian column after an initially vulcanian outbreak (e.g., Redoubt, 1989). The second mechanism produces deposit volumes on the order of 10<sup>-1</sup>–10<sup>0</sup> km<sup>3</sup>, which could only be produced by subplinian or plinian mass flux rates sustained over a period of hours or more. Deposit volumes of <10<sup>-1</sup> km<sup>3</sup> are produced by discrete and pulsatory events and are more proximal to the crater than those related to the second mechanism.

The components of vulcanian fall deposits are characterized by the proportions of nonjuvenile versus juvenile fragments and vesicularity. Nonjuvenile clasts make up a large fraction of the deposits and are presumed to

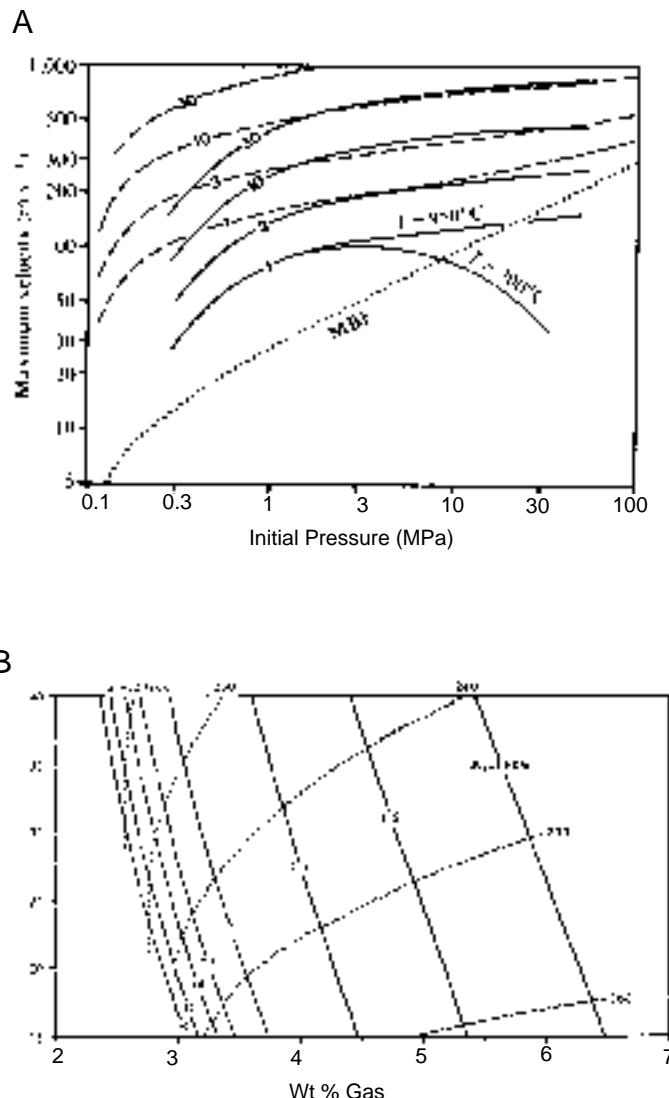

FIGURE 4 (A) Maximum theoretical velocity that can be attained by a mixture of gas and solid particles decompressing from the initial pressure shown on the horizontal axis, and an initial temperature of 950°C. Labels on each line indicate the wt% of gas (assumed H<sub>2</sub>O) in the mixture. Dashed lines assume that the ash and gas are in thermal equilibrium, solid lines assume that the gas expands adiabatically. The dotted line shows the theoretical velocities calculated by the modified Bernoulli equation. [Reprinted with permission from Self *et al.*, 1979.] (B) Maximum theoretical velocity as a function of distance from vent, preburst pressure and wt% gas calculated for the 1975 Ngauruhoe eruption. [Reprinted with permission from Fagents and Wilson, 1993.]

result from the clearing of the vent during these short-lived eruptions. The lithology of nonjuvenile clasts, which include lava dome material or country rock from the vent or conduit walls, may constrain the source depth and intensity of the eruption. Juvenile components may be vitric to crystalline, poorly to moderately vesicular, angular, and block- to ash-sized. The lack of well-vesiculated juvenile fragments in these deposits and the short duration of the eruptions suggest that the upper conduit

contained mostly gas or heated groundwater as opposed to vesiculating magma.

#### D. Seismic and Air Wave Characteristics

Vulcanian eruptions are commonly preceded by long-period and tremor events and explosion earthquakes.

Unlike volcano-tectonic earthquakes, which are thought to reflect the brittle response of the volcanic conduit to stresses induced by magma migration, long-period and tremor events are thought to be the manifestations of pressure disturbances in fluids flowing through the edifice. Long-period events are recognized by a high frequency onset followed by a monochromatic wavetrain with a duration of seconds to minutes, whereas tremors may last for hours to days. These types of seismic events have provided vital information about the role of gases in the eruption process, such as the July 16, 1992, eruption at Galeras volcano, as mentioned previously, and the onset of the 1989–1990 eruption at Redoubt volcano, Alaska. In the Redoubt volcano case, a swarm of 1400 long-period events were recorded over an 18-hour period prior to its onset which was marked by a vulcanian eruption. These seismic events were interpreted as reflecting the pressurization of the volcanic edifice due to the accumulation of exsolved magmatic volatiles at the top of the magma column. At several volcanoes in Japan (Asama, Mount Tokachi, and Sakurajima), explosion earthquakes have preceded the surface outbreaks of vulcanian eruptions by several seconds. Such earthquakes are thought to represent rapid pressurization 2–3 km beneath the volcanic crater which induces the upward flow of either gas or magma. At other volcanoes (e.g., Mount St. Helens), explosion earthquakes are not accompanied by surface outbreaks.

Atmospheric shock waves are another characteristic of vulcanian eruptions. Their occurrence indicates that the erupting fluid at the vent is overpressurized with respect to the atmosphere as illustrated in Fig. 5A and 5B. The air shock propagates ahead of the erupting fluid at a velocity exceeding the atmospheric sound speed (340 m/s at 25°C). The shock wave is momentarily visible above the volcano when it passes through clear air or a preceding eruption cloud and condenses water vapor (Fig. 5C). This process produced short-lived condensation clouds surrounding the expanding eruption plume at Ngauruhoe volcano in 1975 and Sakurajima volcano.

Air shocks have been recorded on microbarographs at distances of >50 km from the active vent and appear as N-shaped signals followed by a long-period coda as shown in Fig. 6A. The N-shape signal is composed of a leading compression wave followed by an expansion wave that raises the pressure behind the shock back to ambient conditions. Results from numerical simulations of vulcanian eruptions shown in Figs. 6B and 6C demonstrate how the peak-to-peak pressure and wavespeed of the signal can be used to estimate the eruption burst pressure and the gas (or steam) concen-

tration in the eruptive ash–gas mixture. For example, the peak-to-peak pressure,  $P_k$ , (0.0004 MPa) of the shock wave recorded during the 1975 Ngauruhoe eruption at a distance of 9 km from the vent corresponds to a burst pressure of 5–6 MPa and 50 wt% gas. These values agree well with those calculated by Fagents and Wilson using ejection velocities. Figure 6C can be used to estimate the weight percent steam in the erupting fluid based on the travel speed of the air shock and recording location.

#### IV. PLUME DYNAMICS

The height, shape, rise velocity, and rise times of vulcanian eruption plumes have been studied by many investigators. Individual vulcanian explosions tend to last only seconds to minutes—not long enough to develop sustained eruption columns unless many follow in close succession. Vulcanian eruption clouds can reach altitudes of several kilometers for individual explosions or <20 km for repeated or pulsatory explosions over periods of hours. Once expelled into the atmosphere, large blocks fall rapidly out of the mass of ejected debris (Fig. 5D).

The remaining cloud of tephra entrains air and generally becomes buoyant, rising as a thermal (Fig. 5E) at velocities of meters to tens of meters per second until its density just equals that of the surrounding atmosphere. The final elevation of the thermal is controlled by the initial diameter and temperature of the plume, the adiabatic lapse rate for air, and the ambient atmospheric temperature gradient with elevation. Plumes with initial diameters of <1 km will generally rise <12 km into the atmosphere and will achieve that height in a few to several minutes. Photographs of discrete thermals were analyzed following individual vulcanian explosions at Fuego volcano.

More commonly, explosions follow closely one after another, producing a semicontinuous plume. Examples of the latter were noted during vulcanian eruptions at Soufrière volcano, St. Vincent, in 1979 and during vulcanian eruptions at Lascar Volcano, Chile, in 1990. These plumes reached heights (15–18 km) significantly greater than one would expect from discrete explosions, apparently due to the accumulated buoyancy of the consolidated thermals. The heights of semicontinuous and continuous eruption columns are controlled primarily by the average magma-flux rate or mass-eruption rate.

Mass-eruption rates for vulcanian eruptions are on

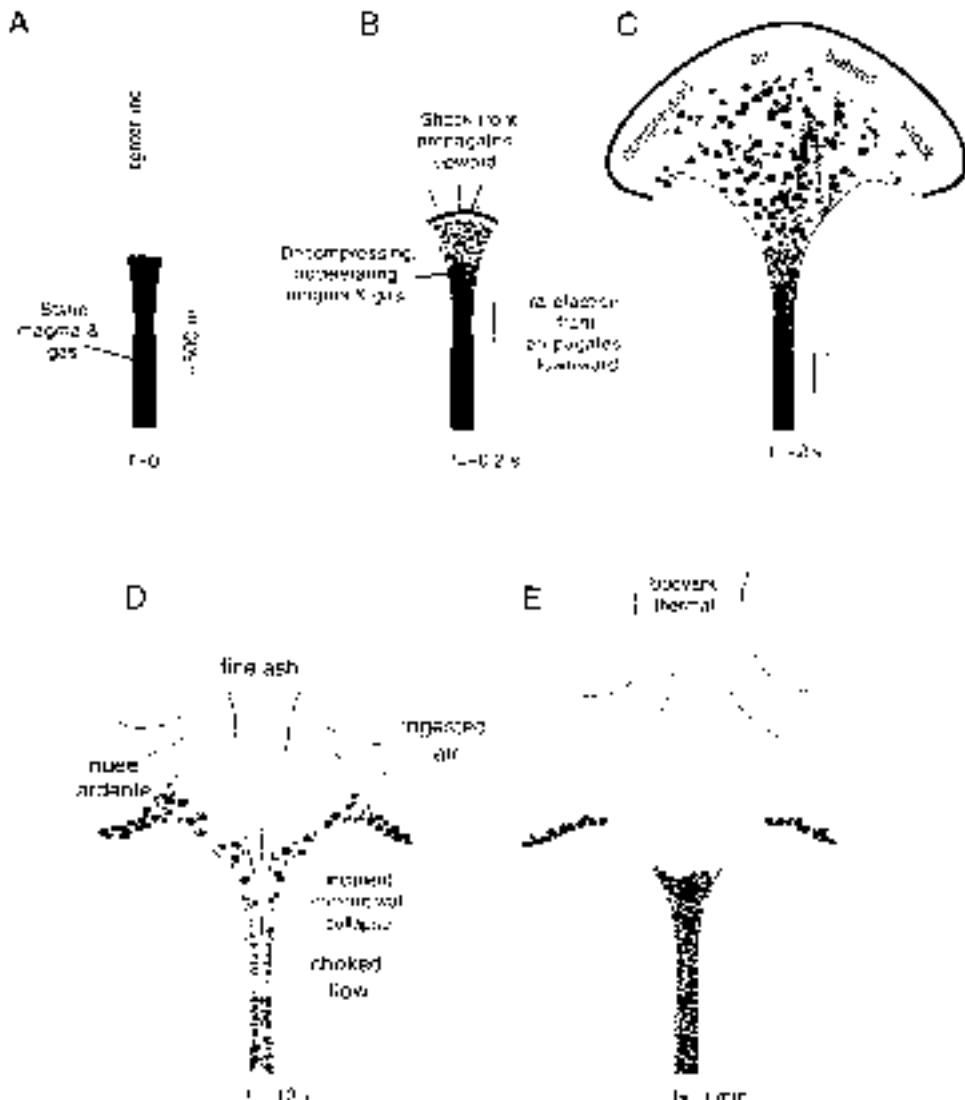

FIGURE 5 Schematic illustration of the development of fluid flow in and above a volcanic conduit during a single vulcanian explosion. (A) Structure of the conduit and crater prior to an explosion. (B) Crater and conduit  $\sim 0.2$  s after initiation of the eruption. (C) Events about 2 s after initiation; (D)  $\sim 10$  s after initiation; (E)  $\sim 1$  minute after initiation.

the order of  $\sim 10^4 \text{ kg s}^{-1} \text{ m}^{-2}$  based on the diameter of the vent and the velocity at the vent. A conduit some tens of meters in diameter would produce mass-eruption rates comparable to subplinian or plinian eruptions, though the duration of vulcanian events is far shorter. For a conduit diameter of a few tens of meters and a depth of half a kilometer, a single explosion would produce about  $10^5 \text{ m}^3$  of erupted magma (dense-rock equivalent).

Vent velocities are constrained by the sound speed of the erupting fluid. Because gases associated with these

eruptions are overpressured with respect to the atmosphere, the flow at the vent is considered choked. This implies a vent velocity at the most constricted part of the vent that is equal to the sound speed of the erupting fluid. The sound speed of the fluid is a function of gas composition, temperature, and volume fraction of solid particulates. A gas at  $900^\circ\text{C}$  composed of  $\text{H}_2\text{O}$  will have a sound speed  $\sim 800 \text{ m/s}$  and one that is more  $\text{SO}_2$ - or  $\text{CO}_2$ -rich will have a sound speed near  $400$ – $450 \text{ m/s}$ . The sound speed will increase with temperature and will decrease as the volume fraction of solids increases.

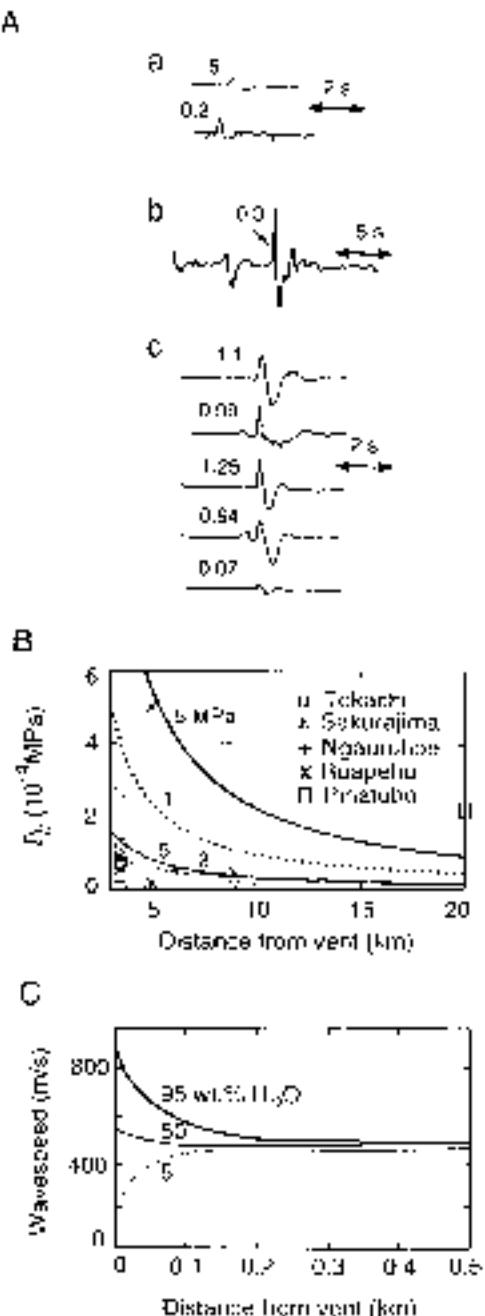

FIGURE 6 (A) Examples of N-shaped air waves recorded on microbarograms from eruptions at (a) Sakurajima volcano in 1989 at 5 km from the vent; (b) Ruapehu volcano in 1995 at 9 km from vent; and (c) Mount Tokachi in 1988 at 3.5 km from the vent. (B) Theoretical decay curves of the magnitude of the difference between the maximum and minimum pressures  $P_K$  on the air wave as a function of distance from vent and 50 wt% H<sub>2</sub>O. Superimposed are  $P_K$  values (in MPa) from (A) and other volcanoes. (C) Theoretical wavespeeds for air waves associated with eruptions of different H<sub>2</sub>O concentrations. (Reprinted with permission from Morrissey and Chouet, 1997.)

Volcanic gas-ash mixtures generally have sound speeds of about 50–150 m/s. Above the vent, the flow velocity increases with height in the supersonic (where velocities are greater than the sound speed) region of the jet. Only fine-grained tephra will travel at these velocities. Larger materials separate from the flow within <1 km above the vent. Thus the travel distance reflects the initial velocity of each block at the vent, plus interactions between the block and the surrounding gas and ash in flight.

#### V. ERUPTION SOURCE MODELS

Several hypotheses have been proposed for the source of gases that drive vulcanian eruptions; they relate either to exsolution of magmatic volatiles or superheating of groundwater. One hypothesis involves pressurizing the lava cap or lava dome by exsolution of magmatic volatiles from rapid microlite growth. This scenario was applied to the eruptions at Galeras in 1992–1993, Mount Unzen in 1991, and Soufriere Hills volcano, Montserrat in 1996. Calculations show how microlite crystallization can increase the pressure within a lava dome and upper conduit by tens of MPa which would be sufficient to cause a lava dome to fail. By this process, the rate of pressurization is on the order of days to weeks. Laboratory modeling of microlite growth using an andesitic melt demonstrates how pressurization rates can occur on timescales of minutes to hours by the subsequent formation of a lava plug. These results may explain pulsatory vulcanian eruptions that recur on similar timescales.

Another hypothesis involving the exsolution of magmatic gases is closed system magmatic degassing at depth (>3 km below the vent). This scenario has been applied to recent eruptions at Sakurajima volcano, the onset of the 1989–1990 eruption at Mount Redoubt as mentioned previously, and the 1992–1993 eruptions at Galeras volcano.

A third hypothesis for a source of gases and pressurization involves rapid heating of groundwater by either conductive heating by an underlying magma body or the physical mixing of magma and groundwater. Conductive heating would gradually pressurize groundwater which would eventually lead to failure of the lava cap. Physical mixing is known as a fuel-coolant interaction (FCI) and is described in detail in the chapter on Phreatomagmatic Fragmentation in this volume. FCIs may be explosive or nonexplosive; the former may produce a vulcanian

type of eruption. An explosive, volcanic FCI arises when rising magma encounters a water-saturated layer or a surface body of water such as a lake. When magma contacts water, the water may become superheated which rapidly raises the temperature of water past its critical point without changing it to steam. The metastable water will flash to vapor which in turn pressurizes the system at an explosive rate (microseconds) when the superheating condition is exceeded or an external force perturbs the system such as fall-back material or seismic events. Once an explosive FCI occurs, another may follow within  $10^{-3}$ – $10^0$  if the surface of the magma becomes fragmented, thus creating new surface areas for heating additional water. This cycle may continue until there is no longer a source of water or the rate of heat transfer between the magma and water is insufficient.

This mechanism does not require the presence of a sealing lava plug/dome but if one does exist, it can easily pressurize the plug/dome above failure conditions. Explosive magma–water interactions (phreatomagmatic) may explain individual vulcanian explosions, or pulsatory vulcanian eruptions on times scales of seconds to minutes. This mechanism was postulated by some investigators for the 1888–1890 and pre-1888 eruptions at Vulcano.

Explosive phreatomagmatic events that appear as discrete finger jets were observed during the 1995–1996 eruption at Mount Ruapehu volcano in New Zealand. The first phase of the eruption involved a crater lake that led volcanologists to consider all these eruptions to be phreatomagmatic. Many of these eruptions were short-duration explosive bursts characteristic of vulcanian eruptions. Similar eruptions occurred during the 1977 eruption of the Ukinrek maars in Alaska. A series of discrete, explosive eruptions occurred over a 10-day period when rising magma encountered a shallow water-saturated sediment layer. Vulcanian eruptions that involve groundwater may be considered a subclassification of phreatomagmatic eruptions.

## VI. CONCLUDING REMARKS

The characteristics that make vulcanian eruptions unique from other eruption styles are that they are short (seconds to minutes) discrete explosions, sometimes pulsatory, capable of ejecting incandescent lava bombs and blocks of fragmented rock to distances  $<5$  km. The associated eruption cloud of fine-grained tephra com-

posed of essentially nonjuvenile lithics, can reach altitudes several kilometers high for individual explosions or  $<20$  km for repeated explosions. Shock waves are another feature that are usually recorded or observed during a vulcanian eruption. Some of these features are also characteristic of surtseyan and subplinian eruptions; however, the combination of all listed features separate vulcanian eruption from the other eruption styles.

During the past few decades, our understanding of the causes and timing of vulcanian eruptions has improved dramatically. The improvements have been the consequence of at least four factors: (1) an increase in the number of volcanoes under observation; (2) incremental improvements in monitoring techniques involving seismic and acoustic measurements; (3) improved communication by volcanologists of the characteristics of these eruptions; and (4) more realistic numerical models that consider both subsurface and surface processes.

## GLOSSARY

**intensity** A measure of the rate at which magma is discharged during an eruption.

**magnitude** The total mass of material ejected during an eruption.

**VEI** Volcanic Explosivity Index. A measure of the size of an eruption, mainly based on magnitude, intensity and destructive power of an eruption. VEI has an eight-point scale.

**I**N PLINIAN AND subplinian eruptions most of the erupted mass is discharged during phases characterized by the formation of high, convective eruption columns resulting in atmospheric ash and particle injection and dispersal by winds over huge areas. The name recalls the 79 A.D. eruption of Vesuvius which provoked the death of Pliny the Elder, which his nephew, Pliny the Younger, narrated in two letters to Tacitus.

---

## I. CHARACTERISTICS

### A. Definition, History, and Characteristic Features of Plinian Eruptions

During an eruption, the style of activity and the nature and type of products can change within minutes, hours, days, or months. Changes in eruption style are functions of changes in magma composition and crystallinity, the amount and nature of exsolved volatiles, vent and conduit geometry, and access of external water to the plumbing system. Any period during which a homogeneous style is sustained, however variable in its intensity, can be referred to as a phase of the eruption.

The systematic study of volcanic eruptions suffers from use of an ambiguous nomenclature. Classical names such as plinian, vulcanian, hawaiian, etc., are used both for well defined single phases of an eruption, as well as the entire complex sequence of events that makes up a polyphase eruption. To avoid ambiguity, we prefer to apply these terms only to those eruptions in which the dominant phase represents clearly one of these styles. For example, a plinian eruption can contain phases with different eruption styles (e.g., ignimbrite-producing), but the dominant phase (in terms of volume and/or intensity) is plinian.

The account of Pliny the Younger is the first description of a plinian eruption. Since then, numerous eru-

tions of similar intensity have occurred, especially concentrated along convergent margins of the lithospheric plates. The eruption that issued from Lake Taupo (New Zealand) around 181 A.D. is an example of the upper limit of size for this type of eruption. In the last century a dozen plinian to subplinian events have occurred. Among the most famous, is the 1912 eruption of Novarupta (Alaska), whose associated pyroclastic flow deposits formed the Valley of the Ten Thousand Smokes and in more recent times, the eruptions of May 18, 1980, at Mt. St. Helens (United States). March 29–April 4, 1982 at El Chichon (Mexico) and June 15, 1991, at Pinatubo (Philippines). These last three eruptions have provided a clearer definition of the eruptive processes and the dynamic evolution of explosive eruptions, giving new insights for the interpretation of deposits from past eruptions.

During plinian phases, a mixture of gas and particles (juvenile and wallrock) is discharged from a vent(s) at velocities between 100 and 400 m/s. The volume of ejected material ranges typically between 0.1 and 10 km<sup>3</sup> (magnitude =  $10^{11}$ – $10^{13}$  kg) with mass discharge rates (MDR) of  $10^6$ – $10^8$  kg/s. The duration of these events is therefore limited, from a few minutes to a few hours.

It is difficult to separate conceptually plinian from subplinian events. In simple terms, the eruptions in the lower ranges of magnitude ( $\sim 10^{11}$  kg) and intensity ( $\sim 10^6$  kg/s) can be classified as subplinian. They are often characterized by important discharge variations that lead to relatively short phases of sustained discharge separated by pauses of variable length or other types of activity. This can result in the frequent generation of pyroclastic density currents (PDC) related to destabilization of the eruption column. Values of the Volcanic Explosivity Index (VEI) of 4–6 characterize plinian and subplinian eruptions. Larger magnitudes and intensities generally induce continuous column collapse and ejection of most of the erupted mass as pyroclastic density currents. These are ignimbrite phases of ultraplinian or ignimbrite eruptions. Table I summarizes the main features of these types of eruption.

The motion in the atmosphere of a plinian plume can be described in terms of three different regions (Fig. 1): (i) a gas thrust region, where the gas–particle mixture rapidly loses its initial momentum by turbulent entrainment of air at its margins; (ii) a convective region, where trapped air is heated and the bulk density is less than the surrounding atmosphere; and (iii) an umbrella region,

TABLE I Main Features of Plinian-Type Eruptions

Type of eruption	Subplinian	Plinian	Ultraplinian or ignimbritic
Magnitude (kg)	$\approx 10^{11}$	$10^{11}$ – $10^{13}$	$> 10^{13}$
Intensity (kg/s)	$\approx 10^6$	$10^6$ – $10^8$	$> 10^8$
Column height (km)	<20	20–35	>35
Thickness half-distance ( $b_1$ , km)	0.5–4	2–10	>10
Clast half-distance ( $b_c$ , km)	1–3	3–8	8–15
Main phases	Unsteady sustained, convective column	Steady sustained convective column	Sustained fountaining
Associated eruptive styles	Surge generation, dome extrusion	Partial or total column collapse	Convective column with increasing flow rate
Dominant fallout deposits	Thinly stratified	Massive to variously graded	Generally reversely graded
Dominant flow deposits	Surges and small sized pumice and scoria flows	Pumice and ash flows	High and low-grade ignimbrites
Fall/flow vol. ratio	>1	>1	$\ll 1$
Typical magma composition	Mildly evolved (dacitic, phonotephritic)	Highly evolved (rhyolitic, trachytic, phonolitic)	Highly evolved (rhyolitic, trachytic)

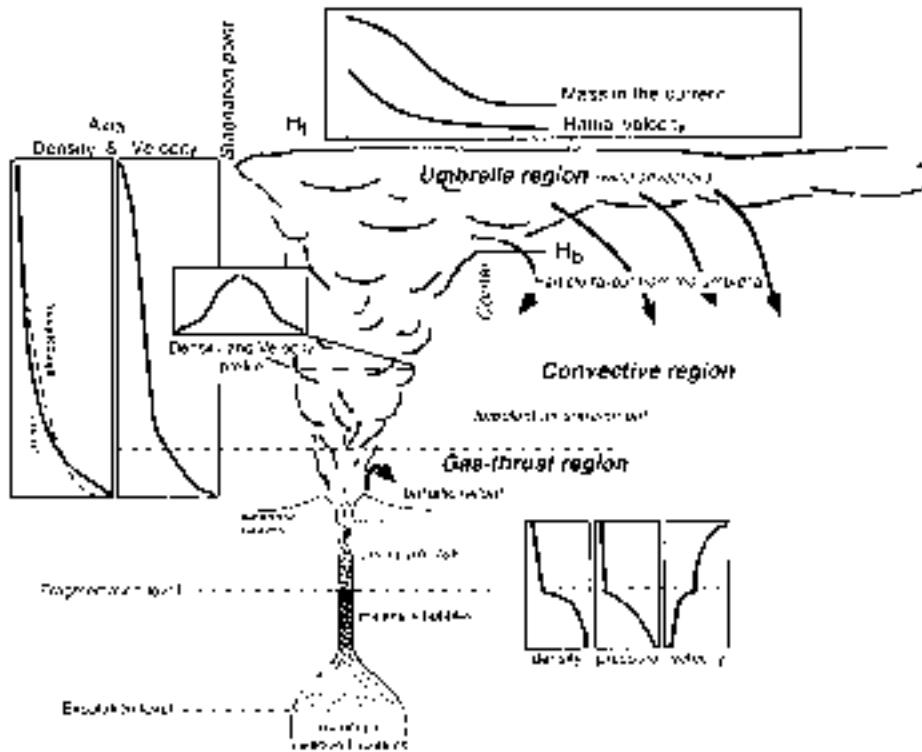

FIGURE 1 From the magma chamber to the stratosphere. The figure shows the different zones, the variation of the main physical properties (density, pressure, velocity) of the erupting mixture, and the main processes associated with the flow of magma in the conduit and the formation of the convective column.

where the mixture, after having reached the height of neutral buoyancy ( $H_b$ ), continues to rise due to its momentum to a maximum height ( $H_t$ ) and expands laterally under the influence of the prevailing winds. The top of the gas thrust region is generally not more than few kilometers above the vent, while the base of the umbrella region can be on the order of tens of kilometers high. The efficiency of air entrainment in the mixture and thermal exchange with pyroclasts is the fundamental key to generating buoyancy needed for the rise of the volcanic plume to great heights in the atmosphere. The thermal energy provided by the magma is a function of its discharge rate. The maximum height reached by the eruptive column, which depends on its momentum at  $H_b$ , is scaled to the fourth root of the mass discharge rate of magma and is on the order of 1.3 times  $H_b$ .

The dynamics of plinian and subplinian eruptions require volatile-rich, high viscosity magmas. Basaltic compositions are consequently quite rare and unusual in these events, which are generally associated with evolved calc-alkaline (high-silica andesite to rhyolite) and alkaline (trachyte to phonolite) magmas. Most magmas erupted during plinian events exhibit clear evidence of being

evolved within shallow reservoirs, with rapid emptying frequently generating collapse of summit calderas.

### B. Magma Fragmentation

Plinian volcanic eruptions are generally initiated by fracturing of the rocks overlying a crustal reservoir and subsequent magma ascent. The fracturing can be related to overpressure by magma influx from depth, volatile exsolution following crystallization, mixing, assimilation, etc., or to external factors such as tectonic earthquakes. The pressure decrease in rising magma progressively induces oversaturation and release of the dissolved volatile components. Acceleration and the volume increase of exsolved fluids result in fragmentation of magma, which is ejected as a gas dispersion of liquid clots and solid fragments. Prior to fragmentation, the high viscosity of silicic melts does not allow an efficient separation of the liquid from the volatile phase, and the magma rises in a bubbly flow regime, with bubbles having a small relative ascent velocity with respect to the liquid. Very high values of mixture acceleration are

reached in the region of fragmentation, with a feedback effect on magma rise velocity related to the rapid decompression of bubbles after reaching volatile supersaturation in the melt (Fig. 1).

Mechanisms of magma fragmentation in plinian eruptions are classically related to a critical concentration of bubbles in the magma (about 75 vol%). At this concentration, decompressional and diffusional growth of the bubbles is inhibited by the viscosity of the residual, volatile-poor liquid, and rupture of the liquid films separating the bubbles can occur. Fragmentation of the magmatic foam is still a matter of debate. Analog experiments have shown that the explosive disintegration of a static foam is an unlikely process, while its acceleration in the conduit could explain the explosive fragmentation. The general evidence is that bubble content is in a relatively narrow range (65–85 vol%), depending on the shape and size distribution of bubbles. The introduction in the volcanological literature of the glass transition concept could help in explaining the fragmentation process. If the timescale for deformation (strain rate) is shorter than the timescale for viscous relaxation of the liquid (the time needed for the liquid to keep pace with an applied strain), the bubble–liquid mixture crosses the glass transition, behaving in a brittle fashion and disintegrating. A process, which may play an important role in the grain-size distribution of pyroclasts generated by fragmentation, is permeability development during vesiculation. Permeability (through bubble coalescence) will favor gas escape and consequent formation of pumice versus ash.

Fragmentation processes acting during subplinian events reflect the unsteady character of many of these eruptions. The alternation of sustained columns with periods of quiescence has been explained in terms of syn-eruptive degassing and viscosity increase of the magma column during the slow refilling of the conduit. The degassed portion of the magma crystallizes rapidly, causing magma stagnation in the upper portions of the conduit (possibly culminating in dome extrusion), and the progressive buildup of pressure that eventually reopens the system. The discontinuous nature of several subplinian eruptions may result from differences between the rates of magma discharge at the surface (MDR) and the rates of magma supply from the magma chamber (MSR). If  $MSR < MDR$ , the fragmentation surface rapidly migrates downward in the conduit, until fragmentation ceases and the eruption stops. MSR is strongly dependent on magma properties and conduit diameter. Conditions which favor a decrease of MSR are viscosity increase of magma during degassing and groundmass crystallization, as well as plating of the walls of the conduit crystallizing magma, thus decreasing its diameter.

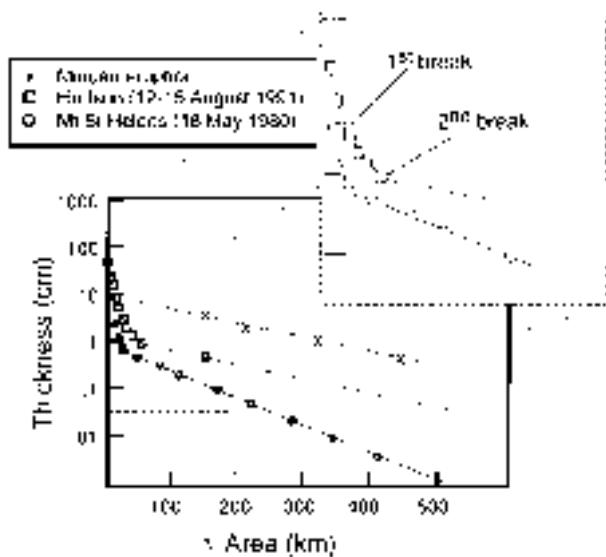

### C. Deposits

The products of plinian eruptions consist of pumice lapilli and ash forming pyroclastic fall and flow deposits. Lapilli fall deposits form thick (up to several meters) blankets over hundreds of square kilometers, while thinner (several centimeters thick) ash layers can be dispersed over thousands of square kilometers. These are well preserved in the marine sedimentary successions, and frequently provide very important chronostratigraphic markers for the correlation and absolute age determination of these sequences.

Plinian falls form sheet-like deposits generally dispersed by the wind field into elliptical fans. Only a few known eruptions have occurred under no-wind conditions, giving deposits with a subcircular distribution. Pumice fall beds are massively to crudely stratified, the stratification being always related to variations in the grain size of the deposit. Pumice vesicularity is very high and it often shows vertical variations within a deposit.

Subplinian deposits generally reveal a stronger stratification into beds of contrasting grain size and dispersal, which is often asymmetrical. Distribution of subplinian ejecta is more susceptible to external parameters such as vent geometry and low level winds. The juvenile fragments show highly variable density even within the same stratigraphic level.

The thickness of proximal to medial plinian fall deposits follows a general exponential decrease with distance from the vent (Fig. 2), often characterized by an overthickening in the most proximal areas related to the fall of ballistic material and increased sedimentation from the outer margins of the convective plume. Detailed mapping of some recent plinian fall deposits reveals that the thickness decrease with distance is well described as three line segments following at least three different exponential or power laws, valid respectively for the proximal, medial, and distal deposits (Fig. 2), as a result of different settling laws involving fragments with different size. The grain size of the deposits decreases with distance from the vent. This is particularly evident when looking at the maximum dimensions of lithic clasts rather than pumice fragments (Fig. 3). Grain-size polymodality can be related to the different terminal settling velocity of fragments with variable density (e.g., pumice vs foreign lithics), or to an efficient separation of crystals from glass during fragmentation, which results in the generation of an important population of free crystals (Fig. 4). Distal deposits consist of massive fine ash layers. The products of some recent eruptions reveals the presence of a secondary maximum (for thickness of a few millimeters) related to an increased rate of ash deposition due to aggregation and

**FIGURE 2** Variation of thickness with distance (represented by the square root of the area enclosed in the isopach of corresponding thickness). Each segment represents an exponential decay. The deposits of the August 1991 plinian eruption of Hudson volcano (Chile) clearly show three different segments, related to differences in the settling velocity of particles with distance [data from C. Bonadonna, G. G. J. Ernst, and R. S. J. Sparks (1998). Thickness variation and volume estimates of tephra fall deposits: The importance of particle Reynolds number. *J. Volcanol. Geotherm. Res.* **81**, 173–187].

subsequent increase of mean grain size of the falling particles.

Plinian and subplinian eruptions have been generally classified on the basis of their fall deposits. In the classical Walker classification scheme, the dispersal and fragmentation of the deposits (measured as two indexes  $D$ , area of the isopach enclosing the deposit with a thickness higher than 1% of the maximum thickness, and  $F$ , percentage by weight of the deposit finer than 1 mm at a distance along the dispersal axis where thickness is 10% of the maximum thickness) are used (Fig. 5). In this scheme, plinian and subplinian eruptions differ in  $D$  by two to three orders of magnitude. Recently, a new classification diagram for explosive eruptions was introduced by David Pyle based only on dispersal features of the fall deposits (Fig. 5). The thickness half-distance ( $b_t$ , the distance at which thickness decays to half of its maximum value) and clast half-distance ( $b_c$ , the distance at which the value of the maximum clast diameter becomes half of its maximum value) appear to have a more stringent physical significance than  $D$  and  $F$ .

Using stratigraphy, plinian fall deposits can be classified as simple, stratified and multiple. Simple plinian

deposits result from a continuous accumulation of pyroclasts from columns, which remain stable for several hours. A massive, generally inversely graded, deposit forms. Stratified plinian deposits result from a single, fluctuating unstable column, sometimes generating pyroclastic flows and surges, which interrupt the fall sequence. In the absence of PDC deposits, the fall sequence contains layers defined by fluctuating grain size that maintain a similar dispersal, testifying to the presence of similar atmospheric conditions during their emplacement. Multiple plinian deposits contain fall beds with different grain size, lithology, and, at times, dispersal. They result from distinct plumes formed at intervals of days or months. Time-breaks are marked by ash partings. The features of the fall layers suggest a brief duration (from several minutes to few hours) of each single eruptive pulse, implying that the feeding system was unable to reach and maintain steady conditions.

In many plinian and subplinian eruptions PDC deposits are frequently interbedded with fall deposits. They result from pyroclastic flows generated by the collapse (partial or total) of the eruptive column. In many cases, a transition from fall, to surge to flow deposits has been recognized; this sequence, however, cannot be generalized, as shown by the following examples (Sections II and III). Asymmetric (or lateral) collapse from the column margins can occur when plume density is very close to atmospheric density. Such a collapse can enhance the buoyancy of the convective part of the column, enabling stronger convection. The deposits related to such partial collapses are interbedded within the fall deposit, with no signs of interruption.

The effect of the sudden release of huge volumes of magma can alter the geometry of the plumbing system, destabilize the shallow reservoir, and induce structural collapse. Such a situation frequently increases the eruption intensity, inducing contact between phreatic fluids and magma, as well as explosive decompression of the hydrothermal system associated with the shallow reservoir. Phreatomagmatic and lithic-rich deposits frequently interbedded in plinian sequences are often generated during these phases.

## II. DIRECT OBSERVATIONS OF PLINIAN ERUPTIONS

Plinian eruptions have been observed and described in the last decades. These observations have enormously

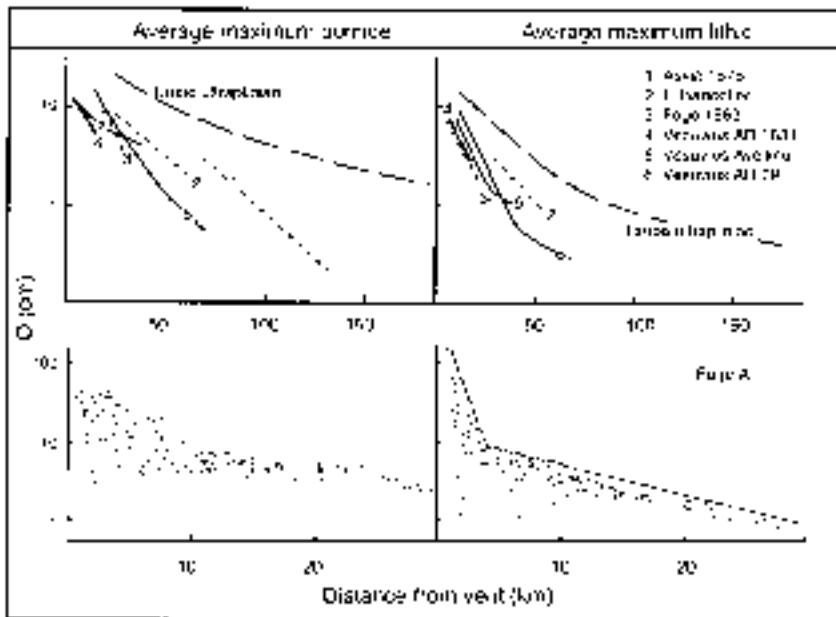

FIGURE 3 Variation with distance of the size of maximum pumice and lithic clasts for different plinian and subplinian eruptions (the ultraplinian eruption of Taupo is reported for comparison). For the Fogo A eruption of Fogo volcano, Azores, the available data show the rather wide variability in this type of data [modified from G. P. L. Walker, and R. Croasdale (1970). Two plinian-type eruptions in the Azores. *J. Geol. Soc. London* **127**, 17–55].

increased and accelerated the knowledge and understanding of eruptive processes. The Mt. St. Helens eruption of May 18, 1980, can be probably considered the trigger of this process. Although it represents a medium-to small-scale event when compared with other historical plinian eruptions it preserves all the major characteristic features of these eruptions.

The other example presented here deals with the eruption crisis of El Chichón volcano (Mexico), in 1982. It can probably be considered as an event transitional between plinian and subplinian eruptions. Its peculiarity lays in the uncommon time evolution, characterized by three major eruptive pulses that occurred over a period of several days, in contrast with the general behavior of the major plinian eruptions, which exhaust their energy in the space of a few hours.

#### A. May 18, 1980, Eruption of Mount St. Helens

The first plinian eruption entirely observed and described occurred at Mount St. Helens (United States) on May 18, 1980. The main phase of the eruption that

was followed for several months by minor subplinian events culminating with dome extrusion phases was preceded by a strong bulging of the north flank of the mountain related to cryptodome intrusion. On May 18, following a magnitude 5+ earthquake, the northern flank of the mountain failed, forming a large debris avalanche. Seconds after the first block slid, a directed blast devastated 600 km<sup>2</sup> and ash rising from the directed blast formed a convective cloud that rose to more than 30 km.

The lateral blast was followed by 9 hours of continuous magma discharge, generating an oscillating plinian column (Fig. 6) in response to flow rate variations. Four main phases have been distinguished in the climactic eruption, which are reflected in the stratigraphy of the fall deposit. The vertical plinian column required around 30 minutes to form and was preceded by a slowly growing cloud, depositing the so-called “preplinian” pumice fall and some pyroclastic flows.

During the first hour-long phase of the plinian eruption the column grew to an altitude of 16 km, forming an umbrella-shaped top near the tropopause that was subsequently dispersed by prevailing westerly winds. Some minor pyroclastic flows were observed spilling over the crater, but they did not interrupt the column.

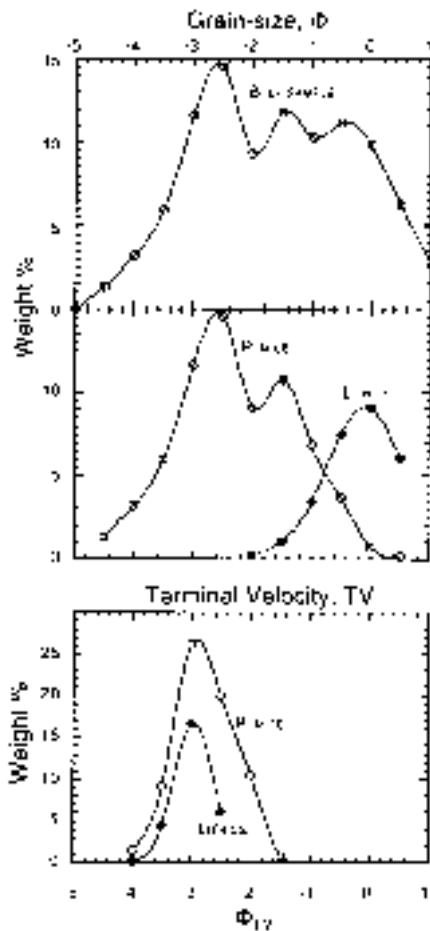

FIGURE 4 Grain-size of plinian deposits is often polymodal (upper). Such polymodality can be related to the presence of fragments with different density (middle), and is reduced by considering settling velocity of the clasts rather than their size (bottom).

During the last 30 minutes of this phase, the column appeared darker, with distinctive feathered lower edges from which large particles fell from the ascending convective cells, indicative of decreased convective power. The resulting proximal deposits consist of a lower, pumice rich, normally graded lapilli layer capped by a thinner, inversely graded lithic ash layer, suggesting that the conduit-crater system was enlarging and the minor pyroclastic flows followed by the darker column were related to lithic loading in the eruptive mixture.

For the next 75 minutes the plinian column contained lighter colored billowing cell structures, increasing its height up to around 18 km. The inversely graded pumice lapilli layer deposited during this phase accounts for the thickest and coarsest portion of the entire fall deposit. The pumice component in tephra from the entire morn-

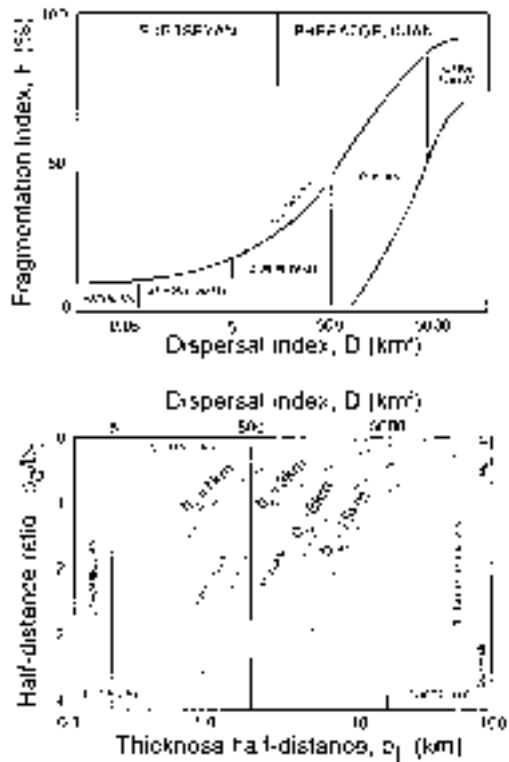

FIGURE 5 The two diagrams commonly used for the classification of explosive eruptions based on characteristics of fall deposits [modified from G. P. L. Walker (1973). Explosive volcanic eruptions—A new classification scheme. *Geol. Rundsch.* **62**, 431–446, and D. M. Pyle (1989)].

ing almost completely consists of highly vesicular, white, mafic dacitic pumice. Denser, gray clasts of silicic andesite are very rare, scattered in the deposit of the more intense, late phase.

For the next 4 hours the eruption progressed toward the formation of a collapsing fountain, which fed numerous pyroclastic flows. During this period, however, a convective cloud rivaling in height the plinian cloud was continuously present, fed by elutriation of ash from the pyroclastic flows and clast release from the fountain. This convective cloud was responsible for the deposition of two thin ash and lapilli layers in the proximal tephra sequence. Pyroclastic flow generation was interrupted, and a strong central column was reestablished for 90 min, rising up to 19 km. Another lapilli pumice layer corresponds to this phase. It shows a dispersal displaced slightly southward with respect to the underlying tephra. Mafic dacitic white pumice and up to 25 vol% of gray silicic andesitic dense scoria, together with abundant lithic fragments, form the deposit. The column then rapidly decreased its height down to 6 km and for the

FIGURE 6 View of the plinian plume of the May 18, 1980, at Mt. St. Helens [source USGS/Cascade Volcano Observatory].

final 90 minute phase minor pyroclastic flows were generated with the continuous presence of a low altitude, co-ignimbrite ash cloud.

On the basis of clast size data and volume estimates, the pyroclastic flow phase probably corresponds to the highest peak in MDR, estimated at  $4.4 \times 10^7$  kg/s. This value is an average over 4 hours, corresponding to the entire central phase of the eruption, during which the activity involved mostly pyroclastic flow generation. The phase of maximum flow rate corresponds to a maximum in magma mixing as recorded by the whole composition of pumice, and also in the largest amount of scoria of silicic andesite. This can be interpreted in terms of maximum depth of withdrawal in a vertically stratified reservoir during the phases of maximum MDR, with contemporaneous extraction of magma from different depths in the chamber.

### B. The 1982 Eruption of El Chichon, Mexico

El Chichon Volcano (Mexico) suddenly awakened in the spring of 1982 after 550 years dormancy. One month of intense seismic activity preceded the first explosive event and seismic activity shifted from 5 to 2 km depth

in the 2 days before the eruption, increasing in frequency from 25 events/day up to 60 events/hour. The eruption lasted from March 29 to April 4, with 10 explosive episodes. Only six episodes had a clear seismic signature and only four of these left major deposits. The seismic activity that followed the eruption lasted until April 16, rapidly decreased in frequency with time, and was very deep, between 12 and 20 km under the volcano.

Of the four main phases that deposited tephra layers, three had a plinian dispersal (March 29, 05.32 UT; April 4, 01.35 UT and 11.22 UT). All of the plinian plumes penetrated the tropopause and were detected by satellite. The duration of each event (respectively 5, 4, and 7 hours) was estimated on this basis. Each event was characterized by a plume dispersal in two main directions, related to opposite stratospheric and tropospheric winds. The resulting isopach and isopleth maps were asymmetrical in shape. Estimation of the column heights from field data gives peak ( $>25$  km) and mean values (respectively 20, 24, and 22 km for the three main phases) in agreement with the satellite observations, corresponding to averaged MDR of  $3.5$  to  $6 \times 10^7$  kg/s.

The three plinian phases left fall deposits of trachyan-desitic pumice whose normal grading suggests that the MDR reached a peak at the onset of the eruption and successively decreased. The deposits are not very thick; the maximum recorded thickness of tephra from the first phase (A1) is 26 cm, while the deposits from the April 4 events (B and C) are always thinner. The A layer thins out very quickly. The estimated volumes of the three events are similar (respectively 0.30, 0.39, and 0.40 km<sup>3</sup> Dense Rock Equivalent). Another episode occurred on April 3, dispersing a thin layer of volcanic coarse and fine ash. It was related to a small eruption generating a plume that reached the tropopause.

Phreatic to phreatomagmatic activity punctuated the eruptive crisis. Repeated small explosions that occurred after the first event of March 29 are interpreted as related to the interaction of external water with hot rocks and/or magma in the vent area. The larger explosion on April 3 involved (newly arrived) magma and marked the transition to the plinian activity of the following day. The 01.35 UT phase of April 4 started with the generation of debris flows, pyroclastic flows, and surge clouds, inducing the complete removal of the remnants of the ancient summit dome. These phenomena were probably related to phreatomagmatic explosions, which cleared the conduit, resulting in a transition to the plinian phase. Tephra from this phase (layer B) was characterized by a high lithic content throughout its duration, indicating a continuous erosion of the crater-conduit system. The last plinian phase, responsible for the deposition of layer

C, was again followed by phreatomagmatic pyroclastic surges.

This eruption is useful in understanding processes governing eruptive style transitions during plinian eruptions. The occurrence of three different sustained plinian columns was in this case probably related to the failure of the system to form a stable conduit–vent system. Water gained access to the plumbing system, resulting in a sequence of phreatomagmatic explosions. The largest eruption, which occurred on April 4, 01.35 UT, was unusual. A transition from fall to surge to flow deposits, generally considered a classical sequence in plinian eruptions, was not seen. The first plinian phase is in fact preceded by phreatomagmatic activity and early emplacement of PDC, while the following plinian phase shows a smooth decrease of MDR after an initial peak. Moreover, final fountaining of the column produced pyroclastic flows and surges unrelated to an MDR increase or to a drastic decrease of magma volatile content, but probably caused by a pressure reduction in the magma chamber.

The El Chichon event was the first eruption of the century with well-documented effects on climate. These effects were significantly stronger than those of the similarly sized Mount St. Helens eruption for two reasons: the column deeply penetrated the tropopause, and the tephra contained up to 2 wt% sulfates. The eruption column injected large quantities of sulfur-rich aerosol, mainly derived from  $\text{SO}_2$ , into the stratosphere. The cloud rapidly drifted around the world, at an average westerly speed of about 20 m/s, returning to Mexico after 22 days. The total amount of  $\text{SO}_2$  released was estimated at  $3.3 \times 10^9$  kg. The  $\text{SO}_2$  was converted into  $\text{H}_2\text{SO}_4$  within the 3 months following the eruption. The climatic effects were a sudden warming of the equatorial stratosphere of about  $4^\circ\text{C}$ , due to the absorption of solar radiation by the  $\text{H}_2\text{SO}_4$  aerosol, and a small decrease of surface temperature ( $0.2^\circ\text{C}$ ) in the Northern Hemisphere in June 1982.

### III. THE INVERSE PROBLEM: FROM DEPOSITS TO THE ERUPTION

A large amount of information about plinian and subplinian eruptions can be derived from the study of the pyroclastic deposits. The recent development of theoretical models on column behavior and clast dispersal enables the reconstruction of the eruption dynamics from the accurate study of the pyroclastic deposits and, where

available, from direct observations. In this section, some examples from Somma–Vesuvius will be reported, using field, compositional, and observational data to reconstruct a likely sequence of events for each eruption.

Somma–Vesuvius is a K-alkaline quaternary stratovolcano of southern Italy, with a somma caldera (Mount Somma) and an inner cone (Vesuvius). During the past 18 ka several explosive eruptions of different magnitude, including at least four plinian and six subplinian outbursts, have occurred. All the main eruptions have both plinian phases and important phases dominated by magma–water interaction, which always involves fluids hosted in the deep Mesozoic carbonate formations or in the shallow volcanic sequences. The detailed stratigraphy of Somma–Vesuvius volcanic successions is an example of how to invert volcanological data from the study of the deposits (and, whenever possible, from eye-witnesses accounts) to reconstruct the sequence of events which characterized the main eruptions and to establish links between preeruption compositional gradients in the magma chamber and variations in the eruption dynamics. Three examples of a relatively complete spectrum from plinian to subplinian eruptions from Vesuvius (Fig. 7) will be discussed.

#### A. Plinian Eruptions

The deposits of the four main plinian eruptions of Vesuvius all reflect a complex sequence of events, with opening phases immediately followed by the generation of high, sustained, columns and their partial or total collapse (plinian phase) and final phreatomagmatic phases, dominated by flow and surge emplacement following caldera collapse. More than 70% of the total volume of products is ejected during the plinian phase of each eruption. The products reflect the tapping of shallow, compositionally stratified, magma chambers. Phreatomagmatic phases that follow caldera collapse, due to the large emptying of the reservoir, are likely related to the entrance of external water into the failing magma chamber rather than to interaction during magma ascent in the conduit. The involvement of hydrothermal fluids from a thermometamorphic halo of the magma chamber is sometimes suggested by the presence of altered lithics and their fluid inclusions.

##### 1. 79 A.D. Pompeii Eruption

On 24th August of 79 A.D. Vesuvius awakened after some hundred years of dormancy, suddenly interrupting the life of flourishing Roman towns such as Pompeii,

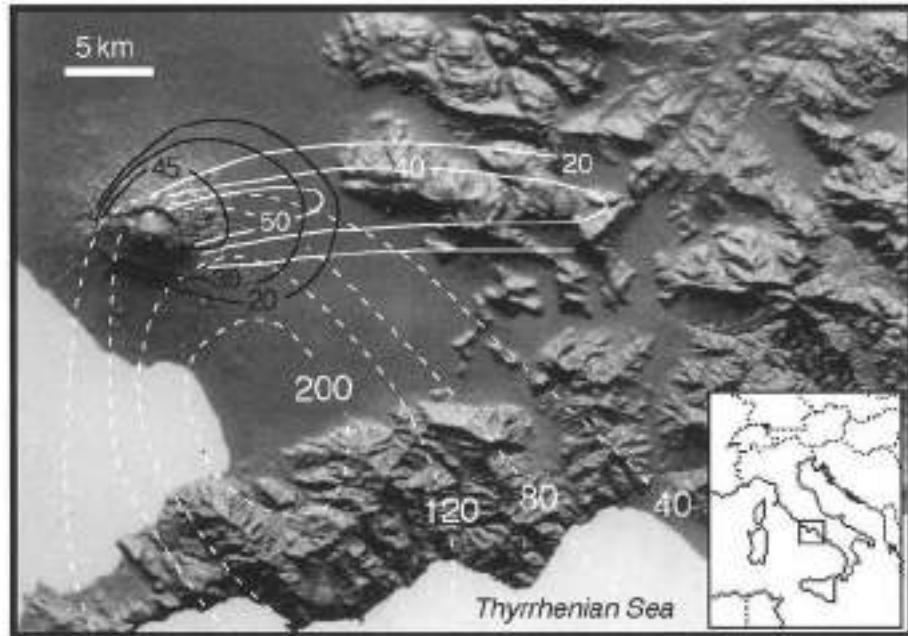

FIGURE 7 Isopachs (in cm) of the Vesuvius eruptions of 79 A.D. (white, dashed line), 1631 A.D. (white, solid line), and AP2 (black line). Note the very different scale of the three deposits [Digital Elevation Model by permission of M. T. Pareschi, CNR-CGSDA, Pisa].

Stabiae, and Herculaneum. The eruption was preceded by only modest seismic activity, except for a strong volcano-tectonic earthquake that had occurred 17 years before. According to the letters of Pliny the Younger, the paroxysmal phase lasted no longer than 20 hours, although there is uncertainty about the duration of the eruption's final stages. The deposits record a complex eruptive sequence (Fig. 8), with a thick blanket of pyroclastic fall and flow products covering the whole volcano and a wide area SSE from it (Fig. 7). Three main phases can be distinguished.

*Phreatomagmatic opening phase.* The basal bed (EU1) of the 79 A.D. deposits is a whitish-gray, fining upward, pisolithic, ash fall deposit, dispersed eastward by low-level winds, and by surge units whose dispersal is strongly controlled by the preexisting caldera walls. The fall bed can be recognized up to 20 km downwind as a thin blanket with a maximum thickness of only 15 cm. The strong fragmentation of the juvenile fragments, the high foreign lithic content and its wet depositional features suggest this bed records a first, transient phreatomagmatic phase, with an oscillating, low plume.

*The plinian column.* During this phase two composite eruption units (EU2 and EU3) were deposited (Fig. 9). They are formed by a thick sequence of white and gray pumice fall deposits, interrupted by at least five ash flow units. The white pumice of EU2 forms a SSE dispersal

fan, with a maximum thickness of 150 cm at Pompeii. It shows a symmetric, reverse to normal grading (maximum grain size at 2/3 of the bed). In some proximal sites it is topped by a thin ash flow layer marking a partial destabilization of the eruptive column just at the transition between the two different magmas. The gray pumice of EU3 has a SE dispersal, with a slight counter-clockwise rotation with respect to the EU2 axis. It forms an inversely graded layer (the lower 1/4 of the sequence) followed by a slow decrease of the grain size with minor oscillations.

In the proximal area the accumulation rate of the fall deposits can be estimated at 10–15 cm/hour. The lithic isopleths can be used to calculate the variation of the height of the column and magma discharge with time and the average wind velocity at the tropopause (around 30 m/s). White pumice shows a progressive increase of MDR (up to  $8 \times 10^7$  kg/s), resulting in the continuous rise of a convective column up to 26 km, followed by a slight decrease prior to the compositional shift to gray pumice. Following the shift in magma composition, a new, rapid increase of MDR (to  $1.5 \times 10^8$  kg/s) occurred, with the growth of a column up to 32 km. During the next 9 hours the column declined to about 17 km (MDR of  $1 \times 10^7$  kg/s).

In the southern proximal sites, the gray pumice fall contains at least four PDC units, resulting from inter-

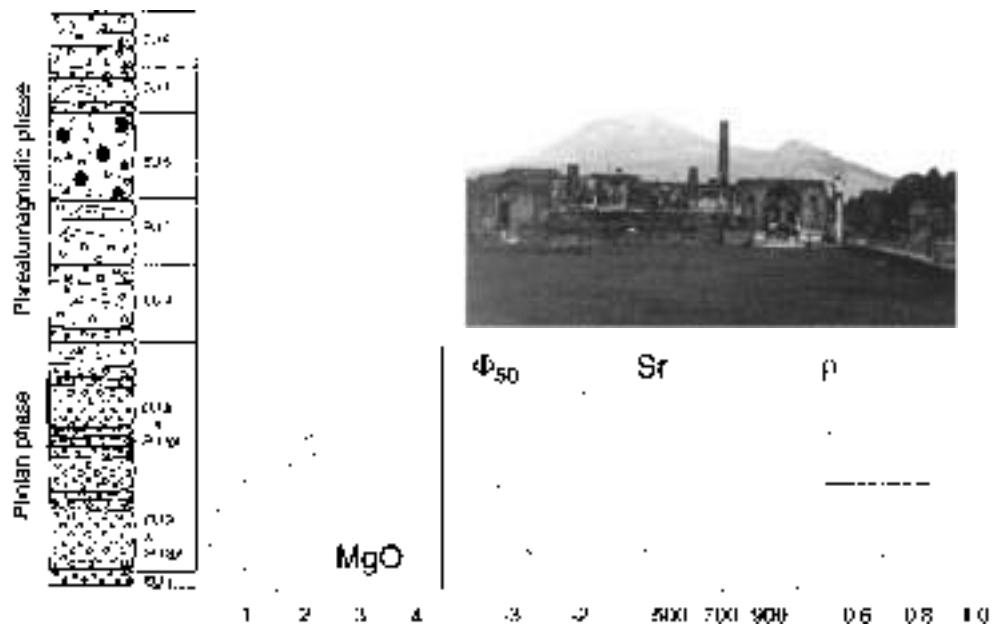

FIGURE 8 Reconstructed stratigraphy of 79 A.D. eruption of Vesuvius (in the photo Vesuvius and Mt. Somma as seen from Pompeii excavations). A nice covariation of compositional parameters (in this example MgO, wt%, and Sr, ppm) with mean grain-size of the fall deposit ( $\Phi_{50}$ ) is observed. A large density contrast ( $\rho$ , g/cm<sup>3</sup>) occurs between white and gray pumice.

FIGURE 9 The 79 A.D. fall deposit at Pompeii, topped by thin ash flow deposits. The transition between white (EU2) and gray (EU3) pumice is evident over the back of the figure.

mittent, partial collapses of the eruptive column. In the northern and western sectors, not covered by the fall deposits, these units laterally pass to pumice and ash flow deposits that are strongly topographically controlled. The fall sequence is closed by thick ignimbrites, which rapidly thin at a few kilometers from the volcano. They record the final collapse of the sustained column.

*Caldera collapse and final phreatomagmatic activity.* During this phase several eruption units were emplaced (EU4 to 8) by phreatomagmatic explosions. Such units consist of PDC deposits with rare, thin, lithic-rich, fall interbeds. They are characterized by a high lithic content, with abundant xenoliths from deep-seated rocks. The ubiquitous presence of highly fragmented limestones suggests that magma–water interaction involved the deep, regional aquifer. Marbles and skarns from the external carapace of the magma chamber suggest that the interaction occurred at deep levels after the destabilization of the magma chamber. The lithic content increases upward, where pisolite-bearing ash beds and vesiculated tuffs are prevalent, suggesting that the phreatomagmatic character of the deposits increases from the base to the top of the sequence.

Lithological and sedimentary features of the lithic-rich bed EU4 suggest derivation from the emplacement of a widespread, turbulent PDC, with a radial distribution around the vent, reaching distances of at least 15 km in the southern plain, which was preceded by a short-lived phreatomagmatic convective column. The strong earthquake and the dark cloud witnessed by Pliny the Younger on the morning of 25 August could correspond to this event. This unit represents the starting of a “caldera-forming phase” in the eruption, culminating in the paroxysmal collapse of the feeding system recorded by the deposits of EU6, on the SE slopes of the volcano. Their areal distribution and lithic type and content suggest eruption from the caldera ring fracture. Protracted withdrawal from the magma chamber, favored by magma–water interaction, led to the tapping of the more mafic crystal-rich melt during the emission of EU7 pyroclastic flow deposits. The waning stages of the eruption are represented by wet, phreatomagmatic, ash-rich pyroclastic flows (EU8).

*Geochemical features of the products.* The plinian phase is represented by a compositionally zoned pumice fall deposit, consisting of white, phonolitic, and gray, tephriphonolitic pumice. EU8 shows a sharp compositional reversal toward the more salic compositions that characterize the initial phase of the eruption (Fig. 8).

The geochemistry of the erupted products has been interpreted in terms of important syneruptive mixing processes. All the products result from admixing of three

end members: a salic end member (the white phonolitic pumice), a cumulate end member supplying mafic crystals (mainly diopside and phlogopite), and a phonotephritic mafic end member, never erupted without being mixed. This situation suggests a magma chamber stratigraphy characterized by a lower, homogeneous, convective phonotephritic magma overlain by a stratified, phonolitic liquid.

A nice relationship exists between composition of tephra erupted during the plinian phase and median grain-size of the deposits (a proxy to illustrate MDR variations), suggesting the tapping of different portions of the magma chamber by varying the MDR, with variable proportions of mixing between the different liquids in the reservoir.

During the white pumice fall, the increase in MDR extracted progressively deeper magma, “reversing” the compositional gradient in the upper portion of the chamber. The first destabilization of the column occurred as a consequence of the onset of an extensive mixing between phonolitic and phonotephritic magmas, which produced an important change in the rheological properties of the erupting liquid. By this time the products had drastically changed composition (mixed gray pumice).

During the gray pumice fall a progressive transition from physical mingling to complete chemical hybridization occurred. Most of the mixing occurred inside the magma chamber. The MDR fluctuated, extracting mixed magma from different depths in the chamber. Initially, the amount of white magma physically mixed in the gray pumice decreased with increasing MDR, but, after a few hours, the mixing inside the chamber went to completion and the erupted products consisted of truly hybrid pumices regardless of MDR and depth of withdrawal. As the eruption proceeded caldera collapse occurred. The structural modifications and the massive influx of external fluids, gases, and water into the plumbing system changed the eruption dynamics, and magma extracted during the phreatomagmatic phase was relatively heterogeneous due to the highly variable content of cumulate crystals from the collapsing walls as well as to the extraction of white magma pockets left untapped and not mixed roofward.

## B. Subplinian Eruptions

Several eruptions of Vesuvius had magnitudes in the range 0.5–0.05 km<sup>3</sup>, and most of the mass was ejected during phases of low intensity (MDR around 10<sup>6</sup> kg/s),

sustained column activity. They are therefore referred to as subplinian. The deposits of each eruption show a range of features varying with eruptive magnitude. The largest events show both fall and flow deposits. Fall deposits are variably stratified, ranging from massive beds with minor grain-size oscillations to strongly stratified alternations of lapilli and ash layers, which reveal a recurrent unsteadiness in the magma discharge. Pyroclastic surges and phreatomagmatic, lithic-rich pyroclastic flows occur frequently during these major events. PDC are not common in the minor subplinian eruptions. The phreatomagmatic phases of subplinian eruptions generally occur during the final stages of the sustained column. The phenomenon is a "classical" magma–water interaction in the conduit, triggered by pressure drops in the ascending mixture, in contrast with the catastrophic phases of caldera collapse that provoke magma–water interaction during plinian eruptions.

A clear distinction between plinian and subplinian deposits on the basis of their dispersal and fragmentation indices is not simple at Vesuvius (and probably anywhere). Two events have been selected to show the variability of the dynamics of Vesuvius subplinian eruptions, 1631 A.D. and AP2, which occurred around 3200 years ago. They well represent the end members of this variability.

### 1. 1631 A.D. Eruption

The biggest explosive eruption of the past 500 years at Vesuvius occurred in 1631 A.D., claiming more than 3000 lives and heavily damaging a large area around the volcano. The eruption started on December 16, with 30 hours of heavily destructive activity. The eruption continued to the end of December with intermittent moderate steam blasts. The depositional sequence consists of five main units. These have been related to distinct phases of the eruption.

*Opening phase.* Shortly after a strong earthquake, a fracture opened in the WSW sector of the cone with the violent discharge of gas, ash, and incandescent material, forming a progressively rising cloud. The deposits consist of a few-centimeters-thick, inversely graded, crystal-rich, ash to lapilli fall layer. The very low content of fine ash suggests its efficient removal by wind, while the fine-grained, inversely graded deposit indicates settling from a low yet progressively rising plume. The fine grain size and the abundance of loose crystals and lithics suggest the involvement of external water.

*Sustained column phase.* The vent migrated to the central crater and a sustained eruption column fully devel-

oped. It remained stable for 8 hours, causing significant downwind tephra fall. The deposits consist of well-sorted, subangular scoriaceous lapilli, with minor lithics and crystals, forming an elliptical fall blanket. The eastward, strongly elongated shape of the deposit (Fig. 7) indicates strong winds driving the dispersion of the cloud, as well as the relatively weakness of the plume. The subplinian fall layer is marked by a sharp darkening upward of juvenile clasts, reflecting a compositional variation from lighter tephriphonolite to darker phonotephrite. The fall deposit is variably graded, reflecting a slight counterclockwise rotation of the dispersal axis of the dark fall in respect to the light one. The crosswind range of the maximum lithic isopleth expands from light to dark fall, suggesting an increase of the column height, from 13–16 to 19–21 km, respectively. The variations in column height reflect variations in MDR from 1 to 1.5 and 8 to  $9 \times 10^7$  kg/s for the light and dark fall phases, respectively.

*Intermediate pulsating "vulcanian" phase.* A series of seismic shocks and violent detonations characterized the night between the 16th and the 17th and the morning of 17th, with short resumption of lapilli and ash fall. Heavy rains induced lahars from the northern slopes of Monte Somma. The fall deposits have very limited distribution and small volume. On the Somma rim they consist of poorly sorted block, lapilli, and ash breccia (50 cm thick) very rich in lithic material. The breccia is remarkably indurated, suggesting that ash was deposited as wet or muddy. It has been interpreted as a compound fall layer from several discrete explosions of variable energy, involving partly degassed magma as well as external water.

*Phreatomagmatic phase.* According to a recent reconstruction, at 10–11 am of December 17 an enormous mass of ash, gas, and stones was spewed from the central crater and poured down the Vesuvius cone, being confined inside the Somma caldera. At the same time a violent, 5 minute-long, earthquake shook the volcano and was felt as far away as Naples. Descending toward the sea the glowing cloud spread and divided into several lobes (Fig. 10). This activity had possibly 2 hours duration and coincided with the structural collapse of the cone (470 m of lowering). It generated massive, valley filling, lithic-rich, ignimbrite deposits and thin pyroclastic surge deposits draping the upper slopes of the cone as well as part of the Somma rim.

On the afternoon of December 17, light clouds slowly rose from the crater and a muddy, pisolite-bearing, fine ash fall started and continued intermittently for several days. Condensation of water on ash particles produced persistent torrential rainfalls, triggering a series of la-

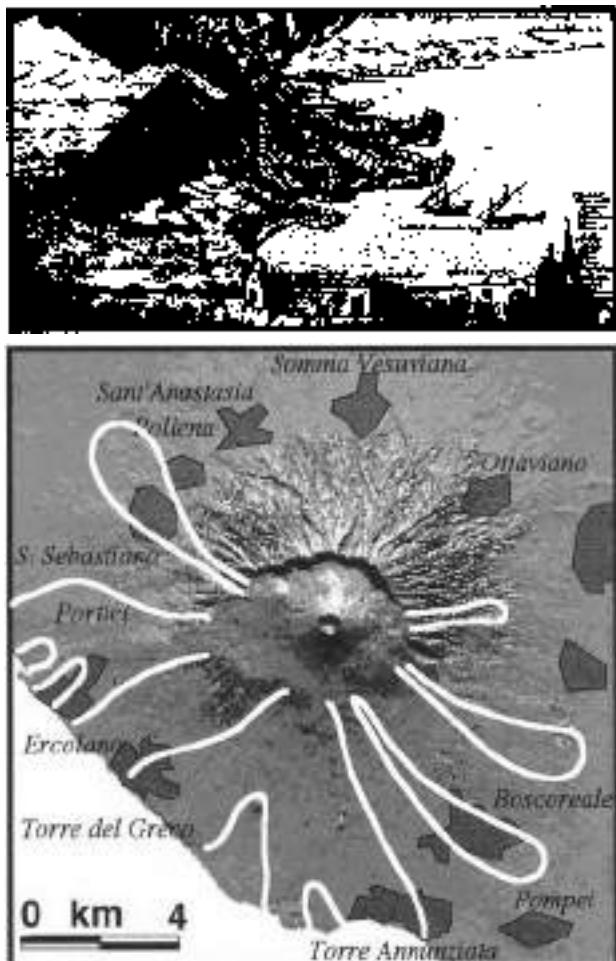

FIGURE 10 The pyroclastic flow deposits of the phreatomagmatic phase of 1631 A.D. eruption of Vesuvius. The distribution of the different flow lobes was strongly controlled by the preexisting caldera wall, as also suggested by a contemporaneous engraving (upper) showing a view of the eruption from Naples [modified from Rosi et al. (1993)].

hars, hyperconcentrated flows rushing down the volcano flanks and the mountains ENE of Vesuvius. Extensive flooding occurred.

This reconstruction of the 1631 eruption is not unanimously accepted. The main controversies concern the timing of pyroclastic flow emplacement and their origin from column collapse, and the existence of an effusive phase of the eruption on December 17–18.

## 2. AP2 Eruption

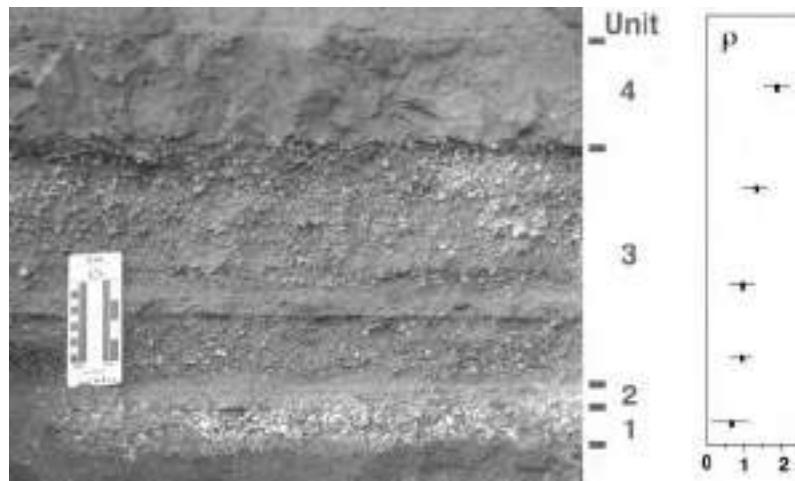

The period between 3500 years BP and 79 A.D. was characterized by several minor events ranging in size

from subplinian (AP1, AP2) to strombolian–vulcanian (AP3, AP4, AP5).

The stratigraphic sequence of AP2 deposits is complex (Fig. 11), and the deposits are dispersed in a subcircular, asymmetrical fan, off-axis from the present crater (Fig. 7). A basal fall bed of phonolitic pumice (Unit 1) is followed by fall ash and minor surge deposits (Unit 2) limited to the more proximal areas. Three beds of massive to thinly stratified, tephriphonolitic fall lapilli with several ash interbeds form the upper layer (Unit 3). Sorting of these beds is poor, suggesting deposition from ash-rich eruptive columns and an important unsteadiness in the magma discharge. An increasing importance of magma–water interaction can be inferred by the increasing amount of altered lithics in the topmost portion of the deposits, closed by the pisolite-bearing ashes (Unit 4). The mean density of the juvenile fragments regularly increases toward the top of the sequence (Fig. 11). Vesicle size and shape vary from the strongly elongated, tubular vesicles of pumice from Unit 1, to the more irregular bubbles in scoria from Unit 3, to small, largely spaced, spherical bubbles of shards from Unit 4. All these features, and the ubiquitous presence of alteration on glassy surfaces of juvenile fragments from Units 3 and 4, suggest that fluctuations in the MDR, revealed by the stratigraphy of the deposits, were probably associated with important, conduit related, magma–water interaction processes.

We infer that a highly efficient syneruptive degassing, as suggested by the tubular shape of the bubbles, resulted in a brief, relatively high MDR ( $10^5$ – $10^6$  kg/s) phase, leading to the establishment of a sustained, quasi-steady subplinian column from which Unit 1 deposited. The alternation of lapilli and ash fall beds in Unit 3 is a typical feature of several subplinian deposits, which are generally interpreted as the repetitive rising of short-lived sustained columns, each depositing thin lapilli layers and ash.

The presence of dense and vesicular fragments in the same stratigraphic levels could suggest both enhanced fragmentation by magma–water interaction and a relatively high MDR associated with a low magma supply rate from the chamber, which induces a rapid downward migration of magma fragmentation toward zones with lower vesicularity. Both these processes could concur in determining the fragmentation mechanism. Rapid drawdown of magma could in fact induce a parallel decrease of pressure in the conduit, causing the contact between phreatic water and fragmenting magma. Involvement of water during such low MDR eruptions could have boosted the eruptive column, increasing the dispersal of the ejecta.

**FIGURE 11** The deposits of AP2 eruption, showing the characteristic stratification related to grain-size oscillation. The continuous increase in density ( $\rho$ ,  $\text{g}/\text{cm}^3$ ) of the juvenile material is interpreted as an evidence for an increasing phreatomagmatic character of the eruption.

#### IV. DISCUSSION OF ERUPTION DYNAMICS

The reconstruction of past eruptions is important if we want to gain insights both into the eruptive process and preeruptive and syneruptive conditions, which determine the onset and progress of a large explosive eruption. All these topics can be tackled by studying the sedimentological, physical, and geochemical features of the products of past eruptions, with the important integration, when possible, of information from direct observations. The examples described above and the analytical data on their deposits offer a database of the different kinds of information we may obtain.

The comparison of plinian and subplinian eruption sequences also allows an understanding of the gradation existing between these two eruption styles. The examples from Vesuvius can help in this goal, because a quite complete gradation between these styles exists in the recent activity of this volcano.

##### A. Constraints from Physical and Geochemical Analyses of the Products

The sequence of events of an eruption is recorded by the stratigraphy of its deposits. The products related to a plinian eruption very often comprise both fall tephra and PDC deposits. Proximal stratigraphy is a fundamen-

tal tool for interpreting and reconstructing the dynamics of the eruption, especially when partial column collapses generate flow deposits which very rapidly thin out from the vent area. Marker beds help in subdividing the deposit in isochronous intervals. Maxima in grain size, lithic enriched layers, and ash interbeds can all represent isochronous markers in the field. The eruption sequence can be reconstructed from the study of the layers sandwiched between these markers.

This approach can trace variations in the dispersal of the fall deposits that are essentially due to column height and wind strength and direction, two factors that can change rapidly during a plinian eruption. Each layer can provide information about the variations of physical parameters such as MDR (from tracing the isopleth of maximum clasts) and exit velocity of the eruptive mixture (from the dispersal of the largest ballistics), the main parameters controlling the stability of the eruption column (Fig. 12). Geochemical and petrologic data of well-constrained eruptive sequences give additional information on eruption processes. Analyses of whole-rocks, melt inclusions, residual glass matrix, and the isotopic composition of separated minerals and matrix allow the reconstruction of the preeruptive condition of the magma chamber and the definition of syneruptive mixing processes and their relationship to eruption dynamics. This is particularly clear in fall deposits, where total grain size and maximum lithic size give insights on the temporal variation of MDR. In general, the compositional gradient observed in the products is not a simple reversal of the gradients in the magma chamber. During

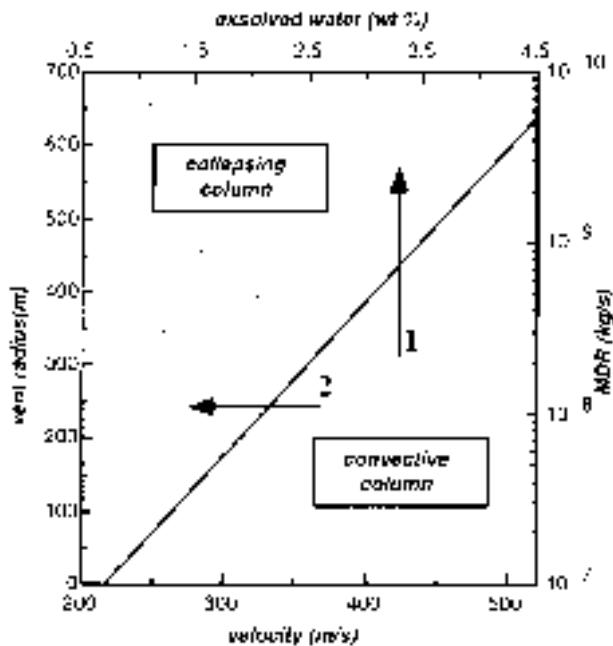

FIGURE 12 Stability of an eruption column (for a rhyolitic magma) as a function of magma discharge rate (MDR), vent radius, exit velocity of the erupting mixture and amount of exsolved water. Starting from convective conditions, column collapse can be achieved through MDR increase (path 1, as generally occurs during ignimbrite-forming eruptions), or by extraction of a magma progressively depleted in volatiles (path 2, generally followed by plinian eruptions fed by small-sized, compositionally zoned, magma chambers) [modified from Wilson *et al.*, (1980)].

an eruption, complex mixing depends on combinations of discharge rate, magma density and viscosity, and the shape of the magma chamber. All these factors affect the dynamics of the eruption column.

In low aspect ratio (height versus width) chambers, the depth of withdrawal is directly correlated to the fourth root of MDR. Larger MDR values correspond to deeper magma tapped in the chamber and, if the magma chamber is zoned, to the extraction of less evolved compositions. Numerical models define, for specific geometric and rheologic factors (size and shape of the magma reservoir, relative dimensions of the reservoir and the conduit system, magma density and viscosity) the evacuation isochrons, representing the "locus of points in two-dimensional space such that magma parcels along a given isochron arrive at the entrance of the volcanic conduit concurrently" (Fig. 13). In these models, magmas from different depths arrive simultaneously at the entrance of the volcanic conduit where the local mixing can be very efficient, due to the turbulent

regime of flow. In a layered magma chamber, portions of magma with different composition are tapped simultaneously, causing syneruptive mixing. Depending on thickness and rheology, the extent of mixing is affected by the dynamics of the extraction. Sudden changes in MDR affect the composition of products and can result in compositional gaps even in the case of a gradually zoned reservoir. All these processes can occur within the draw-up cone and the conduit, but efficient syneruptive magma mixing can also occur inside the magma chamber, as demonstrated for the Pompeii eruption. Initially mingling produces banded pumices. Complete hybridization requires more time and is easier if mixing starts inside the magma chamber. Magma vesiculation following decompression of the reservoir determines the increase of instability of the interface separating different layers of a stratified magma chamber, and a sudden large-scale turbulent mixing which involves the entire volume of the magma chamber. These syneruptive processes are not only reflected in compositional variations of the erupted products, but also strongly affect the dynamics of the eruption.

Stratigraphic relationships and the sedimentological features of the flow deposits interbedded in the plinian fall sequence are important to discriminate partial collapses of the eruption column from fountaining phases. Large plinian eruptions often show a progressive shift from phases of sustained convective column to continuous fountaining, generating widespread ignimbrites. This behavior seems to fit a general model of an increasing flow rate achieved by a progressive enlarging of the conduit (Fig. 12). The Campanian Ignimbrite and several eruptions of Vico and Vulsini in central Italy are

FIGURE 13 Extraction isochrons from a magma chamber as derived from numerical models. During an eruption, deeper portions of the magma chamber are progressively withdrawn; after  $t_2$ , an important syn-eruptive mixing occurs, with the involvement of increasing amounts of the lower (mafic) magma.

well known examples of this type of eruption. On the contrary, the extraction of magma from the small-volume, zoned reservoirs which characterize smaller plinian eruptions (for example those at Vesuvius) are characterized by magma progressively poorer in volatiles. This may result in the formation of a collapsing fountain at the end of the eruption, with the emplacement of small volume PDC.

Plinian eruptions of alkaline magmas often show a progression from magmatic to phreatomagmatic phases (good examples are the eruptions of Vesuvius and those at Laacher See, in West Germany). These eruptions largely evacuate magma chambers, leaving more mafic magma residuals. In this case, the collapse of the shallow reservoir provokes external fluid intervention. During these final phases, volatile-poorer mafic magma and pieces of the cumulate and metasomatic shell of the chamber are efficiently propelled out of the vent from the action of the residual magmatic gases and the phreatic fluids. The Vesuvius examples indicate that hydro-magmatism involves the contact between water and primarily fragmented magma, suggesting that, in these final phases, magmatic gases also played an important role.

Plinian eruptions of calcalkaline composition generally end with dome emplacement, sometimes followed by dome disruption during minor subplinian or vulcanian activity (as in the case of the 1980 Mount St. Helens eruption). This may reflect the generally higher viscosity of calcalkaline magmas with respect to their alkaline counterparts and their generally lower total volatile content. Furthermore, syneruptive variations in the total volatile content or small differences in magma crystallinity, driven by syneruptive degassing, leave high viscosity residuals, favoring a slow rise of these evolved melts.

## B. Gradation between Plinian and Subplinian Activity

Plinian and subplinian eruptions show a continuous gradation in MDR and magnitude. Eruption dynamics are dominated by the rise of convective plumes of varying duration and height (Table I). The variability presented by plinian fall deposits is mirrored in subplinian deposits. The two Vesuvius examples above can be described as simple (1631 A.D.) and multiple-stratified (AP2) fall. The 1631 A.D. represents the upper limit of subplinian events of Vesuvius. It could be also considered a small plinian event, with low MDR and erupted volume, marked by column collapses and phreatomagmatic events. On the contrary, the strongly stratified character of AP2 depos-

its is more similar to most subplinian deposits (e.g., eruptions of Mono Craters (California), to some eruptions of the Azores and to the 1980–1981 postclimactic eruptions of Mount St. Helens). These are typical of the subplinian events in which pulsatory behavior is the most distinguishing feature.

In subplinian eruptions, columns are weakly or discontinuously sustained, resulting in several eruptive pulses separated by periods of days to months, or in the unsteady but continuous feeding to a convective, oscillating column. Longer pauses between the different pulses characterize those eruptions with calcalkaline compositions. In such cases, each pulse is often associated with dome growth and destruction, revealing an important control of volatile content and rheology of magma. The frequent presence in these deposits of degassed clots of magma, with a high content of ground-mass microlites, is generally interpreted as related to low rise velocity of viscous magma which determines conditions of open degassing.

Pulsating subplinian eruptions of Vesuvius are instead characterized by numerous instabilities in the MDR, without long pauses. This could reflect the different response of alkaline magmas to decompression during rise, where lower viscosity inhibits the formation of rigid plugs and domes and favors more rapid changes of the eruption style in response to differences between magma rise and magma discharge. The very different rheological properties of alkaline and calcalkaline magmas must be kept in mind when discussing subplinian eruption mechanisms.

## GLOSSARY

- accretionary lapilli** Aggregates of fine ash, commonly having a concentric structure and formed by accretion of damp ash in eruption clouds.
- armoured lapilli** Lapilli coated with one or more complete or partial layers of accreted fine ash; essentially a variant of accretionary lapilli.
- cock's tail jets** The common type of tephra jet, with an arching, multifingered form likened to the shape of a rooster's tail.
- continuous uprush** Sustained phreatomagmatic eruption column that is fed by ongoing or closely spaced explosions.
- frittering** Erosion of particles from a vent wall by rushing gases.
- pseudo-ballistic lapilli** Lapilli deposited individually by fall

from a plume that form impact sags similar to those from true ballistics transported by momentum.

**spall dome** Subhemispherical gas-driven shock zone expanding outward from a subaqueous explosion.

**tachylite and sideromelane** Basaltic glass. Sideromelane is translucent; tachylite is cryptocrystalline and opaque as a result of microlite crystallization and is inferred to result from slightly slower chilling.

**tephra jets** Discrete ejections containing tephra and steam driven by steam expansion and momentum of large clasts.

**vesiculated tuff** Tuff containing open, fluid-form spaces among the fragments reflecting entrapment of air in wet fine-grained ash.

**T**HE 1963 ERUPTION of Surtsey brought dramatically to the attention of the volcanological community the explosive influence of water on the eruption style of otherwise effusive or only mildly explosive eruptions. Similar eruptions have occurred both at other emergent volcanoes that have grown through water during eruption and at fully subaerial volcanoes to which water had access via streams or aquifers. This chapter uses information from these observed small-volume phreatomagmatic eruptions to show how the entrance of water into the vent of an erupting volcano affects

fragmentation processes and pyroclast populations, ejection and dispersal of tephra, and depositional processes and features. Related chapters discuss mechanisms of phreatomagmatic fragmentation processes (see Phreatomagmatic Fragmentation) and larger scale phreatomagmatism (see Phreatoplumian Eruptions).

## I. DEFINITION

George Walker first applied the term *surtseyan* to a group of fine-grained and locally dispersed pyroclasts inferred to be the phreatomagmatic equivalent of hawaiian and strombolian deposits. Since then some authors have expanded the term to encompass virtually all phreatomagmatic deposits, while others have restricted it to only those eruptions that closely resembled Surtsey, introducing additional descriptive terms, such as taalian, for other styles of pheatomagmatism. This chapter is not the place to propose a new or modified nomenclature for eruption styles and its focus is *all* small-scale phreatomagmatism, that is, the weakly energetic interaction of generally small volumes of magma with external water in a range of environments. We start by reviewing the classical 1963–1967 eruption of Surtsey volcano in Iceland, but the discussion that follows extends to many other phreatomagmatic eruptions in a range of settings.

## II. THE SURTSEY EXAMPLE

Surtsey's eruption was extensively observed and recorded by geologists, and Sigurdur Thorarinsson brought together many observations, photographs, and an informed interpretation of events in the book *Surtsey: The New Island in the North Atlantic* (1967, Viking, New York), from which all quotations in this section are taken. The eruption lasted a total of about 1300 days during which  $>10^9 \text{ m}^3$  of magma was erupted from five clusters of vents along NE trending fissures. The activity passed through submarine and marginally emergent phases and ended in a period of strombolian and hawaiian activity.

### A. Subaqueous Explosions and Emergence from the Sea

Surtsey's eruption began some 100 m below sea level on the seafloor south of Iceland and proceeded unno-

ticed until the volcano had built to perhaps 10 m below the surface. On 14 November 1963, black eruption columns rose just above the sea's surface. The tephra columns soon reached a height of 200 feet (66 m), rising out of the sea in two or three separate places. The eruption was notably silent. A large circle of whitened water lay around the vent, representing a zone of agitation containing vapor bubbles, and long-wavelength concentric waves traveled away from the vent. By the next morning Surtsey had emerged from the sea and was in fairly constant eruption.

Three sets of satellite vents to Surtsey (Surtla, Syrtlingur, and Jolnir) were also observed as they shoaled. Prior to emergence, broad, low-relief tephra mounds were visible near the surface. The mound surfaces accreted tephra from the varied eruptive activity and were disturbed both by normal sea waves and concentric eruption-generated waves. Initial observations of the Surtla vent took place when the mound had closely approached the surface and eruptive activity began to produce turbulence in the water. Steam was reported rising from the sea the next day and

*... the sea showed considerable signs of unquietness ... a short way under the surface—our guess was 2 feet (0.66 m)—three small vents were active in about an 820-foot-long fissure (269 m) ... When we flew very low straight above these new vents quick flashes from fire under the surface could be seen at intervals of half a second, causing abrupt concentric waves all around that made the sea look like quivering jelly. Occasionally steam columns rose above the surface, and in between there were black outbursts of tephra which ejected columns ... highest reached a height of 160 feet (52 m). (Thorarinsson, 1967, p. 21; Fig. 1 of this chapter).*

The eroded remnant of Surtla, 40 m below sea level, was later found to hold plastically deformed clasts and abundant tachylite grains.

Turbulence in the surface waters at the Surtsey vents probably represented agitation of the water surface by hot, convecting water, whereas steam rising above the water indicated passage of vapor bubbles through the water surface. The whitened circles of water surrounding vents during explosive eruption are interpreted as spall domes intersecting the surface; the circles thus represented the zones within the primary pressure waves (shock waves) generated by the explosions (Fig. 2). Slightly later, subaerial tephra jets joined with the turbulence and steam, fed by subaqueous tephra jetting, the result of explosive phreatomagmatic disruption of magma at shallow depths. Vigorous tephra jets from vents slightly below the surface had sufficient momen-

**FIGURE 1** Photograph of tephra jets from slightly submerged Surtla vent representing the earliest phase of volcano-building observed during the eruption of Surtsey. Note the change from dark base to pale tips of the jets, due to steam condensation, and their spreading form. A base-surge of steam spreads outward above agitated, whitened water resulting from intersection of a spall dome with the water surface. [Reprinted with permission from Thorarinsson, 1967.]

tum to clear the water surface. Less vigorous ones lost momentum before breaching the surface but generated sufficient steam, as the jet collapsed and fragments directly contacted the surrounding water, to feed a vapor column rising through the surface. Hot fragments continued to generate steam even after deposition, as indicated by steam from a subaqueous crater rim. Weaker, intermittent bursts agitated the water and sent heated pockets of water to roil the surface, but the steam generated from the bursts was recondensed in the cold ambient seawater before reaching the surface.

Explosive, phreatomagmatic fragmentation is indicated by the subaqueous incandescent flashes noted at Surtla and the subaqueous explosions at all the vents. The subaqueous flashes are interpreted to have been caused by explosive disruption of large lumps of incandescent magma by phreatomagmatic explosions. Shock waves and outward-traveling concentric surface waves were seen at each vent during shoaling. Explosion-induced shaking likely caused local failure of the growing edifice, displacing variably sized parts of the mound downward along local slips. The main effects of the shocks were to agitate the water, generate vapor bubbles, and initiate concentric surface waves.

Wide craters, as observed at Surtla and perhaps at

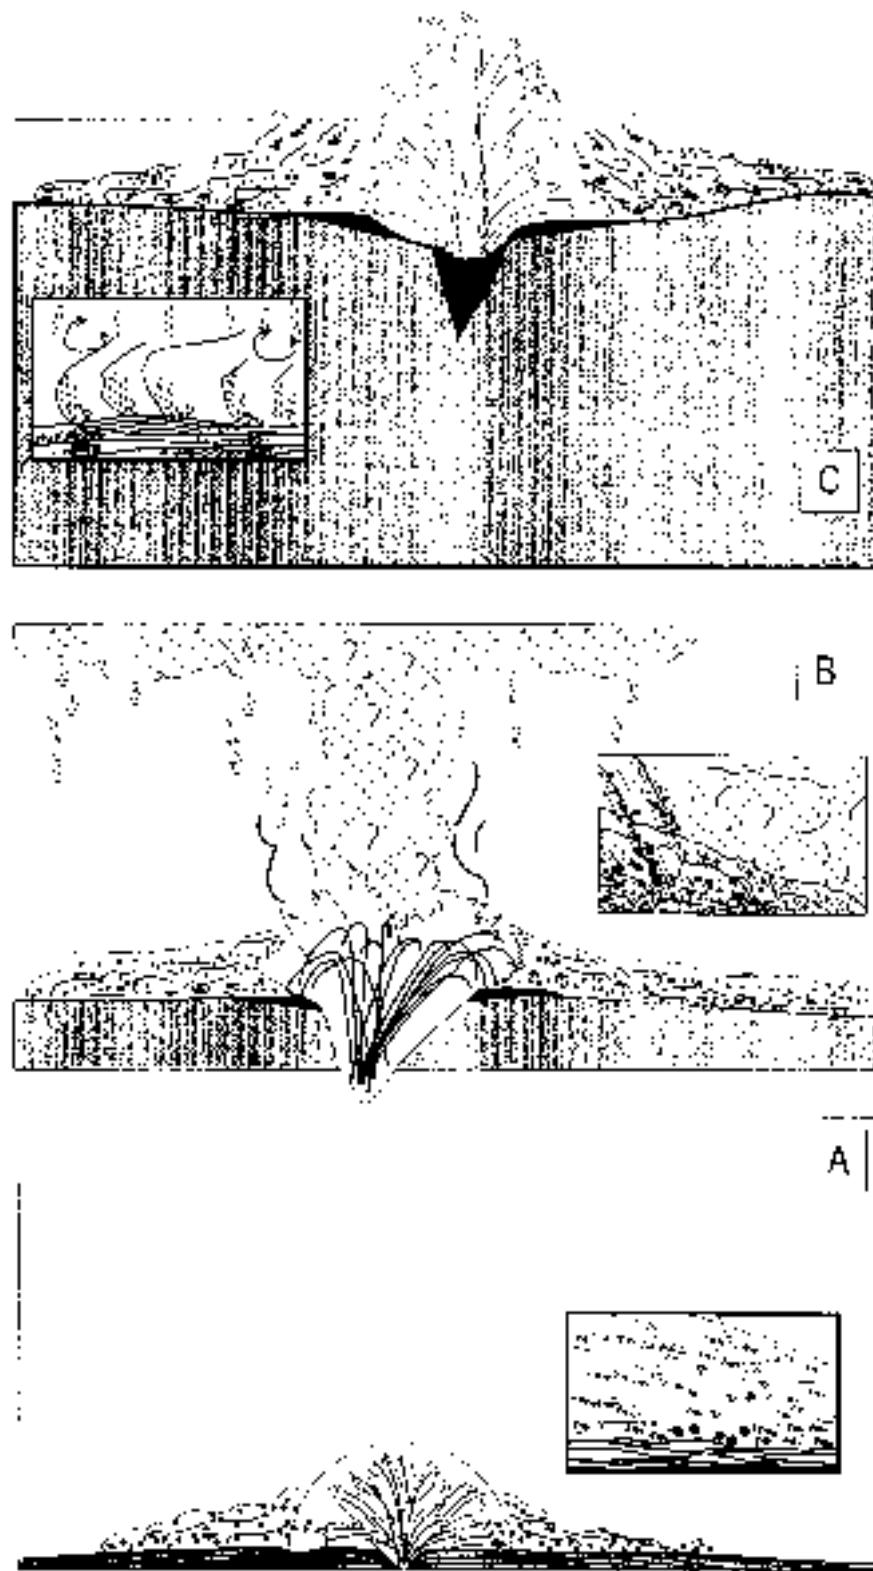

Jolnir, would have accumulated a tephra slurry by fall-back from nonbreaching jets. This *almost emergent* phase of edifice construction, in which emergent eruptive activity is commonplace, lasted for more than 2 weeks at Syrtlingur vent. Including the period during which emergent eruptive activity precedes *lasting* edifice emergence, the time can run to months for single vents (Surtsey itself and the Syrtlingur and Jolnir satellite vents) to decades or longer.

The presence of tachylite grains and plastically deformed clasts suggest that direct magma–water contact was not ubiquitous during the growth of Surtla. These features indicate development of a steam cupola during eruption that shielded much of the erupting tephra from the surrounding water.

### B. Emergence from the Sea

Once Surtsey built above the sea, Thorarinsson (1967) noted

*... two clearly discernible types of activity. When the sea had an easy access to one or more of the vents ... the activity was the typical one for submarine eruptions*

**FIGURE 3** Photograph showing differing eruptive activities from adjacent vents at Surtsey. To the left is a maintained plume of the sort formed by continuous uprush activity. Cock's tail tephra jets occur to the right of this plume, lofting black tephra along subballistic trajectories with condensing vapor forming white moisture laden steam at the margins of the jets. Billowing convective steam clouds form a backdrop. [Reprinted with permission from Thorarinsson, 1967.]

*... After each explosion a tephra-laden mass rushes up, and out of it shoot numerous lumps of liquid or plastic lava, called bombs, each with a black tail of tephra. Within a few seconds these black tails turn grayish white and furry as the superheated vapor ... cools and condenses. (pp. 17–18)*

Such activity from a flooded vent is termed *tephra jetting*, or *cock's tail* plumes (see Fig. 3). In contrast,

*continuous uprush activity was linked with tephra accumulation that blocked seawater from pouring into the vent.*

*Instead of intermittent explosions the uprush of vapor and tephra was then continuous ... at the base of the eruption column the speed of the uprush was about 400 feet per second. The black columns of tephra frequently reached half a mile in height ... accompanied by a heavy rumbling noise. The tephra production from such*

**FIGURE 2** Diagram illustrating inferred subaqueous development of a surtseyan volcano. The top and bottom of each frame represent the sea surface and the seafloor. (A) Early, fully subaqueous jetting activity. Explosions and collapsing jets produce a turbulent, dilute gravity flow having strong temperature contrasts and moving unsteadily outward from the vent. Deposition takes place largely from traction under unsteady flow conditions, but occasional ejection of the vent slurry or collapse of unusually concentrated tephra jets forms high-concentration dispersions that deposit more massive beds. (B) The tephra pile (stippling) is shallowing. Vigorous, more-sustained activity produces local water-exclusion zones at the vent margin in which clasts are transported in part through steam. This results in deposition of armored lapilli and tachylitic clasts having impact sags. Most ejecta are not deposited at vent margins, but are carried laterally in sediment gravity flows. Fragments of marine sediment may result from quarrying into the seafloor during this activity. (C) The volcano has now grown into shallow water (asterisks denote wavebase), and wave-influenced sedimentary structures begin to form during deposition. Jets are intermittently emergent (e.g., Fig. 1). Gravity flows carrying tephra outward along the volcano's surface interact with oscillatory currents beneath ambient surface waves and longer wavelength concentric waves induced by the eruption. [After White, J. D. L., 1996, Pre-emergent construction of a lacustrine basaltic volcano, Pahvant Butte, Utah (USA). *Bull. Volcanol.* **58**, 249–262.]

*a continuous uprush was much greater than from the intermittent explosive activity ... uprush of this kind might last for a few hours at a time. (Thorarinsson, 1967, pp. 18–19)*

Tephra jets carried tephra and steam along modified ballistic paths outward from the vent. Several jets per minute were commonly produced, but jets also occurred in isolation at widely spaced and irregular intervals, or in increasingly close succession at the onset of continuous uprush episodes. Strong pulsatory vapor plumes commonly rose from the vent while jetting took place and were associated with lightning, whirlwinds, and tephra-hail showers, in which each hailstone was cored by a sand-sized tephra grain. As the inner parts of larger jets at Surtsey descended they formed steam and tephra density currents that rolled down the cone and out over the sea.

Continuous uprush activity formed relatively stable, dark-colored eruption columns up to a couple of kilometers in height carrying uncondensed water vapor and heavily charged with tephra (see Fig. 3). Incandescent clasts were abundant in such columns and fell back onto the cone in spectacular abundance. Tephra dams were observed to prevent flooding of the vent during uprush activity.

Subaerially deposited tephra at Surtsey is mostly poorly sorted and often includes vesiculated tuff rich in accretionary lapilli and sideromelane. Deposits contain widely scattered pebbles and local blocks of indurated marine sediments from the preeruption seafloor and pillow basalt. Vesiculated tuff beds on steep cone slopes ( $>20^\circ$ ) are broken by channels formed by small tephra debris flows (Fig. 4); on very steep slopes ( $>35^\circ$ ) such tuff beds slipped downslope, breaking into plastic slabs. Quenched bombs with fluidal internal textures and a rugged, glassy exterior are present in beds formed shortly before strombolian activity began; they indicate heterogeneous interaction of water with erupting magma.

### III. OBSERVATIONS FROM OTHER ERUPTIONS

The eruption styles described above for Surtsey characterize only a small proportion of weak phreatomagmatic eruptions. We describe below the characteristics of six other well-described historical eruptions chosen to illustrate the range of such phreatomagmatic eruptive styles.

FIGURE 4 Eruption-fed lahars are formed by transformation upon impact of water-rich tephra jets and when seawater, ejected onto the volcano flanks during jetting, entrains tephra from the cone. [Reprinted with permission from Lorenz, 1974.]

The selection includes examples of both short-lived and long-lived eruptions, both silicic and basaltic magmas, magmas that were ascending at the time of fragmentation and others that were stagnant or retreating, interaction with standing water and with groundwater, and eruptions where the conduit walls were strong and coherent and others where unconsolidated loose sediment filled the vent and shallow conduit.

#### A. Myojinsho 1952–1953

The 1952–1953 eruption of Myojinsho involved the intermittent interaction of a growing submarine/emergent silicic lava dome with seawater. The 1952–1953 eruption lasted about 370 days beginning 16 September with submarine explosions and generation of small tsu-

namis. Myojinsho, also known as Myojin reef, is a subaqueous cone volcano, 2.5–3 km<sup>3</sup> in volume, which extends to within 30 m of sea level. It has erupted at least a dozen times since 1946, though most eruptions produced no more than discolored water at the surface. A blocky hypersthene–augite–dacite lava dome emerged from the sea by 17 September 1953, was destroyed by two explosions on the 23rd, emerged again in early November, was again destroyed in early March 1953, reemerged in April, and was finally beheaded 1 September 1953; a few weeks afterward all activity apparently ceased. Eruptive behavior followed a pattern in which growth of the dome was accompanied by variably powerful explosions, some initiated subaerially and others originating at depths estimated at between 40 and 70 m. Larger subaqueous explosions produced vigorous tephra jets (cf. Fig. 3), surges, and low (<2 km) eruption columns. Explosions at times occurred at rates of three to five per minute, with one or a few larger explosions each day. The larger explosions were accompanied by freshly vesiculated clear white dacite pumice. This pumice, far more vesicular than the dome dacite, suggests that arrival of fresh magma triggered the blasts, probably by fracturing the dome carapace to allow ingestion of water into direct contact with the new magma. Plumes of water discolored by an abundance of volcanic dust rose in the sea virtually throughout the eruption, including between explosive phases. Recent bathymetric surveys show very smooth, 16°–20° upper slopes on the cone, shallowing to 8°–10° on the lower flanks, with shallow downslope-oriented channels, together suggesting deposition from high-concentration sediment-gravity flows fed from the eruption. Floating pumice and fine particles were distributed by plumes in surface water well beyond the limits of the cone.

## B. Taal 1965

The well-described eruption of Taal volcano in 1965 involved strombolian and phreatomagmatic fissure eruptions as rising basic magma interacted with lake water. It produced about 0.4 10<sup>7</sup> m<sup>3</sup> of ejecta and a crater of 0.24 10<sup>7</sup> m<sup>3</sup> and lasted for 61 hours. Numerous historic small-volume eruptions have occurred from Volcano Island, which lies within Taal caldera surrounded by Lake Taal, with one in 1911 killing over 1000 people. The 1965 eruption began with strong seismicity and vigorous strombolian activity about a kilometer inland from the lake on Volcano Island (Fig. 5). After about an hour, a major explosive phase began and the

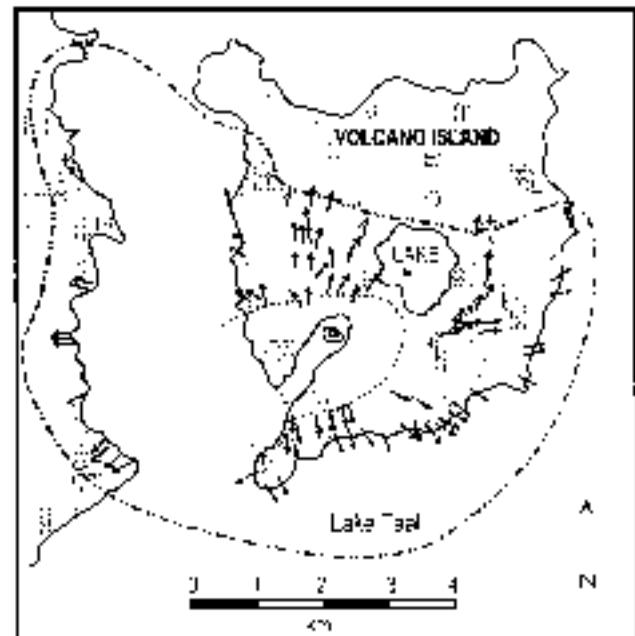

FIGURE 5 Map of Taal volcano showing the elongate eruption crater intersecting the lake. Transport directions of pyroclastic density currents (surges) are indicated by blown down and abraded trees and by surge dunes. [Redrawn after Moore et al., 1966.]

eruption fissure propagated until it reached the lake. Eruption columns attained heights of 15–20 km, and pyroclastic density currents extended radially from the base of the eruption columns. Explosions occurred irregularly at different vents along the 1.5-km-long fissure, with the strongest and most persistent activity at the NE end where the eruption initiated. Activity waned after 7 hours, initially with numerous explosions generating a much reduced column; then after a couple of days there were only small explosions 5–10 minutes apart, which expelled steam and tephra that mostly fell back into the crater area where a small cone was formed.

Deposits of the major explosive phase at Taal are dominated by nonjuvenile material: lake sediment and fragmented older lava, derived from enlargement of the fissure. Deposition during the main explosive phase occurred by fallout of mud rain and accretionary lapilli to 80 km from the vent and by volumetrically dominant pyroclastic density currents (surges) that flowed over the lake surface to between 3 and 6 km from source, forming crudely bedded, poorly sorted wet ash/block beds. Large ash dunes, a meter high with wavelengths of 3–15 m, formed with crests normal to surge transport directions. The surges knocked down trees near the

vent, abraded as much as 15 cm of wood from the vent-facing side of the trees at intermediate distances, and accreted thin, normally graded layers of fine to medium ash to more distant trees. None of the trees were charred. The early and late stage activity produced typical coarse, well-sorted strombolian deposits containing basaltic spatter and ash with some abraded grains.

### C. White Island 1976–1982

The 1976–1982 eruption episode at White Island consisted of seven phases of alternating dry (strombolian) and phreatomagmatic explosive volcanism involving basic andesitic magma and a high-temperature geothermal system. The eruption was associated with the rise of a batch of basic andesitic magma to the surface between 1973 and 1977 but the magma was stationary or slowly retreating through much of the eruption. The eruptions ejected a total of  $10^7 \text{ m}^3$  of ejecta over 2500 days accompanied by the formation of two coalescing maar craters. Discharge rates were 1–2 orders of magnitude higher during strombolian phases relative to the phreatomagmatic eruptions. Vent position changed repeatedly during the eruption along a line connecting two earlier historical vents. The eruption took place through a long-lived hydrothermal system and the conduit walls consisted of soft unconsolidated hydrothermally altered ash. A key feature was the role of decoupled magmatic volatiles, even in the phreatic phases, ejecting less than 1 wt% juvenile material. The phreatomagmatic phases of the eruption contained two styles of activity:

- (1) near-continuous emission of gas and ash, and
- (2) discrete larger explosions.

The near-continuous eruptions resulted from the streaming of magmatic volatiles and phreatic steam through open conduit systems, frittering juvenile particles from the quenched margins of the magma and eroding loose particles from the unconsolidated wall rock (Fig. 6A). The deposits were exceedingly complex with pseudo-ballistic lapilli, dry ash particles, damp ash aggregates, and ash-charged water droplets being deposited simultaneously from the eruption column.

The larger discrete explosions produced ballistic block aprons, downwind lobes of fall tephra, and cohesive wet surge deposits. The key features of the larger eruptions were:

- (1) shallow depth of fragmentation,
- (2) a random frequency and lack of precursors, and
- (3) thermal heterogeneity of the ejecta.

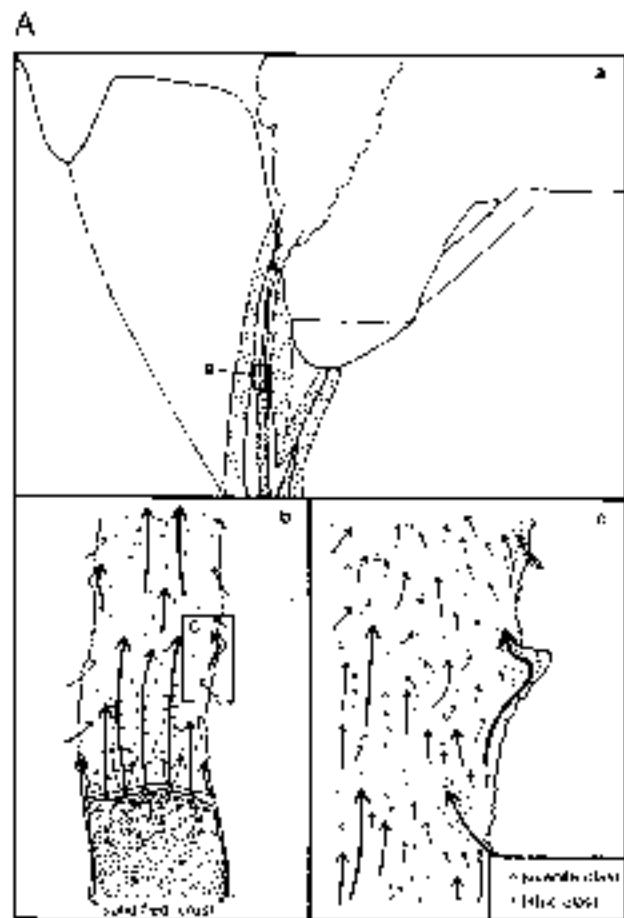

FIGURE 6 (A) Model for near-continuous phreatomagmatic eruptions by frittering. [Reprinted with permission from Houghton and Nairn, 1991.] (continues)

These larger explosions (Fig. 6B) appear to have been triggered by sudden contact of the magma with brine-saturated wall rocks after collapses of the weak conduit walls. The components that were mixed in this fashion were highly heterogeneous: magma that was thermally stratified and partially degassed; magmatic gas, decoupled from the magma and containing both steam and noncondensable gases; wall rock that had widely varying preexisting grain size and was at temperatures from ambient to gas-heated incandescence; and a groundwater component that ranged from cold meteoric runoff through heated brine to brine/vapor mixtures.

### D. Ukinrek March–April 1977

A 10-day eruption at Ukinrek in Alaska resulted from rising and ponded magma interacting with small

**FIGURE 6 (continued)** (B) A 3-km-high convective plume associated with a discrete explosive eruption from White Island volcano on 7 September 1987. [Reprinted with permission from R. Mead.]

amounts of shallow, perched groundwater in glacial till and underlying silicic pyroclastic deposits. It formed two maar craters (of volume  $4 \times 10^6 \text{ m}^3$ ) and ejected  $2 \times 10^7 \text{ m}^3$  of alkali olivine basalt and foreign lithics. The west maar formed over the first 3 days of eruption and was 170 m wide and 35 m deep. The larger east maar formed over the following 7 days and is 300 m wide and 70 m deep. Maar collapse was gradual over the course of the eruption. Magma formed an incandescent pond in the vent and then a dome late in the eruption sequence.

Eruption plumes occasionally reached 6 km in height and distal ash fall was recorded over an area of 20,000 km<sup>2</sup>. The eruptions were phreatomagmatic throughout but activity at both vents showed a progressive trend toward drier activity (transitional to strombolian eruptions), marked by a lower content of foreign lithics and an increased abundance of ragged scoria lapilli in the deposits. This change was interpreted as due to depletion of the supply of external water delivered by flow through and collapse of the shallow aquifers. From day

5 contrasting eruptive styles were observed from two vents within the east maar. One vent within the lava pond experienced relatively dry explosions coeval with dark ash-rich plumes from the second vent.

The deposits, which reach a maximum thickness of 26 m on the rim of the east maar, are of four types: (i) lithic-rich ash and lapilli fall deposits, (ii) scoria-rich lapilli fall deposits, (iii) late-stage lithic block aprons extending to only 800 m from the rims of the maars, and (iv) minor pyroclastic surge deposits. The lithic rich lapilli fall deposits contain up to 75 wt% foreign lithics and subordinate rounded dense cauliflower juvenile lapilli yet are well sorted. On grain size criteria alone, the phreatomagmatic units cannot be distinguished from transitional-strombolian ones.

#### E. Kilauea 1924

An 18-day phreatomagmatic explosive eruption of Halemaumau crater on Kilauea volcano occurred when re-

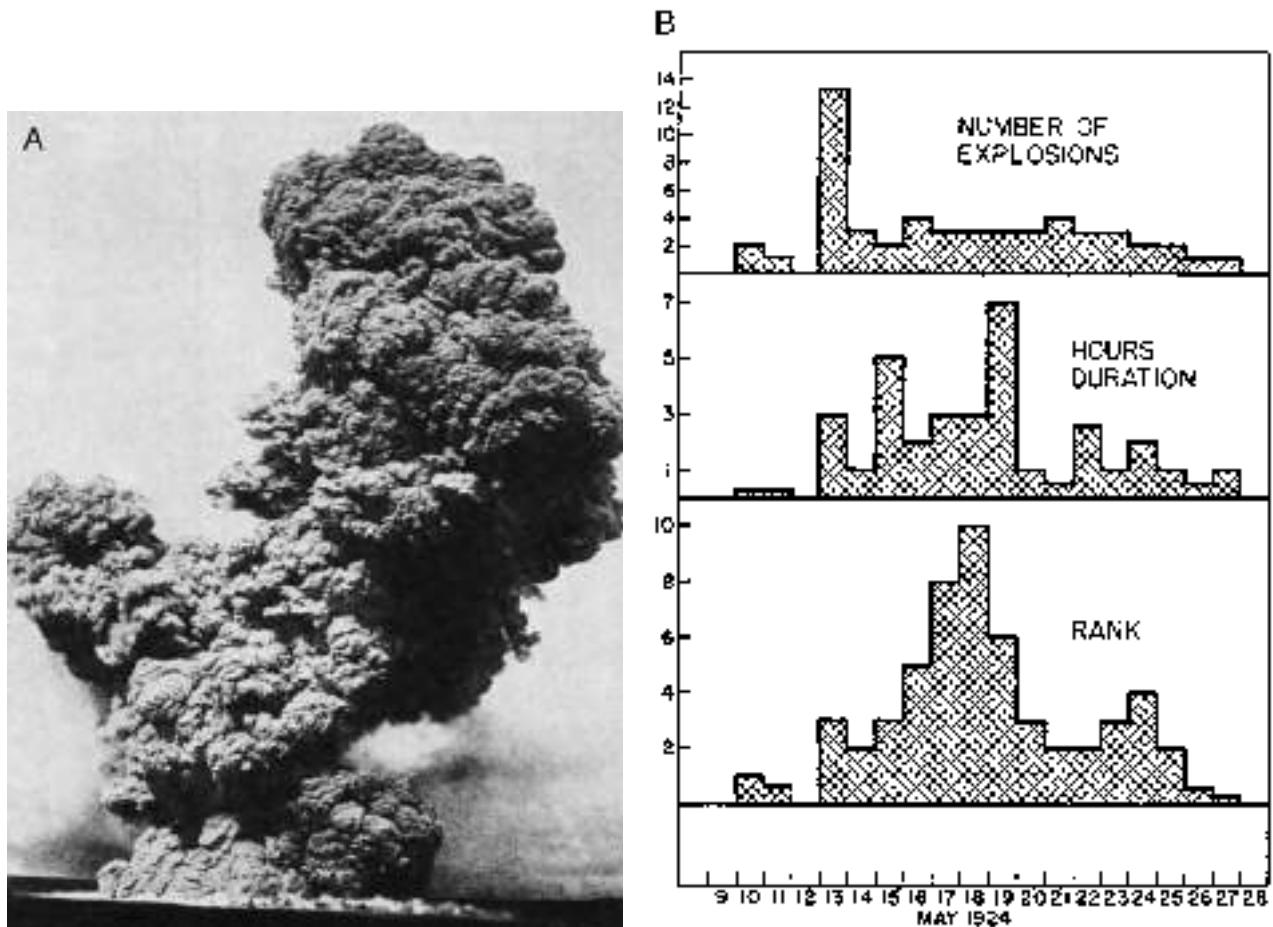

FIGURE 7 (A) Photograph of plume formed by discrete explosion during Kilauea 1924 eruption. (B) Histogram illustrating scale and timing of discrete explosions. [Reprinted with permission from Decker and Christiansen, 1984.]

treat of magma from the lava lake brought hot yet solidified basaltic rock into contact with perched groundwater in the conduit walls, at a depth of approximately 500 m. Up to 13 explosions occurred each day, producing eruption plumes to 2 km in height, depositing ash and accretionary lapilli, and ejecting ballistic blocks to 1 km from the vent (Fig. 7). The blocks ranged greatly in temperature from ambient to approximately 700°C. The total tephra volume was approximately  $10^6 \text{ m}^3$  consisting entirely of previously solidified or at least brittle lava. The crater had widened by 430 m during the eruption but the missing material is largely inferred to have collapsed into the crater and the underlying conduit.

#### F. Teishi Knoll 1989

An eruption of Teishi knoll in Japan in September 1989 intruded approximately  $1.4 \times 10^6 \text{ m}^3$  of basaltic magma

into shallow marine unconsolidated silicic ash, melting some of the ash and triggering a series of five submarine explosions. Five days of volcanic tremor accompanied injection of magma to shallow levels below the 100-m-deep seafloor. Strong tremor on day 3 accompanied the series of five submarine explosions that produced dome-like bulges of the water surface and tephra jets that ascended to >100 m. Material ejected by the eruption consisted of well-vesiculated clear glass pumice enclosed within or coated by basalt scoria with a crystalline groundmass. Comparison of preeruption bathymetric surveys with one during and another after the eruption shows that a small circular knoll 25 m high and 450 m in diameter had formed and then was largely destroyed during excavation of a 200-m-diameter crater. The remnants of the knoll were covered with marine sediment underlain by basaltic lava. Basalt-covered pumice was derived by fusion and vesiculation of the marine sediments as a result of heating by the magma (Fig. 8A). A scenario is that, following intrusion of magma into and

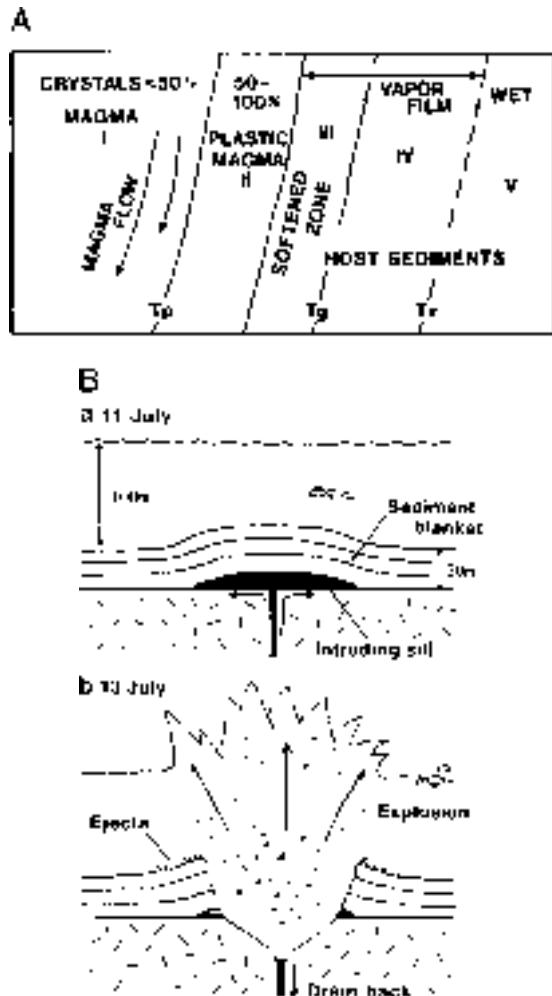

FIGURE 8 (A) Diagram of relationship between intruded basalt magma and marine sediment forming Teishi knoll. (B) Withdrawal of magma and triggering of eruption. [Reprinted with permission from Yamamoto et al., 1991.]

partial melting of the shallow marine sediments, the magma was withdrawn and water gained access to the interior of the basalt intrusion, causing the series of strong explosions (Fig. 8B).

#### IV. SUMMARY OF OBSERVATIONS

##### A. Diversity of Activity

The eruptions described above show great diversity of magnitude, intensity, and eruptive style. This range is widened if we consider the larger database of recent and

well-described events (Table I). The volumes of these deposits range from  $10^4$  to  $10^9 \text{ m}^3$  and the durations of eruptions from as short as 1 hour to as long as 6 years. The eruptions are dominantly basaltic or basic andesitic composition although more silicic compositions occur. If the database is expanded to include prehistoric tuff rings and cones, even rhyolitic compositions occur.

#### B. Heterogeneity of Material

The unifying characteristics of small-volume phreatomagmatic eruptions are the involvement of external water and heterogeneity of eruptive process and products. Dry magmatic eruptions (strombolian, hawaiian, etc.) involve two phases, the silicate liquid phase and a gas phase, both of which we can often pretend are thermally, compositionally, and physically homogeneous. In wet systems the starting point is magma at high temperature in contact with external water and the material that contains or confines the water at much lower and commonly ambient temperatures. The end product is a mixture of juvenile particles, magmatic gas, steam, wall rock particles, and often liquid water (Fig. 9). Both the starting ingredients and the end products are very heterogeneous. Total mixing is rarely achieved, and a wide temperature range often characterizes the products of a single explosion. It is not uncommon for both liquid water droplets and steam to be present in the eruption column and for cold and incandescent clasts to be ejected simultaneously.

In the next section we explore how the properties of these heterogeneous components influence the style of volcanism.

---

#### V. THE COMPONENTS OF PHREATOMAGMATISM

The eruption styles described here involve relatively small volumes of variably yet relatively fluid magma interacting with water or an impure fluid consisting of water and particles. We can picture these types of eruptions as involving three complex and interdependent starting materials: magma, external fluid, and the wall rock that surrounds and defines the vent(s) and conduit(s).

TABLE I Compilation of the Characteristics of Some Relatively Well-Studied Historical Eruptions

Eruption	Duration (days)	Volume ( $m^3$ )	Magma type	Vent type	Magma dynamics	Water source	Other styles during the eruption
Surtsey 1963–1964	1300	$10^9$	Basalt	Four-fissure segments	Advancing	Seawater	Strombolian
Taal 1965	3	$10^8$	Basalt	Fissure	Advancing	Lake water	Strombolian
White Island 1976–1982	2500	$10^7$	Basalt, andesite	Multiple-point sources	Varying	Geothermal system	Strombolian
Capelinhos	480	$10^8$	Basalt	Multiple-point sources	Advancing	Seawater	
Ukinrek 1977	10	$10^7$	Basalt	Multiple-point sources	Ponded	Groundwater	Strombolian
Myojinsho 1952–1953	370	$10^5$	Dacite	Single-point source	Ponded	Seawater	Dome building
Kilauea 1924	18	$10^6$	Basalt	Single-point source	Drain back	Groundwater	Hawaiian

Karymskoye lake 1996	2	$10^7$	Basalt	Single-point source	Advancing	Lake	
Miyake-jima 1983	1	$10^7$	Basalt	Fissure	Advancing	Shallow groundwater	Strombolian/hawaiian
Soufriere 1979	14	$10^7$	Basalt, andesite	Single-point source	Ponded	Crater lake	Dome building
Ruapehu 1945	250	$10^7$	Andesite	Single-point source	Advancing	Crater lake	Dome building
Ruapehu 1995–1996	100	$10^7$	Andesite–dacite	Single-point source	Advancing	Crater lake	Subplinian/strombolian

## A. Magma

As in all volcanic eruptions, magma is the source of energy for surtseyan and related phreatomagmatic explosions. Most phreatomagmatic events are modifications of eruptions that would occur in the absence of external water. Many of the eruptions considered in this chapter are the phreatomagmatic equivalents of hawaiian and strombolian eruptions. Exceptions are the equivalent of extrusive events, for example, Myojinsho and Teishi knoll 1989, which, in the complete absence of water, would presumably have erupted only dacite domes or lava flows, or Kilauea 1929, which at the time of the explosive eruption was, in the absence of water, an actively receding lava lake. In interpreting the style and products of phreatomagmatic eruptions it is important to consider the influences of both the intrinsic physical properties of the magma phase and the background magmatic processes (the dynamic properties of the magma phase).

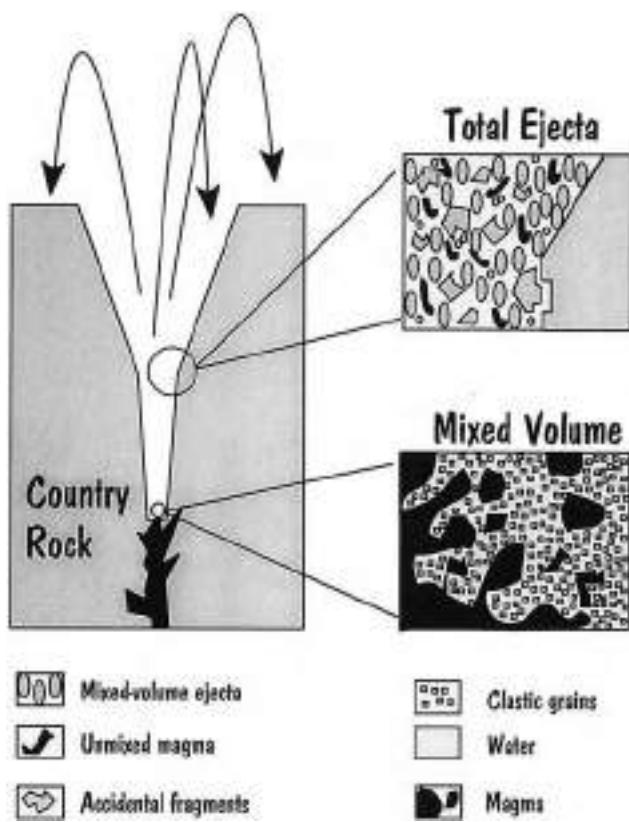

### 1. Intrinsic Properties of Magma

Intrinsic properties of the magma include its temperature, viscosity, dissolved volatile content, and crystallin-

ity. During fragmentation, thermal energy is converted to seismic and acoustic energy, fragmentation energy, and kinetic energy. Magma (and water) temperatures prior to interaction influence the heat transfer rates and the temperatures attained during mixing. The absolute amount of heat available is clearly a key factor; hotter magma has more heat available for conversion to mechanical energy. However, more significant is the extent/efficiency with which this heat can be used during fragmentation and transport; this is strongly influenced by a number of processes described below.

The effect of ambient pressure is not well understood. An increase in confining pressure should boost the vigor of fragmentation and yet, by limiting vapor-film development, it may inhibit fragmentation.

Viscosity is strongly dependent on chemical composition, volatile content, and temperature. An increase in viscosity will retard the mixing of magma and water and yet, by slowing the advance of magma, may prolong the opportunity for contact between the two phases. The magmas described in this chapter show a range of viscosity at liquidus temperatures from a few  $\text{Pa s}^{-1}$  in the case of basalts, to millions of  $\text{Pa s}^{-1}$  for silicic magmas. A 200°C decrease in temperature will produce a 1 to 2 orders of magnitude increase in viscosity. Viscosity of the magmatic phase at the time of fragmentation may

**FIGURE 9** Highly schematic representation of a phreatomagmatic vent showing the different populations of particles that can be formed and ejected and their sites of formation/entrainment. All eruption energy is produced by phreatomagmatic explosions in the *Mixed volume*. [Reprinted with permission from White, 1996.]

reflect both lower temperatures, as a result of cooling during ascent and interaction with the conduit walls, and processes of degassing and microlite crystallization that accompanied ascent. The nonexplosive degassing of magma during ascent has a pronounced effect on temperature and rheology. Vesiculation also increases surface area while reducing the density of the bulk melt phase and may therefore influence the geometry of mixing. Depending on magma viscosity and ascent rates degassing may be *open* or *closed*, and, in an open system, a decoupled gas phase will form a fourth component during eruption.

Rising magma may also partially crystallize during ascent, affecting both magma temperature and rheology. The growth of crystals and/or addition of wall rock fragments increases viscosity as predicted by Stokes-Einstein derivative functions, again by a factor of about 1 order of magnitude (for approximately 25% particles).

Behavior becomes more complex above 40% rigid particles. The presence of numerous millimeter to centimeter sized lithic inclusions in the magma is also a thermal sink, which further increases the viscosity of the magma. Hard to quantify during this process are the effects of the introduction of any external water present in cracks or pores in the conduit walls.

## 2. Dynamic Properties of Magma

Dynamic properties of the magma include its ascent rate, discharge velocity, discharge steadiness, state of vesiculation, and state of fragmentation. The history of magma ascent toward the fragmentation zone has a major influence on the ensuing style of phreatomagmatism. The extent of degassing and microlite crystallization is strongly influenced by the ascent history, and degassing and crystallization in turn influence magma rheology and rise rate at shallow levels. A magma that rises rapidly and continuously to the surface is likely to undergo most of its vesiculation at shallow levels and be relatively fluid, hot, and homogeneous at the point of fragmentation. Relatively simple phreatomagmatic eruption styles result. If magma ascends in staged fashion and/or subsequently ponds in the shallow conduit, then at least some portion of this melt will have undergone quenching, and nonexplosive interaction with material forming the conduit walls, often becoming physically and thermally heterogeneous. Very complex magma:water interaction and phreatomagmatism often results.

If rising magma encounters external water then the fluid magma, often gas-rich and vesiculating, mixes with water or a slurry. Magmatic fragmentation processes (volatile nucleation and expansion) operate simultaneously with explosive and nonexplosive phreatomagmatic fragmentation. Shear along the boundaries of forcefully injected magma inhibits generation of a stable steam film, particularly where magma passes through a slurry (see below). Fragmentation and expansion due to vesiculation similarly create large surface areas that may directly contact water and initiate phreatomagmatic explosions. Shock waves generated by explosive expansion may further fragment the mixture and enhance fluid interpenetration. The frequency with which bursts of decoupled magmatic volatiles are released may determine the tempo of discrete explosions. Sustained phreatomagmatic explosivity is contingent largely upon mixing driven by shear along the margins of continually injected magma (Fig. 10).

Eruptions where magma has ponded or begun to withdraw down the conduit may involve passive frittering of conduit walls by streams of magmatic gas and/

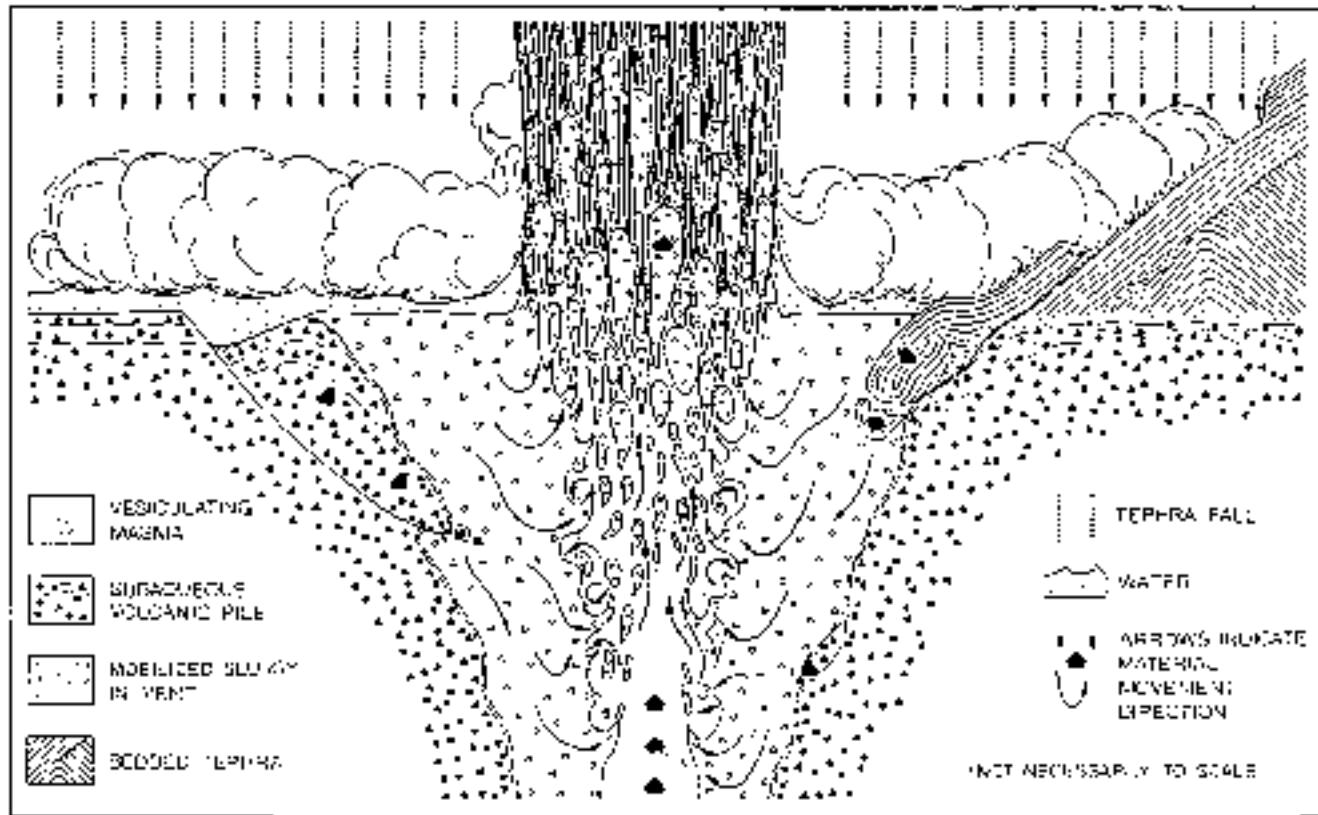

FIGURE 10 Model for processes in the surtseyan vent in which shear-instability entrainment and mixing of a slurry of recycled tephra and water with rising magma drives discrete or continuous uprush activity. [Reprinted with permission from Kokelaar, 1983.]

or collapse of unstable water-laden vent walls triggering discrete phreatomagmatic explosions. Magma withdrawal facilitates interaction in the following manner. Slowly rising or passive magma boils adjacent water, forming a stable steam film in contact with a chilled outer magma surface. Withdrawal of magma buckles the chilled outer surface, which fractures rapidly to allow direct contact of water with magma beneath the chilled surface, which results in a strong explosion. This sort of explosivity is self-driven after triggering and can result in impressive blasts.

## B. Water

The availability of water/external fluid has a first-order influence on the style of phreatomagmatism. The amount of water relative to that of magma and the efficiency with which they mix determine the thermodynamic states of water in phreatomagmatic eruptions. If

very little water is available, it can be heated to high temperatures and high pressures if confinement is available, but its expansion to vapor can fragment only a relatively small volume of magma. (Most of the work of fragmentation is done during the volume increase from liquid water to steam rather than by subsequent expansion of the steam phase.) At the other extreme, abundant water will receive insufficient heat for full vaporization and hence most effective fragmentation. At intermediate mass ratios, the available heat will take all the water to high states of internal energy, thus resulting in efficient magma fragmentation.

A variety of relatively shallow influences can disturb the supply of external water, and so most wet eruptions are characterized by abrupt changes in the proportions of water and magma. In special cases the rate of supply of water can be controlled by external factors, such as the tide or the frequency of rainstorms.

In most situations the water phase included in magma–water interactions is a liquid initially at ambient temperatures. However the eruptions described here also include examples of magma contacting:

- (1) vapor-dominant geothermal fluid at temperatures up to 800°C,
- (2) superheated geothermal liquids at temperatures of 200–250°C,
- (3) snow or ice,
- (4) impure fluids in which sediment particles are suspended in water, and
- (5) vent slurries with significant yield strengths.

Where magma intrudes a preexisting hydrothermal system, the water phase prior to interaction may be steam, two-phase steam–water mixtures, or hot water. Steam is a minor contributor to the explosivity because the major volume change is that of vaporization, and subsequent (super)heating causes only a minor volume increase. The state of water most effective in forming phreatomagmatic explosions is superheated liquid water; it will undergo large volume changes upon vaporization, which can be accomplished by small additions of heat from interaction with magma and by subsequent disruption of the hydrothermal system.

Water involved in the interaction may contain suspended particles (sediment or tephra) or dissolved species (such as silica and chlorine in hydrothermal fluids). These impurities change the physical properties of the water phase and introduce nonvaporizable components. Depending on the concentration of impurities in the water, its viscosity may increase up to an order of magnitude, the density may double, and the heat capacity may decrease by 25%.

## C. Vent and Conduit Wall Rock

### *1. Vent/Conduit Wall Properties*

During phreatomagmatic eruptions the walls of the vent allow, in one or more ways, external water to encounter magma and contribute to initial and/or subsequent fragmentation and expansion. The simplest way in which this happens, exemplified by activity at Surtsey, Ruapehu, and Miyojinsho, is for surface water to occupy or flow directly into the vent during eruption. In such a situation the first phreatomagmatic explosions take place by interaction of magma with some small part of an effectively unlimited supply of clear ocean or lake water, and the ejecta consists of juvenile pyroclasts and H<sub>2</sub>O. Under these circumstances the form of the vent and shallow conduit strongly influences the geometry of the interaction.

Terrestrial phreatomagmatic eruptions, such as at Ukinrek, begin under circumstances different than those

of submerged volcanoes. In particular, there is no body or sizable domain of clear water with which magma can interact. Instead, magma encounters interstitial water contained within a framework of sedimentary clasts. Two endmember modes of interaction can be described for this situation: (1) water flows through the clast framework or fractures in the wall rock to interact with magma; (2) the clast framework and contained interstitial water are disrupted and together interact with magma as an impure fluid.

In many explosions the yield strength of shallow wall rock is negligible and the primary grain size of the vent-wall material has a strong effect on the grain size of the lithic population of the resulting pyroclastic deposit. In particular, if there is abundant ash-sized wall-rock material, its inclusion (often without any modification to its size distribution by the explosions) will lead to a misleadingly high estimate of the efficiency of fragmentation. Surtsey itself exemplifies another type of wall instability, in that the fragmental deposits formed early in the eruption form the walls of the vent later in the eruption. In this situation the vent is occupied by a slurry (see above) of seawater and tephra sloughed and slipped back into the vent, which strongly affects eruption style (Fig. 10).

### *2. Vent Geometry*

The geometry of the vent will change as an eruption proceeds and this may *feed back* to modify the style of the eruption. Cone growth will influence the hydrology of the vent and in general act to restrict ingress of water. Growth of the cone or tuff ring may also permit magma to *pond* in the growing volcano at levels above the water table, bringing an end to *wet* phreatomagmatic fragmentation. Vent wall collapse is more important in phreatomagmatic eruptions than in dry magmatic eruptions. Collapse of the inner walls of the growing tuff cone or tuff ring may promote further magma–water interaction or may temporarily block the vent leading to episodic eruptive activity. Vent widening as a result of shallow collapse may promote a change to wetter explosions if surface water can pond in the crater.

Recycling of clasts is a process strongly influenced by vent geometry. Most pyroclastic deposits contain both first-cycle juvenile clasts, derived from magma at the instant of eruption, and recycled juvenile clasts that were fragmented in earlier explosions but then fell or collapsed back into the vent (e.g., Figs. 9 and 10). The recycled clasts are similar to wall-rock lithics in that they contribute no heat to further magma–water interaction, but they can be difficult to separate from *first-cycle* clasts

in outcrop. Textural features, such as a combination of uneven mud coating and a mixture of fluidal and angular faces on many clasts, indicate that they were fragmented at least twice—once while the magma was fluid and subsequently in a brittle state.

---

## VI. CLASSIFICATIONS AND PIGEONHOLES

There are many parameters that could be chosen to classify styles of mild phreatomagmatic activity. A study could use:

- (1) the geometry of the products, for example, tuff ring versus tuff cone versus maar;
- (2) the inferred setting of the volcano as submarine, emergent, or terrestrial;
- (3) the absolute or relative intensity of the eruptions;
- (4) the involvement of standing water versus groundwater;
- (5) the nature of the external water phase as water, steam, or ice;
- (6) the relative abundance of pyroclastic density current and fall deposits;
- (7) grain size of the eruption products;
- (8) the ratio of juvenile to wall rock clasts.

This range of possibilities reflects the complexity of this class of volcanic eruptions, which are similar only to the extent that they are characterized by abrupt, rapid changes in eruptive style and involve an external aqueous fluid. No existing classification deals adequately with this complexity and we do not attempt to refine these schemes here. Instead, we conclude this chapter with a brief summary of the two principal classes of eruption styles.

### A. Discrete Explosions

A discrete phreatomagmatic explosion ejects a mixture of material that may be partitioned among ballistic blocks, tephra jets, pyroclastic density currents, and non-sustained, generally weak discrete eruptive plumes. Ballistic blocks comprise the largest particles ejected by an explosion and may travel through, or independently of, jets, surges, or plumes formed simultaneously with them. Smaller particles are transported by either tephra jets or plumes. In eruptions involving abundant external water

much of the ejecta is partitioned into tephra jets and the associated convective plumes are essentially thermal in origin. These plumes carry very little tephra and arise from gravitational partitioning at the conduit mouth of steam from the simultaneously originated inertia-driven jet and ballistic transport and expansion-driven density currents. Higher ash-charged vertical plumes are generally associated with drier eruptions, that is, those in which liquid water is less abundant. Such plumes form elliptical fall sheets roughly symmetrical around the vent(s) and extending kilometers to tens of kilometers from the source. Tephra jets form sectoral fall deposits, generally extending only a few hundred meters to a few kilometers from the vent. Tephra jets are characteristic of eruptions through standing water. Surges arise from discrete explosions as both base surges, which strictly are expansion-driven collars of vapor flowing laterally from the base of a jet or plume, and surges fed by descending tephra from a plume or tephra jet.

### B. Continuous Plume

Two types of continuous discharge occur during mild phreatomagmatic eruptions. Persistent and thorough interaction of rising magma with external fluid forms maintained eruption plumes that contain both steam and liquid water and deposit ash-rich fall deposits. Such plumes may be driven by either closely spaced explosions or a sustained discharge. The dynamics of such plumes closely resemble those of better studied endmember dry or magmatic systems. A weaker form of sustained activity occurs where magma is stagnant or receding within a vent, and weak interaction of incoming external fluid with the rigid carapace of the magma and passive degassing produces streaming gas and vapor that fritter ash from the conduit margins as a continuous, but dilute and weak, eruptive column driven by expansion of the gas phases.

## GLOSSARY

**accretionary lapilli** In the strict sense, spherical aggregates of fine ash that form in eruption plumes. In practice used more widely for all ash aggregates including "mud lumps."

**ash aggregation** Processes leading to the formation of clusters of ash particles during transport in an eruption plume.

**dispersal index ( $D$ )** A measure of the area covered by a pyroclastic fall deposit, specifically the area enclosed by an isopach drawn at 1/100 of the maximum thickness of the deposit. Phreatoplhinian deposits have  $D$  values greater than  $50 \text{ km}^2$ .

**external water** Any water phase during explosive volcanism that was not originally dissolved in the magma such as surface and groundwater.

**fragmentation index ( $F$ )** A parameter measuring the grain size of a pyroclastic fall deposit, specifically the percentage of ash finer than 1 mm at the point on the dispersal

axis corresponding to 1/10 of the maximum thickness of the deposit. Phreatoplhinian deposits typically have  $F$  values greater than 80%.

**mud lump/mud pellet** Ash aggregates of irregular shape and with no discernible concentric internal structure.

**mud rain** Fall-out of ash-bearing droplets of water and dissolved gas species from an eruption plume.

**phreatoplhinian deposits** Widespread phreatomagmatic fall deposits (as defined requiring a dispersal index of  $50 \text{ km}^2$  or greater and a fragmentation index of generally greater than 80%).

**T**HE TERM *PHREATOPLINIAN VOLCANISM* has proved an enigma, widely incorporated in theoretical classifications since its introduction in 1978, in practice, it has been applied to only relatively few deposits or eruptions. The term was introduced to describe widely dispersed, fine-grained pyroclastic fall deposits formed when silicic magma interacted with large quantities of surface or groundwater (collectively termed *external water*). Such large *wet* eruptions (see Phreatomagmatic Fragmentation) are a poorly understood style of explosive volcanism, largely because of the lack of observed historic examples. A number of large eruptions in the 1980s and 1990s were probably characterized by

limited involvement of external water, but there have been no observed modern examples of large eruptions with the moderate to high water:magma ratios inferred to typify the phreatoplinian style. Unlike the other eruptive styles described in Strombolian and Hawaiian Eruptions, Volcanian Eruptions, Plinian Eruptions, and Surtseyan and Related Phreatomagmatic Eruptions, phreatoplinian volcanism was first proposed to describe a group of mostly *prehistorical* eruptions.

In reexamining phreatoplinian volcanism and the type deposits we will ask the following questions.

- Is high vesicularity of the erupting magma part of the definition for phreatoplinian eruptions?
- Should all vent-derived, fine-grained fall deposits with wide dispersal be called phreatoplinian?
- Must phreatoplinian eruption columns be sustained?
- What dispersal index is an appropriate lower limit for phreatoplinian deposits?
- How useful are grain size parameters in delineating phreatoplinian deposits?
- What range of water to magma ratios should phreatoplinian volcanism be applied to?

## I. CHARACTERISTICS

### A. Examples

The current definition of phreatoplinian volcanism is based on four type examples. We discuss these below, incorporating information from our more recent studies (Figs. 1 and 2).

#### 1. Askja-C, Iceland, 1875

Phase C of the 1875 eruption of Askja caldera in Iceland remains the only widely recognized historical example of a phreatoplinian eruption. The complete eruption lasted 6.5 hours and consisted of an alternation of subplinian, plinian, and phreatoplinian eruptive styles. Phreatoplinian phase C lasted 1 hour and produced a 0.2-km<sup>3</sup> deposit, consisting of a lower fine-grained, highly stratified unit and an upper, coarser-grained but poorly sorted unit. The Askja-C deposit has a low lithic content similar to that in plinian layer D. Workers envisaged a two-stage fragmentation process for Askja-C, first by vesiculation, with subsequent re-fragmentation of the clast population by magma/water interaction.

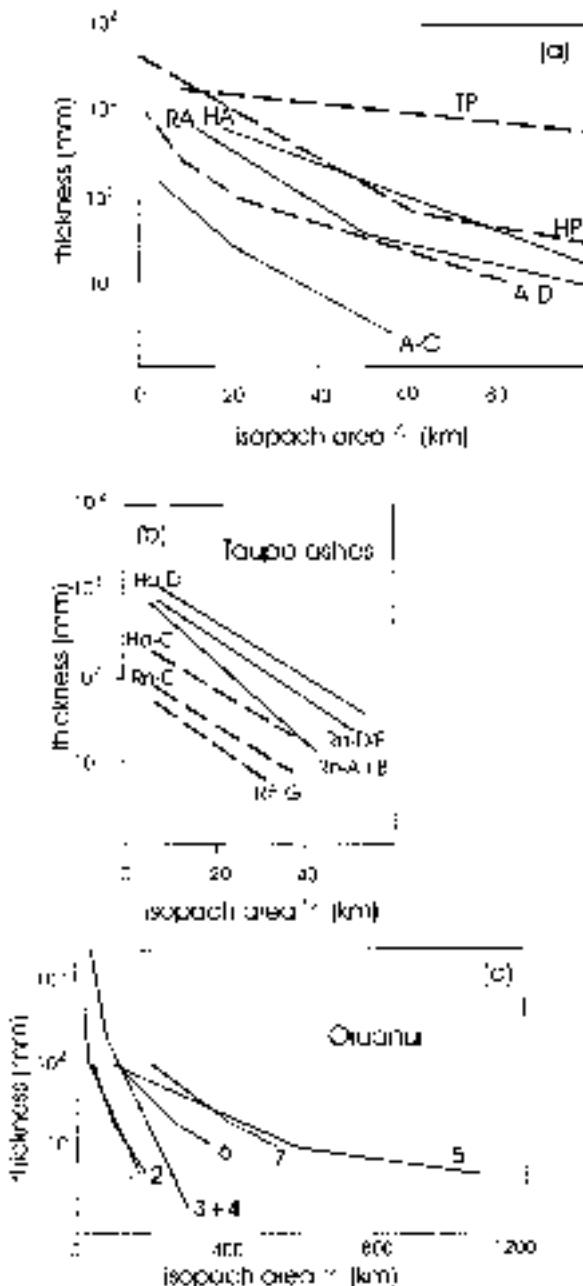

FIGURE 1 Plots of thickness versus square root of isopach area for selected deposits. (a) Contrast between plinian (dashed) and phreatoplinian (solid trace) units from single eruptions. HP and TP are the Hatepe and Taupo plinian deposits that enclose the Hatepe and Rotongaio ashes (HA and RA, respectively). A-C and A-D are the phreatoplinian C and plinian D phases of the 1875 AD Askja eruption. (b) Contrasting ash-rich (solid trace) and lapilli-rich (dashed) phases of the Hatepe and Rotongaio ashes. (c) Subunits of the Oruanui deposit (see Table I).

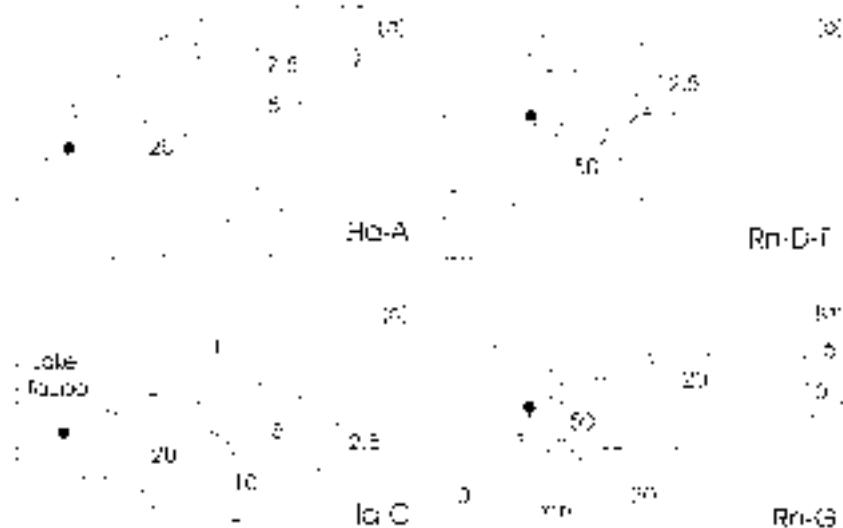

FIGURE 2 Isopach diagrams for selected units of the Hatepe and Rotongaio ashes showing the contrasting patterns of ash-rich (a and b) and lapilli-rich (c and d) beds. Thicknesses in cm (a–c) or mm (d).

## 2. Hatepe and Rotongaio, New Zealand

Two phases of the 181 AD eruption of Taupo caldera, the Hatepe and Rotongaio ashes, are among the type examples of phreatoplhinian volcanism. The Hatepe ash is typical of most phreatoplhinian deposits; shower bedded and rich in fine ash, it is dominated by highly vesicular pumice. It contains four subunits (Fig. 3). Fine ash and accretionary lapilli dominate two subunits, a third is dominantly lapilli-sized, and the fourth contains a mixture of fine ash and lapilli. Medial and distal exposures are of fall origin; proximal outcrops contain a significant proportion of material inferred to have been laterally emplaced by wet, dilute pyroclastic density currents. The vesicularity mode of pumice in the Hatepe ash is only slightly wider than that for the preceding and following plinian fall deposits (Fig. 4), and it can be modeled as produced by the interaction of variable but moderate amounts of lake water with highly vesiculated magmatic foam.

The Rotongaio ash has dispersal and whole-deposit grain size characteristics similar to those of the Hatepe ash (Figs. 1 and 2) but is very different in detail. Its key characteristics are very wide dispersal and exceedingly fine grain size, with close to 100 wt% of the deposit finer than 1 mm; a finely laminated character even in the most proximal exposures; and a lack of lateral continuity for distances greater than 10 m of these fine-grained beds. The Rotongaio ash has an extremely low wall rock lithic content and a predominance of dense

glassy juvenile clasts (Fig. 4). Many laminae consist of partially flattened, structureless, <1–2 mm in diameter ash pellets. A delicate balance apparently existed between accumulation and erosion during its deposition. Individual beds show a complete range of textures from primary fall through slope-affected material to water-reworked ash. The model for the eruption involves abundant lake water coming into contact with magma well after the peak of degassing, with development of highly unstable, short-lived eruption plumes and wide fluctuations of the water:magma ratio in these plumes.

In both the Hatepe and Rotongaio ashes there is a marked contrast in the dispersal pattern of relatively coarse (lapilli bearing) and relatively fine-grained sub-units (Fig. 2). Coarse-grained packages were significantly more affected by crosswinds and hence have more restricted crosswind dispersals similar to the plinian phases of the same eruption; ash-rich subunits have much more symmetrical patterns of dispersal.

## 3. Oruanui, New Zealand

The 22.6  $^{14}\text{C}$ -ka Oruanui eruption of Taupo generated a ca. 500-km $^3$  fall deposit and a ca. 300-km $^3$  nonwelded ignimbrite. Evidences for interaction between magma and water (contained within a large lake) are:

- (1) the exceptionally fine-grained nature of most fall deposits ( $F = 97\text{--}100\%$ , Table I);
- (2) the nonwelded nature of the ignimbrite, even where >200 m thick; and

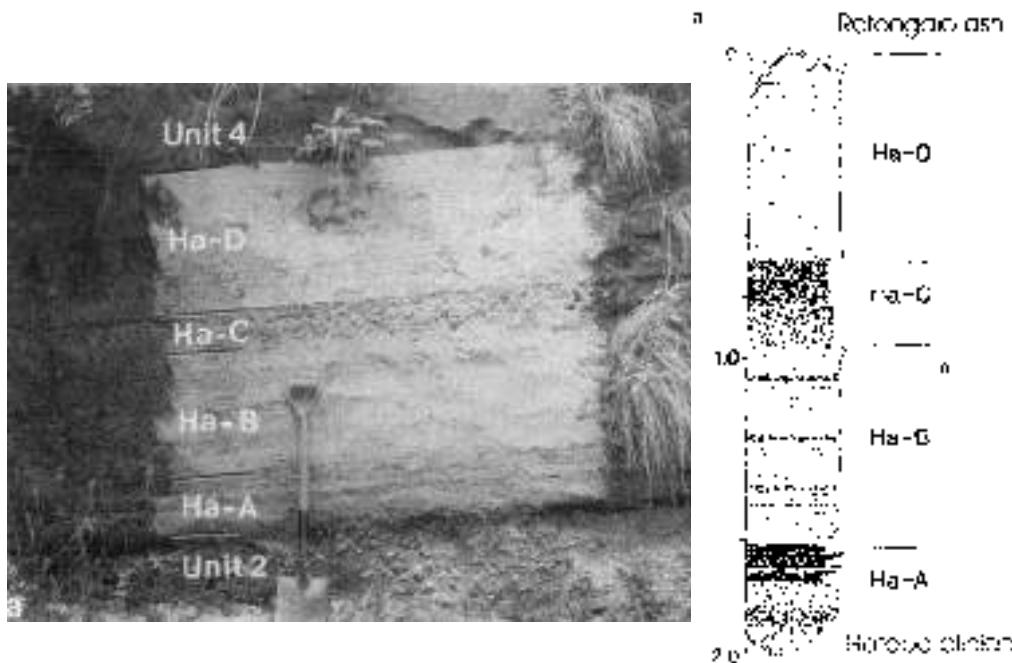

FIGURE 3 Stratigraphic log and photograph of the Hatepe ash, a typical phreatoplinian deposit.

- (3) the abundant accretionary lapilli and vesicular cohesive ash textures in many fall units.

The fall deposits are multiple-bedded, mostly on decimeter to millimeter scale, reflecting the episodic nature of much of the eruption on perhaps a 1- to 20-km<sup>3</sup> volume scale. The eruption contained several time breaks, seen by minor erosion and/or fine ash beds in the deposits. The longest break was perhaps on the order of several months; the shortest was only a few hours to days.

Eight clearly demarcated fall units include (1) moderately to well-sorted pumice-fall beds (units 1, 5, and 7) that superficially resemble normal plinian deposits but show exceptionally wide dispersal, (2) similar beds that contain variable amounts of fine grained, water-flushed ash (units 2, 4, and 6), and (3) two units (units 3 and 8) dominated by cohesive fine ash. The latter are similar to the Rotongao ash. Two overlying fall beds show only indistinct bedding, are more uniformly fine-grained vitric ash, and represent most of the total volume of the fall deposit. The macroscopic juvenile component in all beds is pumiceous, as in the Hatepe ash. All beds show some evidence of water involvement on deposition but, unlike the 181 AD examples at Taupo, there are virtually no signs of syneruptive remobilization of the depositing ash by running water. Water served to promote early deposition of ash by clumping, rain flushing, and forma-

tion of accretionary lapilli, which reach diameters up to 3–4 cm and locally make up to 50% of the volume of the deposit.

The associated ignimbrite was formed by numerous pyroclastic currents over most of the lifetime of the eruption and contains many tens to hundreds of flow units. It shows three unusual features:

- (1) it increases in grain size upward as well as with proximity to the source, such that both the coarsest and the finest grained deposits are found at exposures close to the source;
- (2) it typically contains 10–25 wt% of lithic material in proximal to medial sections, reflecting large-scale (tens of km<sup>3</sup>) excavation of country rock during syn-eruptive caldera collapse; and
- (3) distribution of the ignimbrite is bilaterally symmetric, with the farthest traveled flows reaching to the NE and SW.

## B. General Characteristics

The unifying feature of the phreatoplinian eruptions listed above is that they all involve silicic magma interacting with lake water, yet even in these type examples there is an enormous range of attributes. All have *F*

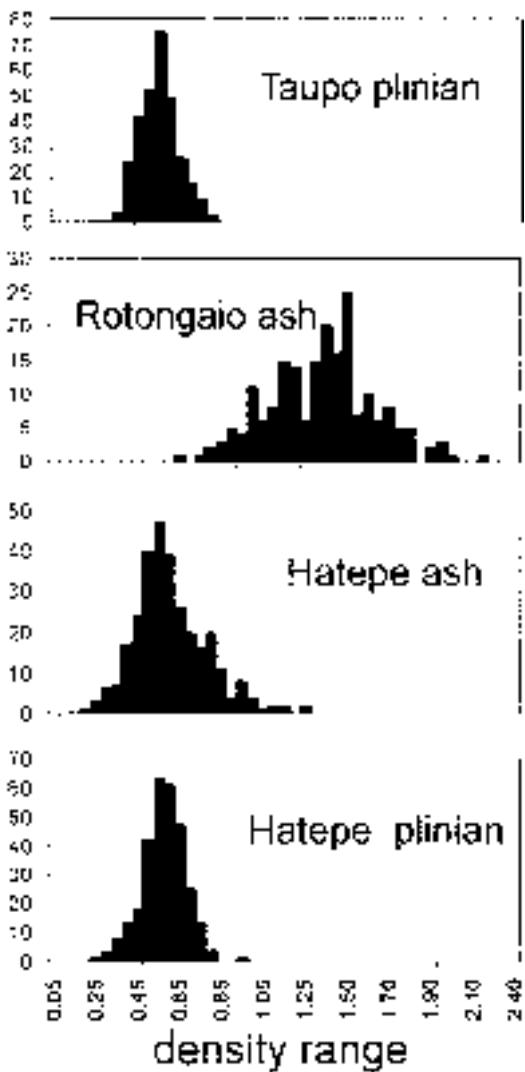

FIGURE 4 Density histograms for phases of the 181 AD Taupo eruption. The Hatepe ash shows density data broadly similar to those of the enclosing Taupo and Hatepe plinian deposits, whereas the Rotongaio ash shows a much wider range of values with no pronounced density mode.

indices of 80% or more, but the volumes of fall deposits vary by  $>3$  orders of magnitude, from 0.1 to  $500 \text{ km}^3$  (Table I). They form thin blankets dispersed over areas of  $10^3$  to  $>10^6 \text{ km}^2$  ( $B_t$  values from 3 up to 150 km,  $D$  values of 400 to 225,000,000  $\text{km}^2$ ). The duration of events has been measured (at Askja) to be as short as a few hours and estimated to be as long as weeks to months (in the case of Oruanui). Inferred intensities (discharge rates) thus overlap the ranges of subplinian and plinian eruptions. Some examples involve sustained discharge of magma on a timescale of hours, but others, notably

the Rotongaio ash, show conspicuous evidence for repeated episodicity. Most examples are rich in pumiceous ejecta, implying that fragmentation may in (large?) part have been due to exsolution of magmatic volatiles prior to interaction with water. The Rotongaio ash, with its abundance of poorly vesicular clasts, and possibly the Askja-C deposit are clear exceptions. Most phreatoplinian fall deposits have very low wall rock contents (typically less than 5 wt%), with surprisingly little difference between ash-rich and lapilli-rich subunits. This implies that the magma : water interaction occurred at very shallow or surficial levels, consistent with the water sources being in crater or caldera lakes, rather than in aquifers. Exceptions are where fall deposition accompanies caldera collapse and emplacement of voluminous ignimbrites, for example, the Oruanui deposits, which typically contain 3 to 18 wt% wall rock.

The diversity between beds *within* individual phreatoplinian eruptions is also extreme, and some units within the phreatoplinian phases are identical in grain size and componentry to the deposits of plinian phases of the same eruption. This review highlights that even these classical deposits are diverse and internally complex. As discussed later, this diversity reflects the varying roles played by external water during fragmentation, transport, and deposition.

The type phreatoplinian deposits are divided here into three facies, which reflect three broad but very different modes of pyroclast transport and deposition. These are lapilli fall deposits, ash accretion fall deposits, and deposits of pyroclastic density currents.

The lapilli fall facies includes both fines-poor lapilli beds and fines-bearing lapilli beds. Fines-poor, coarse ash-lapilli beds are often indistinguishable from the products of plinian fall activity on the basis of grain size alone. Phreatomagmatic lapilli fall beds also show typical plinian isopach geometries and become progressively finer grained with distance from the vent. These features result from relatively dry processes in which clasts fall dominantly as individual particles, and size-fractionation and density-fractionation are effective during transport. Fines-bearing lapilli beds, in which lapilli are typically coated in very fine ash and set in a sparse matrix of massive ash or ash aggregates, are also common. The lapilli fall facies beds are interpreted as relatively dry fall with minor water-aided ash aggregation often due to either mixing with earlier erupted wet ash or due to regional rain storms.

In many eruption plumes, ash particles accrete to form aggregates that behave as individual particles during continuing transport and deposition. Ash accretion textures in the resulting deposits include *matrix-rich* beds

TABLE I Properties of the Type Phreatoplhinian Deposits

Unit	V (km <sup>3</sup> )	b <sub>t</sub> (km)	b <sub>c</sub> (km)	D (km <sup>2</sup> )	F (wt%)
Askja 1875 C	0.2	4.5	4.0	400	79
<sup>a</sup> Oruanui fall 1	0.8	18		10000	100
fall 2	0.8	20		49000	100
fall 3 (distal)	4.8	18		45000	99
fall 5 (proximal)		68			
fall 5 (distal)		148			
fall 5 (total)	14		26	1.6 × 10 <sup>6</sup>	99
fall 6	5.5	44		260000	100
fall 7	15	58	39	470000	96
All fall deposits	500	>79		2.3 × 10 <sup>6</sup>	100
<sup>b</sup> Rotongaio ash G	0.02	4.4		2900	90
F	0.11	3.3		1500	100

Note. Unit 8 of the Oruanui eruption has been excluded because its unusual geometry precludes determination of the dispersal or grain size parameters. Columns are V, eruptive volume; b<sub>t</sub>, thickness half-distance (see Fall Deposits); b<sub>c</sub>, clast half-distance; D, dispersal index; F, fragmentation index.

containing scattered accretionary lapilli, *matrix-poor* beds of closely packed accretionary lapilli, and *vesicular* ash beds with remnant, partially coalesced accretionary lapilli (Fig. 5). A fourth fine-grained ash facies lacks any evidence for remnant accretionary lapilli but commonly passes gradationally, both laterally and vertically, into the other ash accretion facies. These features reflect a wide range of contents of liquid water during transport and on deposition. Field evidence implies that the development of these textures can vary rapidly in time and (in the Rotongaio and Hatepe examples described above) over distances as short as hundreds to a few thousand meters.

The products of pyroclastic density currents (PDC) in phreatoplhinian eruptions are, with few exceptions (notably the Oruanui below), subordinate in volume to the fall deposits and only occur in proximal areas. Because there is so little contrast in grain size characteristics between phreatoplhinian fall deposits and PDC deposits, bedforms yielding evidence for lateral emplacement are

the most important diagnostic feature. These are seen in the form of pinching and swelling of laminae in the Rotongaio ash, through to the development of cross-bedded megaripples in the Askja 1875 deposits, and spectacular megaripples in the Phase 2 deposits of the Minoan eruption of Santorini. Other proximal PDC facies include massive to poorly bedded ignimbrite units, known from the 22 <sup>14</sup>C-ka Aira eruption in Japan (Tsumaya ignimbrite) and phase 3 of the Minoan eruption.

In the Oruanui deposits, two contrasting styles of PDC deposit are seen. The first is relatively normal nonwelded ignimbrite, which extends as far as 90 km from the vent and ranges up to 200–250 m in thickness. The bulk of the ignimbrite was emplaced as nongraded decimeter to meter scale flow units, whose contacts become blurred upward to form a vaguely stratified deposit in proximal areas. This material is interpreted as the product of relatively concentrated currents, that is, pyroclastic flows (s.s.). The second style of deposit forms a small proportion of the main ignimbrite (particularly

**FIGURE 5** Photographs of ash aggregates: (a) a single accretionary lapillus from Sakurajima. [From *Volcanic Plumes* R. S. J. Sparks et al. Copyright John Wiley & Sons Limited. Reproduced with permission.] (b) a mixture of ash aggregates and disaggregated fine ash, and (c) a unit in which ash aggregates have partially coalesced to leave an open vesicular structure.

the distal fringes of flow units) and much of the proximal parts of fall unit 3. It consists of beds that are normally graded from coarse-ash bases (with nonerosive to mildly erosive basal contacts) up to fine-ash dominant material that is indistinguishable from the contemporaneous fall material. These units resemble turbidites in their grading and are interpreted as the products of relatively dilute suspension currents that temporarily interrupted fall deposition at any particular locality.

Grain size data from phreatoplinian ignimbrites are limited, but suggest that they are somewhat finer grained than typical ignimbrites, both lacking abundant lapilli-to block-sized material and having a higher proportion of  $<1/16$ -mm ash. Both features are attributed to enhanced fragmentation during magma : water interaction.

### C. Other Potential Candidates for Phreatoplinian Eruptions?

#### 1. Vesuvius

The type plinian and subplinian eruptions of Vesuvius end with phreatomagmatic phases for which there is compelling evidence that the external water phase was groundwater, in an aquifer at kilometer scale depths beneath the volcano. Typically each phreatomagmatic deposit contains two phases: a lower unit characterized by ignimbrite, lapilli fall, and surge deposits (e.g., the 79 AD phreatomagmatic dry phase) and an upper unit rich in fine ash containing surge and fall deposits often rich in accretionary lapilli (e.g., the 79 AD phreatomagmatic wet phase). The upper units are generally limited in their dispersal (i.e., analogous to subplinian) but are otherwise texturally identical to the classical phreatoplinian deposits described above. The lower portions of the phreatomagmatic units are multiple bedded and these beds are coarser grained and better sorted than the type phreatoplinian deposits and, in these regards, more similar to the associated plinian falls. However there are two forms of textural evidence from the pyroclasts that support the notion that magma : water interaction occurred during fragmentation in both types of phreatomagmatic product. First, the juvenile clasts show a wide range of vesicularities and coatings of fine ash particles, the glass phase is commonly altered, and secondary minerals encrust clasts and fill vesicles. Second, these deposits contain a high proportion of deep-derived wall rock lithics that can be matched only to the lithologies encountered in drill holes at the level of the deep aquifer. Whether either or both types of phreatomagmatic deposit at Vesuvius should be termed phreatoplinian is discussed in Section IV, A.

#### 2. 18 May 1980, Mount St. Helens

The fall deposit associated with the 18 May 1980 eruption of Mount St. Helens is a widespread unit that has generally been regarded as classically plinian and coignimbrite in nature. Accumulation of the distal fall is inferred to have involved significant aggregation of very

fine ash, leading to a secondary thickness maximum 325 km from the vent. The 18 May 1980 deposit is one of few fall deposits for which a calculation can be made of the whole deposit grain size. The deposit is strikingly fine-grained, polymodal, and poorly to very poorly sorted at all medial to distal sites, leading to the suggestion, made in the principal study of the ash, that the deposit could be classified as phreatoplinian. The proximal equivalents of the ash fall are principally the accretionary-lapilli-bearing unit A3 (a coignimbrite fall deposit) and the vent-derived lapilli fall units B1, B2, and B4. The latter are lapilli or coarse-ash sized and relatively well sorted.

---

## II. ERUPTION AND TRANSPORT PROCESSES

### A. Fragmentation and Eruption Mechanisms

Fragmentation (and explosive eruption) in the majority of the examples described here was brought about by vesicle nucleation and growth as well as by quenching by external water. The high degree of vesiculation of the juvenile clasts has generally been taken to imply that the magma was already a foam and perhaps starting to fragment when it first encountered external water. The precise mechanism for both of these processes is far from well defined (see Magmatic Fragmentation, and Phreatomagmatic Fragmentation). In one significant exception that we are aware of, the Rotongaio ash, fragmentation appears to have taken place after degassing, and explosivity driven by the rapid exsolution of large volumes of magmatic volatiles appears to have been unimportant.

Most of the documented phreatoplinian deposits represent eruptions where the frequency of individual explosions was such that a continuous plume was maintained for periods of hours or more. There are three significant exceptions to this: the Rotongaio ash, the Ikeda ash from Ikeda caldera in Japan, and Unit E of the 260AD Terra Blanca Jovan tephra from Ilopango caldera in El Salvador. Each of these deposits contains numerous sharply defined millimeter- to centimeter-thick beds suggesting that the deposits are the products of numerous powerful but discrete explosions that gave rise to individual short-lived plumes and numerous short-lived episodes of deposition.

### B. Accretionary Lapilli and Ash Aggregation

The processes of collision, binding, and breakup of particles in moisture-bearing eruption plumes lead to the formation of aggregates of ash (Fig. 5a) that in turn play an important role in the deposition of ash from phreatoplinian plumes. Ash aggregates fall with greater velocities than their component particles and so the process of aggregation results in the premature flushing of large quantities of fine ash and the simultaneous deposition of a wide range of grain sizes. This creates poorly sorted and fine-grained fall deposits even close to the vent.

The formation of aggregates is governed by factors such as the concentration, shapes, and size distributions of ash, the abundance and physical state of water in the plume, and the temperature and relative humidity of the plume and surrounding atmosphere. Phreatoplinian ash aggregates form a spectrum, which can be related, in the first instance, to the liquid content (water plus dissolved gas species) of the depositing pyroclast assemblage. The spectrum ranges from weak clusters of grains at the dry end to ash-free rainfall at the wet end. In between these two endmembers are accretionary lapilli of various types, sizes, and structures and mud rain. The dry end of the ash aggregation spectrum is represented by weak clusters of grains, which have been observed to fall from dry plinian plumes. With condensation of water in an eruption plume, ash will accrete into denser clumps as accretionary lapilli. Recent experimental work shows that the likely origin of accretionary lapilli is through collision of liquid-coated ash particles in the plume. Ash particles in a water-rich plume act as condensation nuclei for water vapor and clasts and may be continually coated in acidic liquid or ice. When clasts collide, due to different fall velocities and convection in the plume, the potential for binding is enhanced because of the effect of strong, short-range surface tension forces. Electrostatic attraction is also important for attraction of particles and the fine-grained outer layers on many accretionary lapilli probably form this way.

### C. Pyroclastic Density Currents and Phreatoplinian Volcanism

In phreatoplinian eruptions, formation of pyroclastic density currents occurs both on a local scale by lateral ejection of material directly from the base of an otherwise stable plume and through partial or complete col-

umn collapse, forming flows on a large scale. A wide spectrum of PDC has occurred in phreatoplinian events:

- (1) weak dilute currents (e.g., Rotongaio) that leave only subtle evidence for lateral transport,
- (2) energetic dilute currents that generate cross-bedded surge deposits (e.g., Minoan phase 2, Hatepe) or normally graded turbidite-like beds (e.g., some Oruanui units), and
- (3) concentrated flows of low to high energy that deposit conventional ignimbrite (e.g., most Oruanui units).

Two features are useful in distinguishing phreatoplinian PDC deposits from their dry counterparts: first, the presence of accretionary lapilli and, second, evidence for cohesion (induced by liquid water) on deposition, such as oversteepened beds and plastering of vertical surfaces.

#### D. Numerical Models for Phreatoplinian Plumes

There are some indications that existing models for eruption columns are inadequate to quantify phreatoplinian systems, due to complexities and uncertainties in the nature of surficial magma: water interaction. Theoretical models suggest that limited amounts of added water (to about 15 wt%) serve to expand the field of stability for buoyant plumes (which produce fall deposits) and have little effect on the height (i.e., dispersal power) of the buoyant plume. Excessive amounts of water (>40–50%) cause column collapse, generating pyroclastic density currents. Field evidence to test against these hypotheses is generally lacking, because there is no linkage in the published literature between estimates of water contents in the depositing material (which is all that can be assessed) and the inferred water contents in the eruptive plumes.

There is, however, sufficient field evidence to suggest that the models for stability fields of phreatoplinian plumes are not adequate at present. The Hatepe and Rotongaio units were deposited with enough water to locally generate contemporaneous streams, yet are dominantly (>95 vol%) composed of fall material. The large amounts of water involved in these eruptions apparently did not cause major fountain collapse, and only local, proximal PDC deposits are known. In contrast, in the Oruanui eruption, the volumes of fall and PDC deposits are similar (and large) but the plume water content was probably much lower. In addition, the extremely power-

ful dispersal of the Oruanui fall units (both drier and wetter deposited) seems at odds with the suggestion that the height of phreatoplinian plumes is reduced relative to their dry analogs (as theory predicts for such large events). Perhaps either phreatoplinian plume expansion rates are correspondingly more rapid or some unknown mechanism is operating to carry pyroclasts further from the vent prior to their deposition.

---

### III. DEPOSITION PROCESSES

#### A. Processes of Fall Deposition

Phreatoplinian deposits contain mixtures and alternations of clasts that were deposited as discrete particles and as ash aggregates. Lapilli-rich units contained within the type phreatoplinian deposits share the grain size and dispersal characteristics of plinian falls and were not significantly influenced by processes of particle aggregation. The type examples also contain some beds of relatively well-sorted, fine or medium ash. These are likely to have been products of fallout of loosely bound dry aggregates of grains and weakly cohesive accretionary lapilli that disintegrated on impact.

Ash aggregates are deposited with a wide range of water contents. Direct observations of historical eruptions include very dry clusters that crumbled on impact (Mount St. Helens 1980), aggregates that remained intact (e.g., Sakurajima), those that splashed on impact (Soufrière, St. Vincent 1979), and those that landed intact but defrosted into a mud slurry (Ruapehu 1969).

At the very wet end of the spectrum of ash deposition is mud rain. Where a plume is rich in water vapor and liquid, droplets form up to a few millimeters in diameter and scavenge particles as they fall, leading to rainout of wet mud. Quantitative records of this style of ash fall are rare.

We infer that beds containing accretionary lapilli/mud lumps in a matrix of loose ash of comparable grain size (Fig. 5b) reflect simultaneous deposition of accretionary lapilli/mud lumps that crumbled and were destroyed on impact and aggregates that fell frozen/cemented and intact. Beds of well-sorted accretionary lapilli reflect deposition of intact frozen accretionary lapilli or lapilli cemented by secondary mineral growth during transport. Beds of partially coalesced accretionary lapilli (Fig. 5c) represent deposition of accretionary lapilli that deformed plastically at or soon after deposition and adhered at contact points (note that the contrast

with the well-sorted beds of accretionary lapilli may simply reflect the ambient temperature at the Earth's surface at the time of deposition). Massive fine ash beds with relict vesicular textures are more difficult to interpret unequivocally, but may represent the deposition of wet mud lumps, transitional to mud rain. The degree of agglutination of the aggregates probably reflects both liquid–ash ratio and accumulation rate. In either case the process requires liquid–ash ratios higher than those of the other facies types. Thick beds of coalesced aggregates may represent prolonged episodes of wet mud lumps/mud rainfall, whereas thin, irregular intervals may reflect ephemeral changes in accumulation rate.

### B. Syneruptive Erosion

The products of secondary processes occur interbedded with primary phreatoplhinian products on a centimeter or decimeter scale in some units and, locally, secondary beds can be found juxtaposed with, or transitional into, primary beds at the same stratigraphic level (Fig. 6). Field evidence clearly shows that such secondary processes were *syneruptive* and a complex and intimate relationship existed between primary pyroclastic deposition and secondary reworking. The relative timing of primary depositional events and secondary modification is

variable and in many instances secondary modification must have been coincident with primary accumulation, both temporally and spatially.

Throughout deposition of units such as the Rotongaio ash there was always a delicate balance between accumulation, reworking, and erosion. This balance was affected by factors related to vent conditions, plume dynamics, regional scale topography and local relief, hydrological conditions at the point of deposition, external meteorological influences, and the interaction between many of these factors. The extent to which a bed is secondary was, in large part, a function of primary deposition of the ash, controlled by eruptive conditions but influenced by aspects of the local depositional environment.

The products of reworking range from well-sorted ash lenses, produced by sheet washing, to channel-confined, well-sorted, lithic- and crystal-rich fluvial sand. The sheet wash lenses are diffuse, millimeter scale fines-poor partings or wisps that are laterally discontinuous and occur within otherwise primary fall beds. The fluvial beds are typically massive and well-sorted with no evidence for tractional structures. This reflects the scale of the sedimentary processes involved, with typically very short transport distances (i.e., meters rather than kilometers).

A feature of all ash-rich beds of the Rotongaio ash is plastic deformation and thickness variations along out-

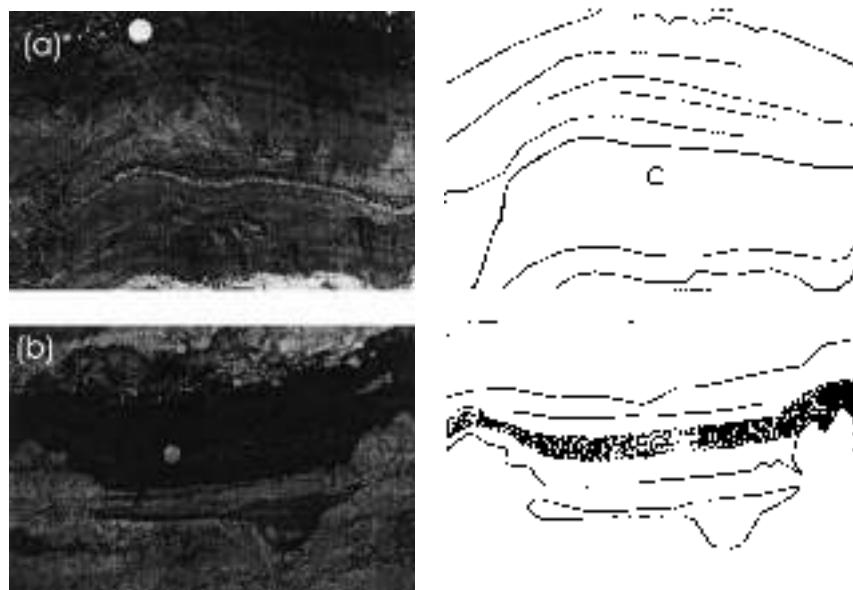

FIGURE 6 Photographs showing syneruptive reworking of the Rotongaio and Hatepe ash. Note the multiple gullies within the Rotongaio ash in (a) and the presence of lenses of reworked Hatepe ash (pale material) within the overlying Rotongaio ash in (b). Subunit Rn-C is labeled C for reference.

crop in response to the local topography. The extent of these variations is a function of the liquid–particle ratio of the deposition system, the extent and form of the micro- and regional topography, and the nature of the underlying bed at the time of deposition. In some cases ash has clearly flowed off high ground as a viscous liquid producing flat-topped gully infills.

---

#### IV. DISCUSSION

##### A. Wet Eruption versus Wet Deposition

One of the major outstanding problems in studies of phreatoplinian volcanism is that there is some degree of independence between processes occurring at the eruptive vent and those influencing deposition. Phreatoplinian volcanism, by definition, implies wet activity at the vent, but the extent to which that is revealed in wet *deposition* is highly variable, as discussed in previous sections. For example, in the Rotongaio ash, liquid : ash ratios during deposition varied significantly on a *local* scale of tens to hundreds of meters, from locations where matrix-free pellets were being deposited to sites where surface erosion and rilling was occurring through runoff of excess water. Thus even where reconstruction of the proportion of water involved on deposition can be carried out, the ash : water ratios thus derived need not reflect relative or absolute values of the magma : water ratio at the vent.

Equally well, explosive eruptions that are dry at the vent can generate deposits that in many respects are indistinguishable *on the outcrop scale* from phreatoplinian deposits, reflecting entrainment of atmospheric moisture or the impact of regional weather systems. Rain-flushed beds within dry plinian fall deposits are attributed, for example, to the chance passing of storms during the eruption. The most extreme example of this occurred during the 15 June 1991 climactic phase of the Pinatubo eruption, when the plume interacted with a tropical cyclone, and much of the proximal to medial fall deposition was as wet, water-saturated material.

In young well-exposed deposits commonly there are additional kinds of evidence, apart from that of wet deposition of ash, to facilitate identification of phreatoplinian volcanism. However, in ancient or poorly exposed deposits the discrimination of phreatoplinian deposits from other fine-grained, poorly sorted deposits is problematic.

##### B. The Spectrum of Widespread, Phreatomagmatic Fall Deposits

The type phreatoplinian deposits are conspicuously fine grained and were singled out on the basis of the presence of ash-rich beds often containing accretionary lapilli. However within these predominantly fine-grained phases there are coarser grained and better sorted beds (e.g., Oruanui units 1, 2, 5, and 7; Rotongaio ash C; Hatepe ash C; Table I). A key question is, are these units plinian, that is, the products of absolutely dry or magmatic fragmentation, or do they represent phreatomagmatic intervals with a low water:magma ratio?

All these type units, fine-grained or coarse-grained, aggregate-bearing or aggregate-free, are inferred, on the basis of the known hydrology of the vent area, to have resulted from the interaction of magma with surface water. The equally well-studied historical eruptions of Vesuvius contain similar deposits where the evidence is equally compelling that the erupted magma encountered deep groundwater contained within a limestone aquifer. The Vesuvius deposits also contain ash-rich, poorly sorted beds rich in accretionary lapilli and coarse-grained, better sorted lapilli fall deposits. By comparing these two types of youthful well-studied deposits we can observe some differences between the interaction of silicic magma with surface water and with groundwater. In comparison to the former, the latter contain a wider range of vesicularities and morphologies among the juvenile clasts, evidence for coating and alteration of juvenile clasts and a generally (but not exclusively) higher abundance of wall rock lithic clasts linked to stratigraphic units found only at great depths below the volcano. However it is extremely doubtful whether such a distinction between surface water and groundwater sources could be made consistently during study of ancient deposits.

The Vesuvius phreatomagmatic deposits help us with the dilemma over units like Oruanui units 1, 2, 5, and 7; Rotongaio ash C; and Hatepe ash C. The Vesuvius beds show much more convincing evidence that low water:magma ratios have little effect on fragmentation levels and hence the grain size properties of the deposits, yet other indicators, such as clast vesicularity and morphology, lithic clast abundances, and coatings of ash and secondary minerals, show that some external water was involved in the eruption. This is strong circumstantial evidence suggesting that grain size parameters are not the most sensitive indicators of limited magma:water interaction and conversely that moderate-to-high water/magma ratios are required to produce fine-

grained, poorly sorted deposits rich in accretionary lapilli.

### C. Gradation to Other Eruptive Styles

The distinction between plinian and phreatoplinian styles of explosive eruptions is in the involvement of recognizable quantities of external water in eruption and transport processes; in practice, the distinction between plinian and phreatoplinian deposits is based on grain size parameters. In outcrops of the Askja 1875 and Taupo 181 AD deposits there is a clear distinction between plinian units, which are both coarse-grained and relatively well sorted (Askja-D, Hatepe plinian, Taupo plinian), and phreatoplinian deposits, which are dominantly fine-grained and very poorly sorted (Askja-C, Hatepe ash, Rotongaio ash). However within the fine-grained phreatoplinian units there are beds or packages of beds whose grain size characteristics are indistinguishable from those of plinian deposits.

Some vulcanian eruptions have instantaneous discharge rates equivalent to phreatoplinian and plinian events and produce widely dispersed sheet-like fall deposits. They differ from plinian and most phreatoplinian eruptions in that they are nonsustained and are typically a sequence of discrete explosions. In vulcanian deposits the time breaks are recorded by the presence of sharply defined, centimeter to meter scale bedding.

### D. A Practical Definition of Phreatoplinian Volcanism

Plinian and phreatoplinian deposits were first distinguished on the basis of the *fragmentation index*. More recent classifications (see Pyroclastic Fall Deposits) lack a measure of absolute grain size and thus do not distinguish even the type phreatoplinian units from plinian deposits.

The classical examples of phreatoplinian eruptions involved sustained eruption of highly vesiculated silicic magma through a source of abundant lake water. The Rotongaio ash is an exception to this in two ways. First, the eruption was not sustained but formed a sequence of short-lived high plumes, related to discrete explosions, and, second, the juvenile component was largely degassed at the time of fragmentation. A key question is how significant are these differences and how restrictive should the definition of phreatoplinian be? At its broadest this definition could be *Phreatomagmatic eruptions whose products have plinian or subplinian dispersal*. This

definition would include the Rotongaio ash and also widespread phreatomagmatic falls associated with magma interacting with groundwater, for example, phreatomagmatic phases of the historical Vesuvius eruptions. We strongly favor adoption of such a broad definition. The most obvious flaw in this definition is that proof of a phreatomagmatic origin becomes more difficult as the water:magma ratio decreases—how different for example are the lapilli falls in the Hatepe ash from dry plinian falls?

In answer to the questions asked at the start of this chapter:

- *Is high vesicularity of the erupting magma part of the definition for phreatoplinian eruptions?* No, the Rotongaio and Askja-C ashes and many of the Vesuvian phreatomagmatic deposits contain dense, relatively poorly vesicular clasts.

- *Should all fine-grained fall deposits with wide dispersal be called phreatoplinian?* Yes if one can infer or observe the involvement of external water in the eruption process (thus excluding, for example, equally fine grained layer 3 deposits of ignimbrites).

- *Must phreatoplinian eruption columns be sustained?* No, although, at some stage in the future, it may be practical to separate a class that includes units like the Rotongaio and Ikedako ashes from units like the Hatepe and Askja-C deposits.

- *What dispersal index is an appropriate lower limit for phreatoplinian eruptions?* The current limit seems a better alternative to the introduction of a name such as *phreato-subplinian*.

- *How useful are grain size parameters in delineating phreatoplinian deposits?* Grain size criteria alone can be used to identify deposits corresponding to moderate to high water:magma ratios but not the products of weakly phreatomagmatic eruptions.

- *What range of water:magma ratios should phreatoplinian volcanism be applied to?* Low water:magma ratios often cannot be detected either during eruptions or from deposits. In a philosophical sense a lower limit corresponding to equal amounts of external water and intrinsic dissolved volatiles is appealing but, for a practical classification, it is preferable not to set a rigid hypothetical limit.

## GLOSSARY

- advection** Horizontal transport of material.
- chaotic advection** The stretching of air parcels into complex shapes by wind.
- co-ignimbrite plume** Plume produced from a pyroclastic flow.
- elutriation** Loss of small particles by the upward flow of gas through a pyroclastic flow.
- entrainment** The process of picking up and carrying along.
- hemispheric flow** The largest scale of the atmospheric flow, generally in distinct latitudinal bands; also called zonal flow.
- latent heat of condensation** Heat released upon conversion of vapor to liquid.
- neutral buoyancy level** Height at which the plume density is equal to the surrounding atmosphere.
- stratosphere** The upper portion of the atmosphere from an altitude of about 10 to 50 km.

**thermal** A discrete mass of air or particles and gases that rise in the atmosphere by buoyancy.

**troposphere** The lower portion of the atmosphere from ground level to about 10 km.

**tropopause** Boundary between the troposphere and stratosphere.

**turbulent diffusion** Mixing by turbulent flow.

**V**OOLCANIC PLUMES are mixtures of volcanic particles, gases, and air that are produced mainly by explosive eruptions. They are injected into the atmosphere and can disperse ash and gases on a global scale. Buoyancy plays a fundamental role in the motion of plumes and determines how they interact with the atmosphere. Energetic plumes can rise to altitudes as great as 50 km above the Earth's surface. Many different types of eruptions can produce plumes and their behavior is controlled by such factors as the composition of erupted magma, the amount and nature of volatile components, the rate of magma discharge, and the geometry of the source vent. Some plumes are maintained for relatively long periods of time by the continuous discharge of material from a vent. For example, the eruption of Mount St. Helens (United States) on May 18, 1980, produced a volcanic plume for over 9 hours. In other

cases, plumes form discrete injections of gases and particles into the atmosphere that may last for only a few minutes.

Plumes are a complex phenomena to model and understand because they are mixtures of gases, solids, and liquids. However, much has been learned about volcanic plumes through the application of basic theories on turbulent convective plumes. In particular, the transition in plume behavior from convective rise to collapse is especially important. Rising plumes are generally able to disperse volcanic particles and gases over large areas by transport and fallout through the atmosphere. This type of activity poses relatively low deadly volcanic risk to the surrounding population. An exception, however, is the hazard to aircraft in flight that inadvertently encounter volcanic plumes. Ingestion of particles and gases can lead to engine failure and the potential for disaster. In contrast, collapsing plumes generate hot mixtures of gases and particles (pyroclastic flows and surges) that move down the slopes of a volcano at high speeds and can result in large numbers of fatalities.

---

## I. GENERATION OF VOLCANIC PLUMES

Volcanic plumes are generated when magma is fragmented into small pieces and discharged from a vent at high velocity. The erupted mixture consists of partially molten or solid particles that represent the magma, gases from the magma or the surrounding environment (which may condense to liquids), and pieces of the volcanic edifice, referred to as wall rock lithics. Rapid acceleration of this material into the atmosphere is largely driven by the expansion of gases due to the decrease in pressure as material is erupted at the surface.

### A. Fragmentation by Volatile Degassing

Most magmas contain small amounts of dissolved volatile components such as water, carbon dioxide, and sulfur dioxide prior to eruption when they are stored beneath the Earth's surface. The solubility of these components increases as a function of pressure, or depth. Conversely, as magmas rise to the surface these volatile components begin to come out of solution to form bubbles (Fig. 1). Bubble expansion occurs by a combination of pressure drop and diffusion of the volatile components from the

dissolved state in the magma to a gas phase. As the volatile components form bubbles the magma's viscosity increases. As a result of the high viscosity, bubble growth is impeded and high internal pressures develop within the bubbles. The net result is that bubble walls rupture and the magma is transformed into a mixture of broken bubble fragments and gas in the conduit. Above this fragmentation region gas becomes the continuous phase carrying particles suspended in a rapidly accelerating and turbulent mixture (Fig. 1). Discharge of this material out of a vent forms volcanic plumes. Examples of such plumes include the explosive eruptions of Mount St. Helens in 1980 (Fig. 2; see also color insert), the 79 A.D. eruption of Vesuvius, and the great 1815 eruption of Tambora in Indonesia (see Magmatic Fragmentation).

### B. Fragmentation by Interaction with External Water

Volcanic eruptions often involve the interaction of hot magma with water at, or near, the Earth's surface. Under certain conditions the transfer of heat from magma to water can result in the explosive conversion of water to steam and fragmentation of magma into small pieces. This type of activity is referred to as phreatomagmatic. The factors that influence whether the magma–water interaction will be explosive or not include the mass ratio of water to magma, the degree to which the interaction is confined, and the rate at which the interaction takes place. The maximum energy release occurs when the ratio of water to magma is about 0.3. Volcanic plumes generated by this mechanism may contain larger quantities of water and be cooler than those produced by degassing of volatiles directly from magma. Spectacular examples of plumes generated by magma–water interaction occurred during the emergence of Surtsey Volcano from the sea south of Iceland in 1963. Instantaneous releases of particles and steam may also occur when magma encounters water under confined conditions. One example would be when rising magma intersects an aquifer during its ascent beneath a volcano (see Phreatomagmatic Fragmentation).

### C. Elutriation from Pyroclastic Flows and Surges

In most cases the mixtures of hot gas and particles that are ejected from volcanoes during explosive eruptions have an initial bulk density (gas + particles) that is higher

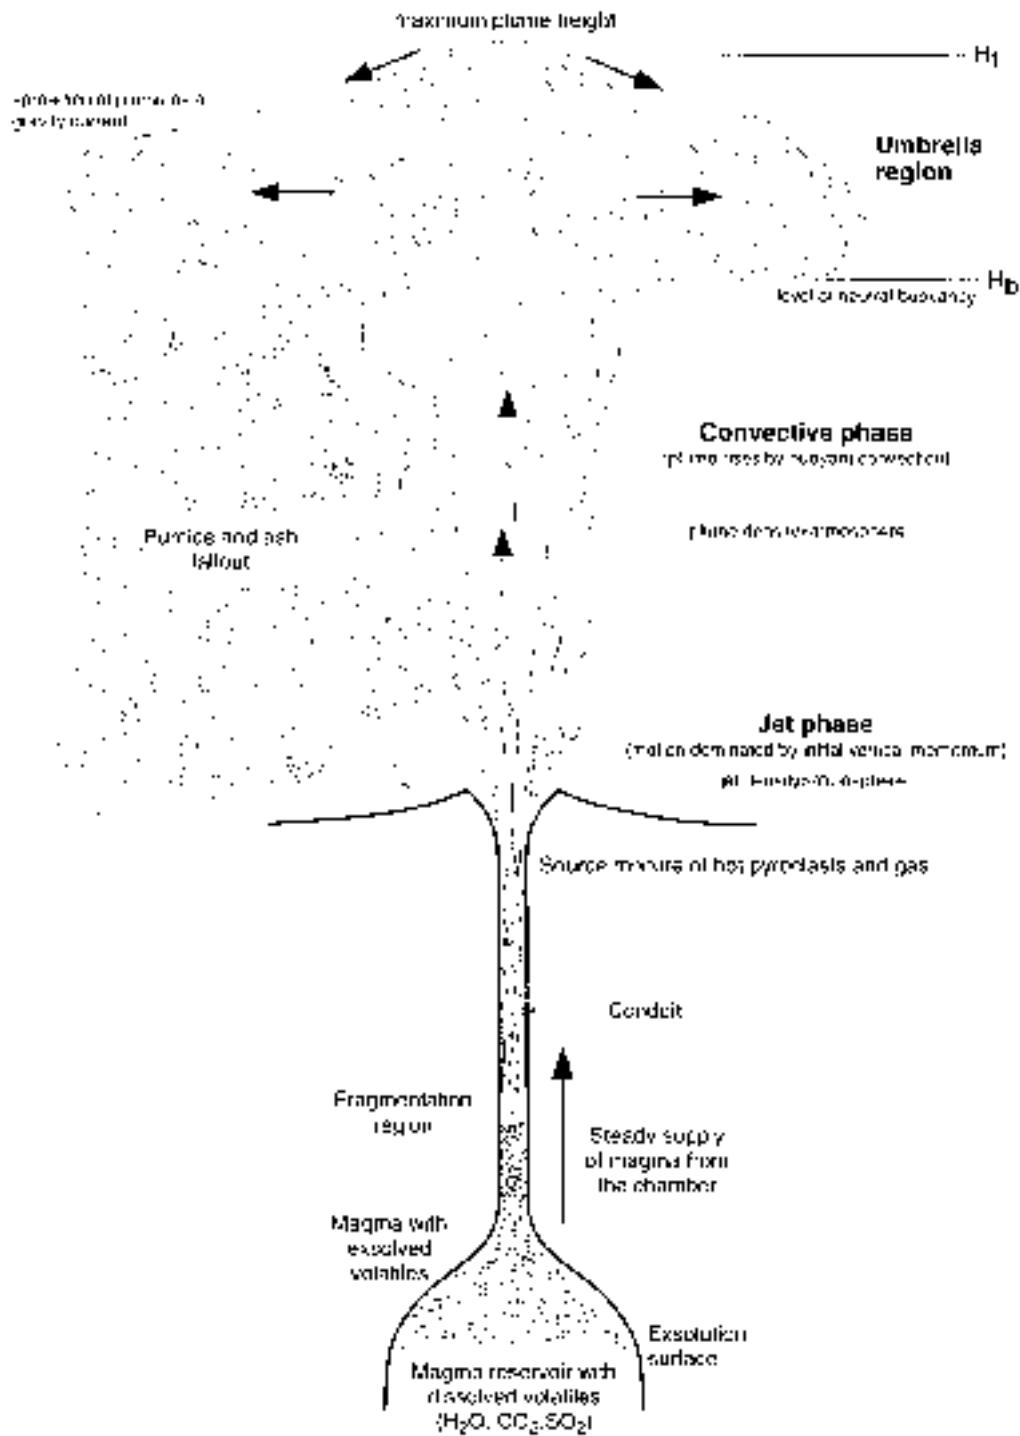

FIGURE 1 Formation of a volcanic plume by the degassing of volatile components ( $H_2O, CO_2$ , and  $SO_2$ ) from a high silica magma. Magma with bubbles (foam) is converted to a highly turbulent mixture of gas and magma fragments within the fragmentation region. Above this level the mixture accelerates and is discharged from the vent at high velocity, forming a jet phase. Entrainment and heating of air causes the plume to rise buoyantly in the convective phase. At high levels in the atmosphere the plume reaches a neutral buoyancy level and spreads out to form an umbrella region.  $H_t$  is the maximum height attained by the plume and  $H_b$  is the height at which the plume density is equal to that of the surrounding atmosphere.

FIGURE 2 Volcanic plume generated by the July 22, 1980, explosive eruption of Mount St. Helens volcano. Magma fragmentation was driven by exsolution of dissolved volatiles in a dacitic magma. [Photo by Michael Doukas, reprinted with permission of the USGS Cascades Volcano Observatory. See also color insert.]

than that of the surrounding atmosphere. Unless they can achieve positive buoyancy they will collapse and flow down the slope of the volcano as pyroclastic flows or surges. As these flows travel away from their sources, sedimentation of particles from their bases and the heating of entrained air leads to a decrease in bulk density. Secondary plumes, or co-ignimbrite plumes, are then generated from the tops of flows by buoyant rise. The source of the plume is thus displaced laterally away from the source vent and may encompass an enormous area. During the initial phase of the Mount St. Helens eruption in 1980 a giant plume was generated from the top

of a pyroclastic surge that traveled up to 29 km from the volcano.

#### D. Heat Transfer During Effusive Eruptions and Fire Fountaining

Particle-poor volcanic plumes may be generated during eruptions that discharge large volumes of basaltic magma. In general, basaltic magmas contain lower amounts of volatile components, such as water and car-

bon dioxide, compared to more silicic magmas. In addition, their low viscosity allows for the differential movement and coalescence of bubbles to take place during magma ascent. Consequently, the degree of fragmentation is poor and the acceleration of material out of the vent is not as great as during the explosive eruption of viscous magma (see Hawaiian and Strombolian Eruptions). The ejected material commonly forms fire fountains that rise to only a few hundred meters above the vent. The majority of particles follow ballistic trajectories because their large size enables them to decouple from the motion of the gases. Plumes can be generated, however, by heat from the limited amounts of small particles and high temperature gases exsolved from the magma and by heat exchange between entrained air and the large clasts that fall back quickly to the surface.

---

## II. STRUCTURE AND BEHAVIOR OF VOLCANIC PLUMES

### A. Sustained Plumes from a Single Vent

Large-scale volcanic plumes are generated during the continuous discharge of fragmented silicic magma and gases from a single vent. A classic example of this was the 79 A.D. eruption of Mount Vesuvius that buried the ancient cities of Pompeii and Herculaneum. This style of volcanism is referred to as plinian, in honor of Pliny the Younger, who provided the first written description of an explosive eruption (see Plinian Eruptions). He described the appearance of the plume over Vesuvius as resembling a giant tree with the main part rising along a trunk but then spreading out at the top like a series of branches.

Plinian plumes are fed at their base by the discharge of hot gas and particles rising at velocities of 100–600 m/s. Production of this mixture is due to fragmentation of magma as dissolved gases are exsolved during ascent. As the material exits the vent its bulk density is usually greater than that of the surrounding atmosphere and rise of the material is due to the momentum gained by gas exsolution. Rapid deceleration occurs from the effects of gravity and by drag from the surrounding atmosphere. This jet phase typically extends up to several kilometers above the vent and is characterized by highly turbulent flow (Fig. 1). Atmospheric air is drawn into the gas thrust region by the development of turbulent eddies along its margins. The air is heated and

expansion results in a decrease in plume density with height.

A critical transition occurs when the bulk density of the gas thrust material becomes less than that of the surrounding atmosphere. The forces driving the motion of the plume now become dominated by buoyancy and continued rise occurs like a hot air balloon. This convective phase represents a large part of the plume "trunk" and may extend for tens of kilometers into the atmosphere (Fig. 1). The width of the plume increases progressively with height as entrainment of air continuously adds to the mass flux. Vertical velocities are of the order of 10s to 100 m/s, but their variation is related to the source conditions. Small vent radii promote a rapid transition to a convective regime and the vertical velocity decreases monotonically with height (Fig. 3). However, as vent radius increases the entrainment of air becomes slower and deceleration of the jet phase can lead to a nonlinear variation of velocity where there is an acceleration of the plume above the jet phase (Fig. 3). This condition is referred to as superbuoyancy.

Within the convective phase the vertical velocities are highest along the central axis and decay exponentially toward the plume margin. For plinian eruptions these velocities are sufficient to support centimeter-sized particles to tens of kilometers into the atmosphere. However, some are lost from this region when they migrate towards the margins and encounter lower average vertical velocities. In addition to losing particles, the temperature of the convective part of the plume decreases with height and its density difference with the surrounding

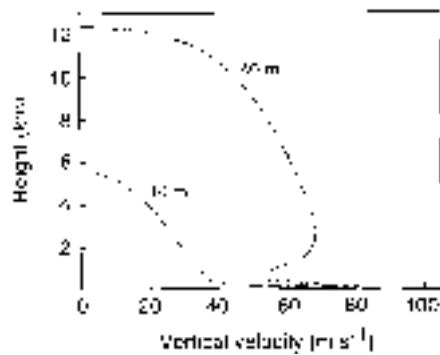

FIGURE 3 Variations in the vertical velocity of volcanic plumes from a central vent with radii of 10 and 40 m based on theoretical modeling. The initial conditions for both were an eruption velocity of 100 m/s, a magma temperature of 1000 K (727°C) and a water content of 3 wt%. Note the acceleration of the 40-m plume between 1 and 2 km height. [Modified from "Volcanic Plumes," Sparks et al., 1997; copyright John Wiley & Sons, Ltd. Reproduced with permission.]

atmosphere decreases as colder surrounding air is drawn into the plume.

The Earth's atmosphere decreases in density with height and eventually the convective part of a volcanic plume will reach a level where densities of the plume and surrounding atmosphere are the same (Fig. 1). At this point buoyancy is no longer a driving force of the plume and material will begin to move laterally at a level of neutral buoyancy,  $H_b$ . The ultimate top of the plume,  $H_t$ , will, however, be higher than this level because of the excess momentum that the plume has when it reaches the neutral buoyancy level. Between  $H_t$  and  $H_b$  material spreads out laterally to form a large intrusion into the atmosphere (Fig. 1). This umbrella region forms a distinctive mushroom-shaped cap to plinian plumes and corresponds to the spreading branches described by Pliny the Younger during the 79 A.D. eruption of Vesuvius. The proximal behavior of umbrella regions is similar to the movement of large-scale gravity currents.

The dynamics and dimensions of umbrella regions can be remarkable. Because large amounts of particles and gas enter the umbrella from below, conservation of mass requires that the flux of material be maintained between  $H_t$  and  $H_b$ . Near the plume axis lateral velocities are of the order of tens of meters per second and symmetrical spreading can occur over a large area. A good example is the umbrella cloud formed during the 1991 eruption of Mount Pinatubo in the Philippines (Fig. 4). Lateral expansion of material produced an umbrella region that had reached a diameter of 400 km after

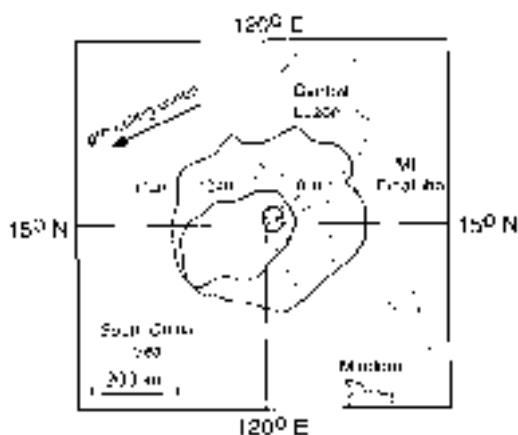

FIGURE 4 Sequential enlargement of the umbrella region during the 1991 eruption of Mount Pinatubo in the Philippines. Traces of the plume margins are shown for the times 1040, 1240, and 1540 local time. The prevailing upper level winds during the eruption were from the northeast. FIGURE 5 Eruption column height versus magma discharge rate for historic eruptions (solid circles). The solid line is the predicted relationship from Eq. (34.1) in the text. [Modified from "Volcanic Plumes," Sparks et al., 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

about 5 hours. At least 200 km of horizontal expansion took place against the prevailing northeasterly winds, attesting to high values of mass flux.

An important aspect of plumes from maintained sources is the height to which they will rise in the atmosphere. The maximum height,  $H_t$ , is a function largely of the thermal flux at the vent, the stratification and moisture content of the atmosphere, and the volatile content of the magma. Thermal flux is the most important factor and is related to the mass discharge rate of magma and its thermal content. A simple approximation for column height can be found from

$$H_t = 1.67Q^{0.259}, \quad (1)$$

where  $H_t$  is the maximum plume height,  $Q$  is the volume discharge rate of magma in  $\text{m}^3/\text{s}$ , and 1.67 is a constant related to the stratification of the atmosphere. Observations of historic eruptions are in good agreement with this simple relationship (Fig. 5).

A consequence of magma–water interactions is an increase in the degree of fragmentation and the production of large volumes of fine grained volcanic ash. Phreatomagmatic eruptions that produce high altitude, maintained plumes are called phreatoplinian and often involve viscous high silica magma such as dacite, rhyodacite, or rhyolite (see Phreatoplinian Eruptions).

Plumes produced by phreatoplinian eruptions bear many similarities to those of plinian eruptions with the development of gas thrust, convective, and umbrella regions (Fig. 1). However, the presence of additional water has important effects on plume behavior. One

effect is that as liquid water is converted to steam the bulk density of the erupting mixture will decrease and the formation of buoyant plumes is enhanced. However, an offsetting effect is that incorporation of relatively low temperature water results in an overall decrease in the temperature of the erupting mixture and a reduction in the thermal flux. A lower thermal flux tends to reduce the potential buoyancy of the plume and decrease its ultimate height.

The effects of external water on the behavior of an eruption plume are illustrated in Fig. 6, for fixed initial conditions. Under conditions of no external water, buoyant plumes are generated for mass eruption rates of up to  $10^8 \text{ kg/s}$ . Above this value an eruption will produce a low collapsing fountain that yields pyroclastic flows and surges. With the addition of 10 to 30% external water buoyant plumes can be generated at higher mass eruption rates ( $>10^8 \text{ kg/s}$ ) because of the higher initial buoyancy flux of the mixture. However, when the amount of external water is 40% or greater, the plume becomes unstable at lower mass eruption rates owing to the lower initial temperature of the mixture and its higher density. Thus, phreatoplinian eruptions that involve large quantities of external water would be expected to produce more pyroclastic flows and surges than plinian eruptions with the same mass eruption rate.

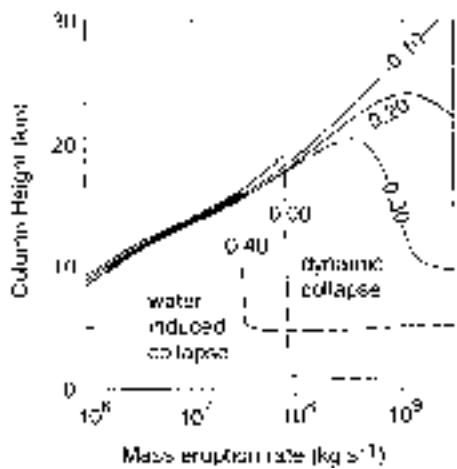

FIGURE 6 Effect of external water on the stability of eruption plumes produced by different magma discharge rates. Values on curves correspond to the weight fraction of water in the erupting mixture. The presence of water initially expands the conditions for a stable rising plume (up to 30%), but higher values (e.g., 40%) cause the plume to collapse at much lower magma discharge rates. [Modified from "Volcanic Plumes," Sparks et al., 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

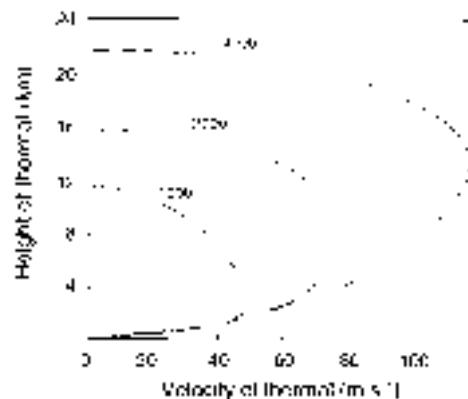

FIGURE 7 Theoretical modeling of the rise speed and maximum height of thermals with initial radii of 1000, 2000, and 4000 m. Thermals with the largest radius rise the highest and have the greatest vertical velocities. [Modified from "Volcanic Plumes," Sparks et al., 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

### B. Discrete Plumes from a Single Vent

Vulcanian eruptions differ from plinian events in that the discharge of gases and particles occurs as a series of discrete explosions separated by a few minutes to several hours (see Vulcanian Eruptions). The process of fragmentation may involve the exsolution of juvenile gases and/or interaction of magma with external water at shallow levels of a volcano. A characteristic feature of such eruptions is the discharge of a large amount of lithic material that had previously blocked the path of magma to the surface. The eruptions are thus more analogous to a canon-like discharge of material. In some cases, however, the frequency of eruption may be sufficiently high to generate a near-continuous discharge of material.

Plumes generated by vulcanian eruptions exit the vent at high velocities (up to 400 m/s) and may rise into the atmosphere as discrete pulses or collapse to form small volume pyroclastic flows or surges. If the time between eruptions is greater than the ascent time of the plume, then the plume is considered as a thermal and its behavior will be different than that of a plume generated by a continuous discharge of material. The rise height of a thermal is given by

$$H_t = N^{-0.25} F_t^{0.25}, \quad (2)$$

where  $F_t$  is the initial buoyancy and volume of the thermal and  $N$  is the ambient stratification of the atmosphere. Modeling of thermals has been carried out assuming that they entrain air in a similar fashion to laboratory thermals and that they possess no initial momentum (Fig. 7). Heating of entrained air causes a ther-

mal to ascend as its density decreases. The rise velocity initially increases but then decreases with height (Fig. 7). Deceleration of the thermal occurs because the density contrast with the surrounding atmosphere begins to diminish as the thermal energy is exhausted. Larger initial thermals (large radius) rise to higher elevations than smaller ones because they are able to entrain less air per mass of erupted material in a given time than thermals with a small radius, and therefore it takes longer for the thermal energy to be exhausted. During vulcanian eruptions the plumes possess an initial vertical momentum controlled by the discharge of material from the vent at high velocities. Thus, model predictions of plume rise are not expected to fit well at low rise heights.

Vigorous steam-rich plumes are often generated when magma is erupted in shallow water. A surtseyan eruption sends steam-rich cock's-tail style plumes along parabolic trajectories. The tephra-laden plumes are produced as a series of discrete events that may take place on a variety of timescales ranging from minutes to hours. The vent area of a Surtseyan eruption is a slurry of hot water and tephra mixed with new magma. Upward migration of the mixture and heat transfer causes the hot water to flash to steam and be rapidly accelerated out of the vent as a jet.

Observations of the 1963 Surtsey eruption in Iceland indicated that during ejection of material as a series of cock's-tail jets there is rapid decoupling and fallout of large poorly fragmented clasts. The remaining steam-rich parts of the plume rise as a series of thermals or, if the frequency of explosions is high, they may coalesce to form a steam-rich convective plume that carries small highly fragmented particles. Such plumes rarely rise to high altitudes because the thermal flux is generally low.

### C. Maintained Plumes from Extended Sources

An important mechanism for the generation of volcanic plumes is the buoyant rise of gas and particles from the top of pyroclastic flows and surges. These flows are concentrated mixtures of hot particles with gases and entrained air that form by a variety of mechanisms during explosive volcanism (see Pyroclast Transport and Deposition). Observations of historic flows at volcanoes such as Mount Pelee, Mount St. Helens, Soufriere Hills, and Mount Pinatubo have shown that they are invariably associated with turbulent co-ignimbrite plumes that can rise to great heights in the atmosphere. A dramatic example of this process occurred during the initial phase

of the May 18, 1980, eruption of Mount St. Helens Volcano. A hot flow of gas and particles moved to the north of the volcano at speeds up to 100 m/s and covered an area of about 600 km<sup>2</sup>. The surge rapidly decelerated at a distance of about 25 km from source and became buoyant, generating an enormous mushroom-shaped plume that rose to an elevation of 25 km (Fig. 8). Volcanic ash from this plume was spread over a large part of Washington and Idaho. Evidence from the geologic record indicates that large volume explosive eruptions have generated enormous co-ignimbrite plumes that are likely to have caused global environmental change. An eruption of the Toba caldera in Indonesia 75,000 years ago spread ash from a co-ignimbrite plume over much of the northern Indian Ocean and may have initiated a switch to an ice age climate.

A basic requirement for the generation of a co-ignimbrite plume is the formation of a mixture of hot particles and gas that is less dense than the surrounding atmosphere. Even though pyroclastic flows begin as mixtures that are denser than the atmosphere, modification of their physical properties occurs during flow that allows for plume development. The lateral movement of pyroclastic flows is driven primarily by gravity, but the support of particles within the moving flow is the result of particle to particle collisions and, most importantly, the velocity of hot gases. Fluxing of gas through the flow results in drag on the solid particles and can fluidize a bed of solid particles and enable it to move downslope at high velocities. Explosive eruptions produce a very large range of particle sizes, and some of the smaller particles are lost from the flow by elutriation with the flux of gases into a more dilute, overlying portion of the pyroclastic flow (Fig. 9). The sources of gas for the fluidization process include exsolution from juvenile clasts, vaporization of vegetation ingested by the flow during its movement downslope, flashing of water to steam as flows move over rivers, lakes, or the sea, and the entrainment of air. Heating of entrained air is a particularly important mechanism in the generation of co-ignimbrite plumes. Air enters a moving flow at its head and along its upper surface where a turbulent mixing zone is established. The entrained air is rapidly heated and its expansion results in enhanced fluidization and elutriation of small particles.

A second process for the reduction of pyroclastic flow density and the generation of buoyancy is sedimentation of particles. As flows move downslope, larger and denser particles move to the base of the flow where they are deposited. Thus, with increasing distance from the source the concentration of particles decreases as a result of both sedimentation and dilution by the entrainment

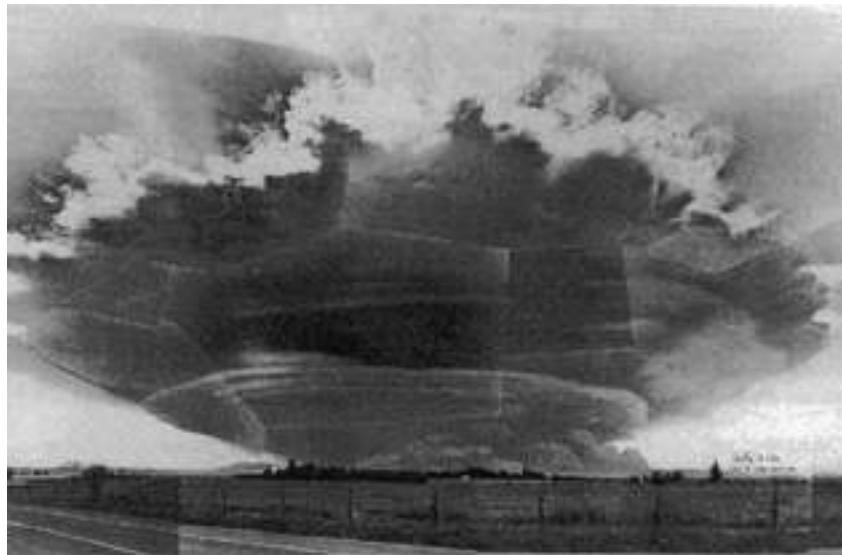

FIGURE 8 Giant plume formed at the beginning of the May 18, 1980, eruption of Mount St. Helens. Generation of the plume was by buoyant uplift of a pyroclastic surge that traveled up to 29 km away from the volcano. [Photograph used with permission from J. G. Moore, USGS.]

FIGURE 9 Small co-ignimbrite plume rising off the top of a pyroclastic flow descending the slopes of Mount St. Helens volcano. [Photo used with permission from the USGS Cascades Volcano Observatory.]

and heating of air. Eventually the flow will reach a point where the bulk density becomes less than the atmosphere and convective rise of its upper part will occur (Fig. 10). Depending on the initial flow conditions, this buoyant lift-off may occur over an extensive area, as shown by the Mount St. Helens example (Fig. 8). This process can generate plumes from a source area with a width of tens to hundreds of kilometers and is probably the main plume-generating mechanism during large-scale pyroclastic flow-forming eruptions. During such events the discharge of magma can occur for prolonged periods of time, feeding a giant maintained flow source area.

The structure of a maintained co-ignimbrite plume

differs substantially from a large-scale convective plume generated from a central vent. First, the co-ignimbrite plume does not have the high velocity jet phase associated with a single vent eruption (Fig. 1). It begins its ascent with very low velocity and little initial momentum. Second, the source area, and thus radius, of the plume base can be very large. Entrainment of air is therefore quite different for a co-ignimbrite plume. The large initial radius means that it entrains a larger fraction of dense lower atmospheric air compared to a central vent plume that starts out with a small initial radius and then expands upwards. Thus, the buoyancy of the co-ignimbrite plume is reduced compared to a single vent eruption having a similar thermal flux.

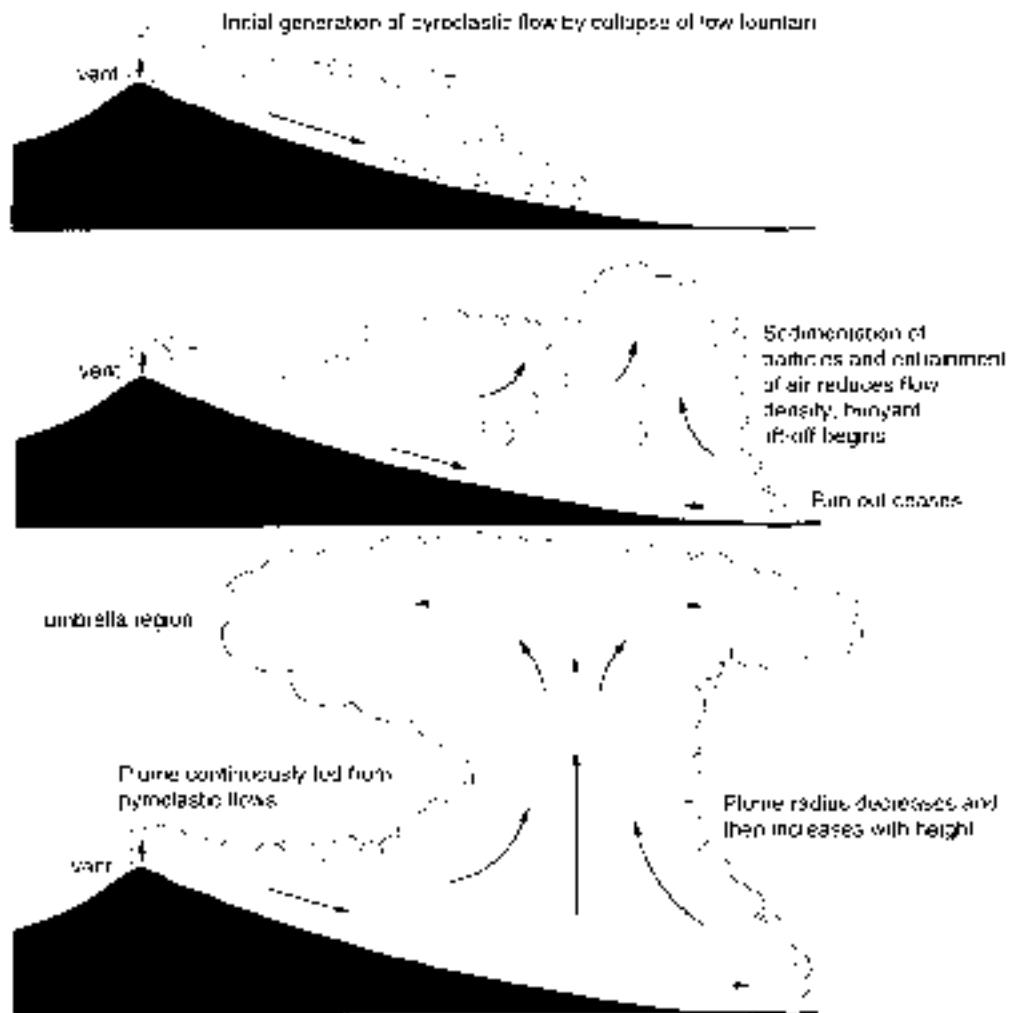

FIGURE 10 Development of a co-ignimbrite plume from a pyroclastic flow descending the slopes of a volcano. The initial erupted mixture is denser than the atmosphere and flows down the slope of the volcano under the influence of gravity. During flow, particles are deposited and air is entrained and heated. The bulk density of the flow decreases until the upper part is less dense than the atmosphere and a plume rises off the top.

Modeling of large co-ignimbrite plumes predicts that the radius of the plume initially decreases but then increases again with height (Fig. 11). This predicted behavior has been observed during some historic eruptions and is portrayed in Fig. 11. The velocity of the plume increases with height to a maximum and then decreases to the final height (Fig. 11). As with a plume from a single vent, a co-ignimbrite plume will also form a well-defined umbrella region where the plume density is similar to that of the surrounding atmosphere and lateral advection of material takes place as a large-scale gravity current. The ultimate height of the plume is also primarily related to the magma discharge rate. However, during pyroclastic flow-forming eruptions only a fraction ( $\approx 30\text{--}40\%$  maximum) of the total thermal energy can be utilized for co-ignimbrite plume generation. The remainder is retained in the hot pyroclastic flow deposits formed from the basal part of the moving flow. Consequently, for a given magma discharge rate a co-ignimbrite plume will not rise as far as a plume from a central vent. However, mass eruption rates are often higher during pyroclastic flow forming stages of explosive eruptions. There is geological evidence to suggest that this is true for very large explosive eruptions associated with caldera formation and discharge of large volumes of magma ( $>25 \text{ km}^3$ ).

Many pyroclastic flows are not maintained for long periods of time and may last for only a few minutes. Under these circumstance the release of hot particles and gas occurs on a timescale that is less than the total ascent time of the plume. In this case the plume behavior is best approximated as a thermal that begins with fixed radius and rises as a discrete volume of particles and gas. The behavior of such plumes is similar to that described in Section II.B and shown in Fig. 8.

Another type of co-ignimbrite plume may be developed over the source vent where material is feeding pyroclastic flows. Formation of a plume in this area may be related to either (1) segregation of large clasts or (2) inhomogeneities in the eruption mixture. If rapid segregation of large clasts can occur shortly after the erupting mixture exits the vent, then the bulk density of part of the plume may be reduced sufficiently that it becomes buoyant. Such a process would be expected to occur during eruptions that generate a very large range in particle sizes during fragmentation. Alternatively, variations in volatile content or physical properties of the magma may lead to a range of bulk densities within the erupting mixture. Under these circumstances, low density portions of the erupting mixture would feed a quasi-steady convective plume centered over the vent while the denser portions of the mixture would collapse to form pyroclastic flows.

Large-scale basaltic eruptions often take place from fissures that may extend several to tens of kilometers in length (see Flood Basalt Provinces). Plumes are generated above the fissures if fragmentation can produce a source of sufficient small particles and gas. The generally low fragmentation of basaltic magmas means that only a small fraction of the total thermal energy can be utilized to drive a convective plume above the vent. As with ignimbrites, a large fraction of the heat is retained in the clasts that fall back to the surface near the vent at high temperature. There are three main sources of thermal energy for the production of plumes above a large fissure eruption (Fig. 12). The first are small fragmented particles (millimeters or less in size) that can be carried aloft by the gas. This fraction is generally less than 20% of the total erupted magma. A second source is the hot gas, either water, carbon dioxide, or sulfur

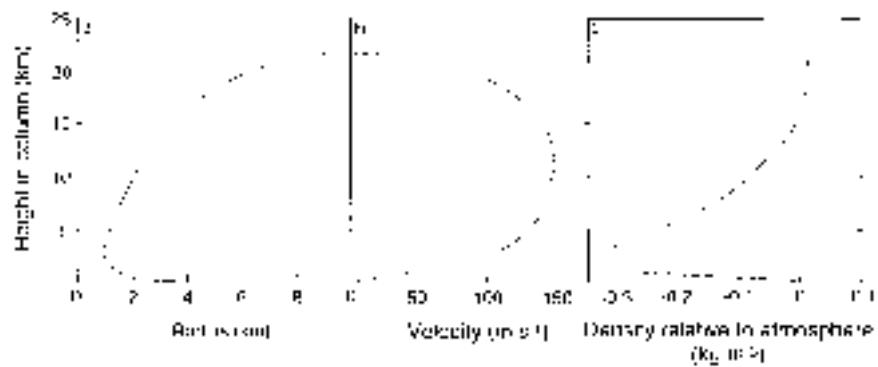

FIGURE 11 Variations in radius, velocity, and density relative to the atmosphere for a co-ignimbrite plume based on theoretical modeling. Note that the radius of the plume initially decreases as it rises but then increases up to the top. Initial assumptions of the model were a magma temperature of 1000 K, starting velocity of 1 m/s, and source radius of 5 km. [Modified from "Volcanic Plumes," Sparks et al., 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

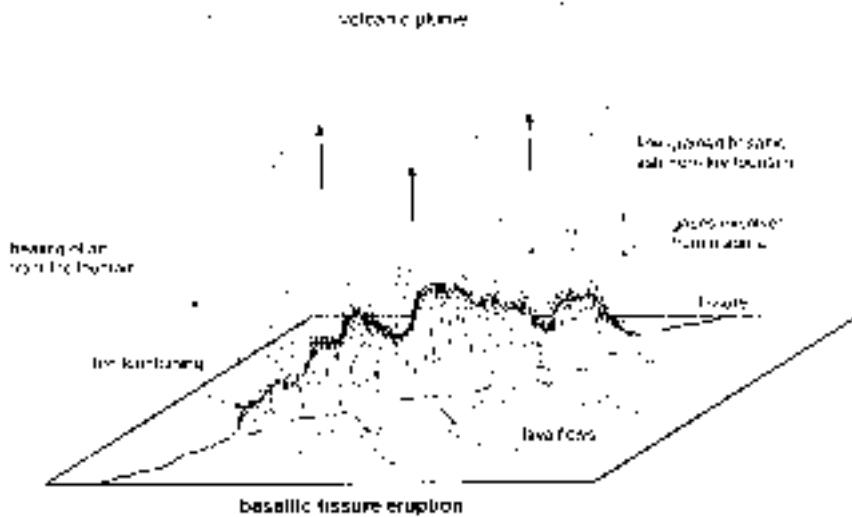

FIGURE 12 Development of a volcanic plume over a basaltic fissure eruption. The plume is fed by thermal energy from fine grained basaltic ash, gases exsolved from the magma, and air heated by the cooling of magma in fire fountains.

dioxide that is decoupled from the magma upon eruption. The amount of gas may vary considerably depending on the original volatile content of the magma and any enrichment or depletion processes that may have affected the distribution of bubbles. The third source is heat exchange between the fountain and the surrounding air. Temperature decreases of a few to tens of degrees have been inferred for the main volume of magma in the fountain. These three sources can contribute to the development of a gas and particle plume that ascends above the top of the fountain by convective rise (Fig. 12).

Plumes developed over large basaltic fissure eruptions are important because of their potential for climatic impact. Basalt carries higher amounts of sulfur per unit mass than more evolved magmas and sulfur is an especially important agent for altering the heat budget of the atmosphere (see Volcanic Aerosol and Global Atmospheric Effect). However, for sulfur injection to be important for climate change it must reach high altitudes ( $>10\text{--}15$  km) in the atmosphere. The height to which a basalt plume will rise in the atmosphere is a function of the mass eruption rate of magma, the fraction of ash produced by fragmentation, and the amount of cooling experienced by the eruptive fountain (Fig. 13). For a given magma discharge rate, the eruption of basaltic magma generates lower plumes than eruptions of more evolved magma (Fig. 13). This is mainly because of the inefficient use of thermal energy to drive the buoyant

plume. The 1783 basaltic fissure eruption of Laki in Iceland generated a plume that rose to a height of at least 12 km. This height implies an eruption rate of about  $1 \text{ m}^3/\text{s}/\text{m}$  of vent length based on theoretical modeling of basaltic plumes (Fig. 13). Although such rates are unusual for historic eruptions, there is evidence in the geologic past for very large fissure eruptions that exceeded discharge rates of  $10 \text{ m}^3/\text{s}/\text{m}$ . For example, the great Roza basaltic flow in eastern Washington (United States) is inferred to have been fed by a discharge of 10

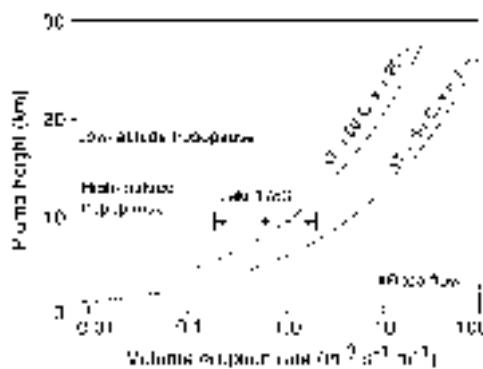

FIGURE 13 Plume height versus magma discharge rate for basaltic eruptions. Solid curves show the predicted heights based on theoretical modeling. Each curve assumes a cooling of the fire fountain by  $50^\circ\text{C}$  and utilization of 20 and 1%, respectively, of the energy in fine grained basaltic ash. [Modified from "Volcanic Plumes," Sparks et al., 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

$\text{m}^3/\text{s}/\text{m}$  (Fig. 13). It is likely that major atmospheric plumes are generated during such events, with the potential for significant climatic impact.

### III. ATMOSPHERIC EFFECTS ON PLUME DISPERSAL

For several hundreds to thousands of meters above the vent, the motion of a volcanic plume is controlled by the source conditions. Differences in atmospheric conditions play little if any role in determining plume motion in this jet phase. Once plume velocity has slowed, at the top of the jet phase, the plume motion involves the convective entrainment of vast quantities of air, and the driving upward of the plume material relative to an atmosphere in a specific state, in terms of relative humidity, wind speed, and temperature stratification. In the umbrella region, where the column material spreads around the neutral buoyancy level, the gravity-driven outward flow can be modified and even counteracted by the winds. Because of the typical sizes of volcanic plumes, the neutral buoyancy level is often within or near the jetstream. The high wind speeds typical of the jetstream play a profound role in distal plume transport.

#### A. Crosswinds

All volcanic plumes are eventually distorted by the wind. The largest plumes and those erupted into a still atmosphere are able to form umbrella clouds. In contrast, less vigorous plumes rise buoyantly in a wind field even as they are carried along by it. These plumes do not form umbrella clouds. Once a plume is completely bent over in the wind field, it begins to move with the wind and travels as a downwind plume. In general, downwind plumes seem to be oval in cross section, with their long axis horizontal. In planview, they often consist of downwind-elongated lenses of gas and ash that become detached from the volcano when the eruption ceases. Sometimes, however, smaller plumes can have rather irregular outlines because of their susceptibility to local atmospheric motions (Fig. 14). They can even have several lobes at different heights due to wind shear effects.

Based on how they are affected by the wind, plumes can be thought of as being of two types: strong and weak. Strong plumes are those that form an umbrella cloud, whereas weak plumes do not. The difference be-

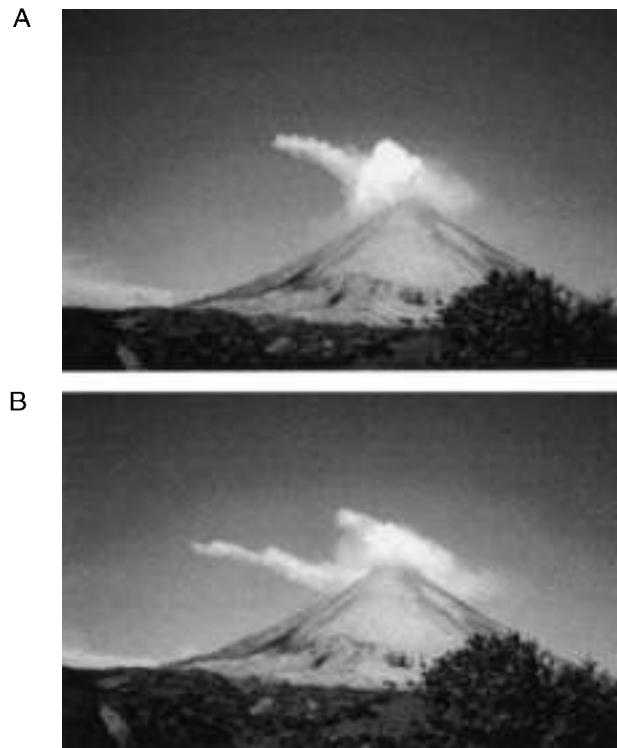

FIGURE 14 Sequence of two photographs (A, B) of small plumes from Karymsky volcano, Kamchatka, Russia, showing effects of wind shear to produce highly irregular plume shapes. Note that different parts of the plume are spreading in different directions. [Photo used with permission from M. Bursik.]

tween strong and weak plumes can be expressed in terms of the ratio of the wind speed to the upward plume speed. A weak plume, for which this ratio is large ( $>1$ ), is much affected by the wind, taking on the characteristic “bent-over” shape (Fig. 15). A strong plume, for which

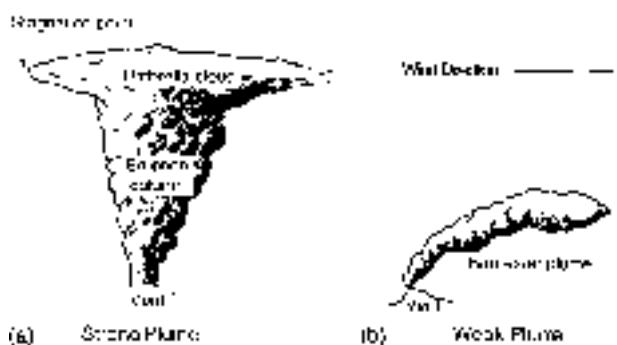

FIGURE 15 Schematic illustration of eruption plumes generated from a volcanic vent. (a) Eruption of a strong plume; (b) eruption of a weak plume under windy conditions in which the plume is bent over.

the ratio is small, is little affected by the wind as it rises. In general, for plumes with a total rise height greater than 20 km, no typical values of windspeed are able to affect plume rise substantially, and all eruption columns above this height will develop umbrella clouds.

Most tropospheric plumes in weak winds are strong plumes, as are most plumes that reach the stratosphere. These plumes rise relatively unmodified through the atmosphere to form typical umbrella clouds. As the gravity current spreads upwind, it encounters resistance. At the stagnation point, the wind speed and the current speed are equal, and the upwind progress of the current is halted (Fig. 15). For strong plumes the stagnation point can occur at substantial distances upwind of the vent. For example, the umbrella cloud from the May 18, 1980, Mount St. Helens blast plume spread upwind 15 km before it was balanced by stratospheric winds. In the crosswind direction, the plume may continue to spread as a gravity current to hundreds of kilometers from the vent, as was the case with the Pinatubo eruption of June 15, 1991 (Fig. 4). In the downwind direction, the plume is carried along in the windfield. As the plume propagates progressively further downwind, its speed approaches the windspeed as the plume loses pyroclasts and the gravity-driven spreading weakens.

Further downwind from the vent, the wind completely dominates plume motion. Shearing stresses between the upper and the lower interfaces of the downwind plume and the atmosphere and direct atmospheric entrainment result in downwind transport at the windspeed. The plume loses its density contrast with the atmosphere and can be advected as a lens of aerosol and gas with nearly constant width. Only slowly might it thin, spread, and disperse as shearing and small-scale atmospheric turbulence act at its margins and as very fine ash settles out. The elongated shape of such plumes is illustrated by the aerosol band generated during the El Chichon eruptions of 1982. This band maintained nearly constant width and became gradually more dilute due to shearing at its margins as it completely encircled the globe.

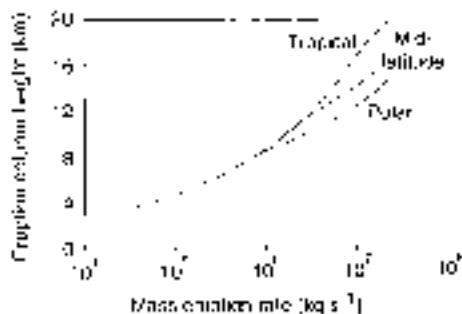

In the case of weak plumes, a subvertical eruption column cannot develop. Instead, a bent-over plume whose motion is dominated by the wind rises from the vent. Unlike strong plumes which form umbrella clouds, weak plumes maintain a cloudlike structure as they reach their maximum rise height, since their flow characteristics are not reorganized in the upper atmosphere by gravity current motion. The plume is not only bent over by the wind, but also mixes with the turbulent atmosphere as it is carried along. This enhanced entrainment results in lower total plume heights for a given

mass eruption rate as the wind speed increases, because of the more rapid dilution of the plume's thermal energy by the entrained air. The plume-wind interaction in weak plumes can also result in spectacular organized motions under certain conditions. The combination of an upward-directed plume meeting a horizontal wind can create vorticity in the downwind side of the plume. This vorticity has occasionally manifested itself as a line of tornadoes shed from the plume margin, as occurred during the eruption of Surtsey in 1963.

## B. Latitudinal Control of Vertical Temperature Profile

Variations in the atmospheric stratification result from vertical temperature variations caused by the differential heating of the solid earth and air. In particular, the height of the tropopause is strongly dependent on surface heating and hence on latitude. In general, the troposphere is only weakly stratified, while the stratosphere is more strongly stratified. In a typical mid-latitude atmosphere, the temperature decreases steadily to the tropopause, which is located at about 11 km. The temperature then remains nearly constant up to a height of about 20 km, where it begins to increase, and the atmosphere becomes strongly stratified. In the tropical atmosphere, the tropopause is located at about 16–18 km. The temperature increases steeply above this point, producing a very stably stratified atmosphere. In polar latitudes, the tropopause may occur as low as 8 km, and the stratosphere above is much less strongly stratified than it is in the tropics or mid-latitudes.

As a result of such variations in the ambient stratification, the maximum rise height of an eruption column at a fixed eruption rate can vary by a few kilometers. In a given atmosphere, the rate of increase of column height as a function of the mass eruption rate decreases for columns that penetrate the tropopause. This can be seen in Fig. 16 by comparing results for plume rise models in tropical, mid-latitude, and polar conditions. In conjunction with this effect, as the latitude of a hypothetical eruption changes from tropical to polar, a given column will penetrate the tropopause at ever-decreasing heights. Therefore, the plume ascends to a lower height for a given mass eruption rate and eruption temperature in a polar atmosphere (lower tropopause) because the plume propagates through a deeper region in which the temperature increases with height. The modeled rise heights of eruption columns can be compared in polar, mid-latitude, and tropical atmospheres, in which the

**FIGURE 16** Variation in the rise height of an eruption column as a function of latitude. Differences in column height correlate with differences in altitude of the tropopause; thus there are no differences in column height for eruption columns that do not pierce the tropopause. [Modified from “Volcanic Plumes,” Sparks *et al.*, 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

tropopause are located at 8, 11, and 17 km, respectively and the ground temperatures are chosen to be 263, 273, and 293 K, respectively (Fig. 16). In the tropical atmosphere the model plumes rise significantly higher as expected, owing to the deeper troposphere.

### C. Atmospheric Moisture

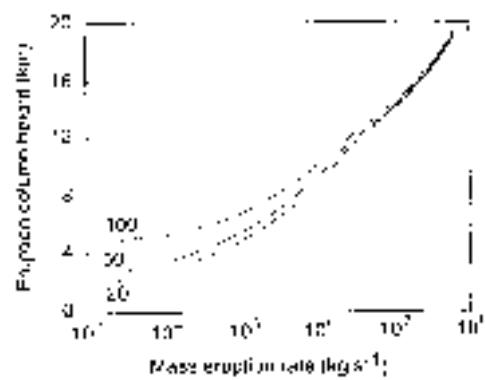

The volatile content of magmas is too low for the exsolved gases to have a major impact on column motion. However, in moist air, a significant mass of water vapor can be entrained and convected upward in the column. This air will be cooled and become saturated. Once saturated, the vapor condenses into liquid water, releasing its latent heat of condensation. The latent heat increases the temperature of the gases in the eruption column, thereby increasing the buoyancy and ultimately the eruption column height. For low mass eruption rates, the entrainment and convection of atmospheric moisture upward in the plume can provide the dominant energy source driving the motion of the eruption column. An analogy is provided by forest and brush fires, which heat the air near the ground. As this heated air rises, the water vapor within it becomes saturated and condenses. The latent heat released provides thermal energy, which enables the hot smoke to continue to rise. Such a fire plume thus ascends higher when the relative humidity is high than it does when the relative humidity is low.

In humid air, the height to which a small volcanic plume rises is likewise considerably greater than it is in dry air (Fig. 17). This is because the thermal energy

released by the condensing atmospheric vapor is comparable to or even greater than is the thermal energy associated with the erupted material. For small eruptions in relatively dry air, the column remains unsaturated. In larger eruptions or in moister air, the column becomes saturated and therefore the height of rise of the column increases significantly. However, as the erupted mass flux increases above about  $10^6 \text{ kg s}^{-1}$ , the erupted thermal energy begins to significantly exceed the energy that can be extracted from condensing water vapor even at 100% relative humidity. This is because the ambient moisture is confined to the lower atmosphere. Only smaller columns can entrain a sufficient mass of water vapor relative to the erupted thermal energy so that the latent heat produced on condensation is comparable to or exceeds the thermal energy erupted in the pyroclasts. Larger columns ascend far above the region in which most of the atmospheric water vapor is found, and so only a small fraction of the entrained air is moist. As a simple criterion, eruption columns whose total ascent heights exceed about 12 km are not significantly affected by atmospheric moisture.

### D. Downwind Evolution

As an eruption comes to a close, the accumulated volcanic gas and ash ejected into the atmosphere assumes one of two typical forms. Smaller plumes are often markedly elongated in the downwind direction, with a prominent taper toward the upstream end (Fig. 18; see also color

**FIGURE 17** Variation in the rise height of eruption columns as a function of atmospheric relative humidity (numbers on the curves). The more humid the air, the more vapor is entrained and carried upward in the column, thus releasing more latent heat and increasing column height. Because most of the vapor is in the lower atmosphere, larger eruption columns are less affected. [Modified from “Volcanic Plumes,” Sparks *et al.*, 1997, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

FIGURE 18 Photograph from the Space Shuttle mission STS-068 showing the elongated spreading of the October 1, 1994, plume of Klyuchevskaya near the tropopause. Note also that the plume border becomes smoother with height and distance because of the weakening of the internal turbulence. (See also color insert.)

insert). The taper is the result of either the gravity current spreading or atmospheric turbulent diffusion having affected the downstream end of the plume for a longer time than the upstream end. Lareer umbrella clouds are more often subsequent in planview, with an elongation in the downstream direction that makes them occasionally ovoid (Fig. 19). Because they are often the result of a complex sequence of events, larger, developed umbrella clouds may be compounded from several separate clouds. They can therefore display a complex digitate geometry. In addition, the most massive umbrella clouds, such as that from the 1991 eruption of Pinatubo, display another type of digitate margin that indicates they have reached the Rossby radius, the size at which the Earth's rotation begins to affect cloud motion.

When any volcanic plume has persisted for a sufficiently long time, it becomes fully subjected to atmospheric motions. These motions fall into a spectrum of characteristic sizescales, from microscopic molecular agitation to hemispheric flow. To gain an understanding of the effects of the atmosphere on the long-range dispersal of eruption clouds, horizontal and vertical mo-

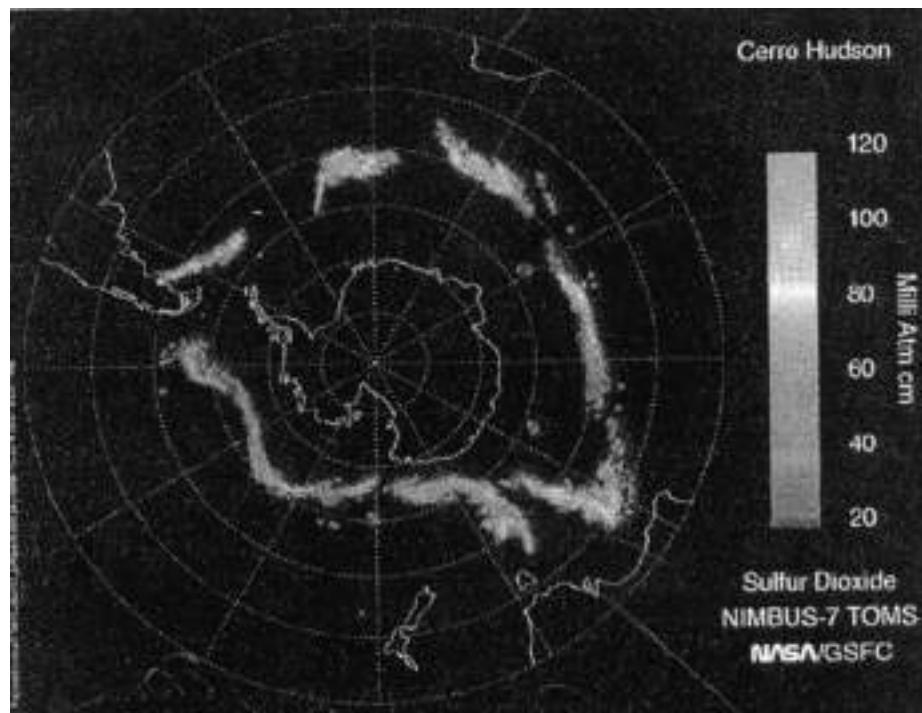

FIGURE 19 Satellite image of the giant June 15, 1991, umbrella cloud of Pinatubo, Philippines. Outline of the Philippines and lines of latitude and longitude are shown for scale. tions can be thought of separately. Horizontal dispersal is controlled by the nearly two-dimensional nature of the largest atmospheric motions that transport ash on regional and global scales. The vertical dispersal of the particles is controlled by the smallest scale turbulence and gravitational settling, which act on much smaller length scales. In addition, aggregation of small ash and aerosol particles in the months and years following an eruption results in the gradual increase of particle size. Eventually particles become sufficiently large that their settling speeds cause the particles to be deposited.

The large-scale, quasi-two-dimensional atmospheric motions responsible for the distal transport of ash clouds can be described by a “turbulence energy spectrum.” The effect of the different scales of motion in this spectrum on plumes of different characteristic sizes is vastly different despite the fact that all atmospheric agitation has its origin in the heating of the Earth and air by the Sun. The largest scale motions ( $>\sim 10^3$  km) primarily draft along virtually all plumes, but cause little growth or turbulent spreading. Observations of plumes distorted in these zonal winds suggest that distortion primarily occurs as simple stretching and very moderate bending of plume outlines. Intermediate scale turbulence structures

( $10^2\text{--}10^3$  km) are primarily responsible for complex bending and relative diffusion (spreading and dilution) of small to moderate-sized ash clouds. The complex bending or contortion is known as chaotic advection, as plume–fluid elements are distorted in a chaotic fashion, despite the completely deterministic nature of the velocity field itself. The plume from the Hudson eruption of 1991 exhibited this phenomenon as it drifted at the edge of the polar vortex (Fig. 20). The motion of the largest volcanic ash clouds, such as that generated by the eruption of Pinatubo, seem to show almost exclusively relative diffusion by the intermediate scale motion, with little apparent stretching or bending.

Vertically, a downwind volcanic plume does disperse, but at rates very different from the horizontal dispersion rates discussed above. This vertical dispersion occurs because of the coupled effects of the settling properties of the particles and of the turbulence structure of the stratosphere. The stratosphere consists of alternating layers of 1 to 2 km thickness. Every other layer seems to display turbulent motions with vertical wind speeds between  $-0.5$  and  $0.5$  m/s. The intervening layers are relatively quiescent. These observations are consistent with the layered temperature structure observed in
