stratospheric soundings. The turbulent layers will be able to retain particles longer than will the quiescent layers because the turbulence will hinder particles from settling from the convecting layer. Particles will fall out relatively rapidly from the quiescent layers which lack a counteracting agitation. Because of this alternating turbulent and quiescent structure in the stratosphere, volcanic ash and aerosol clouds will tend to separate into layers over long time periods, lending to them a distinct banded appearance when viewed from the side. Over a period of months to years, however, virtually all volcanic particles settle completely from the atmosphere.

#### IV. FUTURE RESEARCH

Volcanic plumes have the potential for affecting human society on both a local and a global scale. Areas close to active volcanoes are subject to tephra fallout and the effects of deadly pyroclastic flows and surges. In more distal areas, volcanic plumes can lead to global environmental change by injecting aerosol-forming gases into the stratosphere. Although much progress has been made toward understanding the nature and behavior of volcanic plumes, several areas need to be emphasized in future research. One area deals with the conditions whereby volcanic plumes change from buoyantly rising conditions to collapse. Understanding the parameters that control this transition is essential because these determine whether an eruption will pose significant threat to local populations by the generation of pyroclastic flows and surges.

A second area is concerned with the dispersal of large-scale plumes in the atmosphere. In particular, how do such plumes evolve with time in terms of their geometry and composition? The hazards of volcanic plumes to commercial and military aviation have been highlighted by several dramatic encounters and are likely to increase in the future as air traffic expands over volcanically active areas. Because the impact of volcanic plumes to aircraft is related to the particle concentration in the atmosphere it is critical to understand how plumes lose particles as they move downwind from source. Prediction of the path and particle composition of volcanic plumes should

be a high priority in order to minimize accidental encounters with aircraft and the potential for disastrous results. Furthermore, an understanding of how plumes are dispersed on a global basis is necessary for predicting the potential climatic effects of volcanic aerosols. Sophisticated supercomputer models coupled with analog laboratory experiments are two of the tools that volcanologists can use to better understand the dynamic processes of volcanic plumes.

## GLOSSARY

**deposition system** The entity that deposits pyroclasts and forms pyroclastic deposits. This term is used to emphasize the controls on the manner in which particles come to rest.

**particle cohesion** The sticking together of particles due to either the presence of water (at low temperatures) or to particle plasticity (at high temperatures).

**particle trajectory** The path taken by a moving particle. Used here to describe the inclination of a pyroclast as it comes to rest.

**pyroclastic density current** A gravity-controlled, laterally moving mixture of pyroclasts and gas.

**pyroclastic fall** The rain out of clasts through the atmosphere from an eruption jet or plume during an explosive eruption.

**pyroclastic flow** A pyroclastic density current where most of the material and momentum is contained in a basal concentrated particulate dispersion.

**pyroclastic surge** A pyroclastic density current where the material and momentum are widely distributed through a deep, dilute, highly turbulent particulate suspension.

**solids concentration** The volume concentration of particles in a transporting or depositing medium, ranging from low (discrete particles) to high (dense-packed assemblages of particles).

**transport system** The entity that carries pyroclasts from vent to the depositional system. This term is used to emphasize processes responsible for the transport of pyroclasts.

**T**HIS CHAPTER GIVES a framework for the main stages by which fragmental materials ejected in explosive eruptions are transported and deposited to form pyroclastic deposits in the subaerial environment. It mentions the behavior of buoyant plumes only in passing (see Volcanic Plumes) and describes only general characteristics of the deposits (see Fall Deposits, Deposits of Surges and Directed Blasts, and Ignimbrites and Deposits of Block-and-Ash Flows). We define and distinguish transport and deposition systems to describe key processes involved during emplacement of fall, surge, and flow deposits. Four principal controls (particle trajectory, solids concentration, the extent to which

this concentration fluctuates with time, and the presence or absence of cohesion during deposition) are used to explain the characteristics of the great proportion of subaerial pyroclastic deposits and provide a framework for the spectra of processes and products between the three end-member types of deposit. Further complexities arise, particularly in the proximal environment, out to a maximum of 3–5 km from the vent, but are not volumetrically important in most pyroclastic deposits.

---

## I. GENERATION OF PYROCLAST ASSEMBLAGES

Explosive volcanism involves the transfer of fragmented magma (together with phenocrysts, dissolved volatiles, and country-rock material entrained from the conduit walls or ground surface) from some depth onto the Earth's surface. A widespread convention, which we follow, is to distinguish between a *transport system*, which is responsible for the movement of the assemblage of fragmental material, and a *deposition system*, which controls the manner in which the material comes to rest to form a deposit. Most pyroclastic transport systems (including virtually all explosive eruptions of volume  $>1 \text{ km}^3$ ) begin with expulsion of the fragmental material from a conduit as a high-speed jet that interacts with the atmosphere. However, in some cases, the transport system is created via an intermediate process of lava extrusion or cryptodome formation and is initiated by either (i) rupture of overpressured systems especially cryptodomes (e.g., Mount St. Helens 1980, Mont Pelée 1902) or (ii) gravitational collapse of nonoverpressured to partially overpressured lava flows or domes (e.g., Unzen 1990, 1991).

---

## II. TRANSPORT SYSTEMS

### A. Introduction

Two major classes of transport systems are identified in explosive eruptions. They are primarily distinguished by the density of the emerging jet with respect to the atmosphere in the first hundreds of meters to kilometers above the vent, that is, buoyant versus nonbuoyant behavior. To a first order, these correspond respectively with

- (1) vertical plumes (where the dominant trajectory of motion is upward initially) that generate fall deposits by deposition from wind-driven clouds at elevations of several kilometers to tens of kilometers above the Earth's surface, and
- (2) laterally moving systems (where the dominant trajectory of motion is sideways initially) that generate surge and flow deposits from gravity controlled, ground-hugging density currents (Fig. 1).

In reality the situation is more complex, for example, because of the interaction between pyroclastic density currents and the atmosphere which will generate buoyant material that can rise to form second-order vertical plumes. The structure and dynamics of buoyant plumes are dealt with separately in Volcanic Plumes, while the variety of density currents are reviewed briefly here.

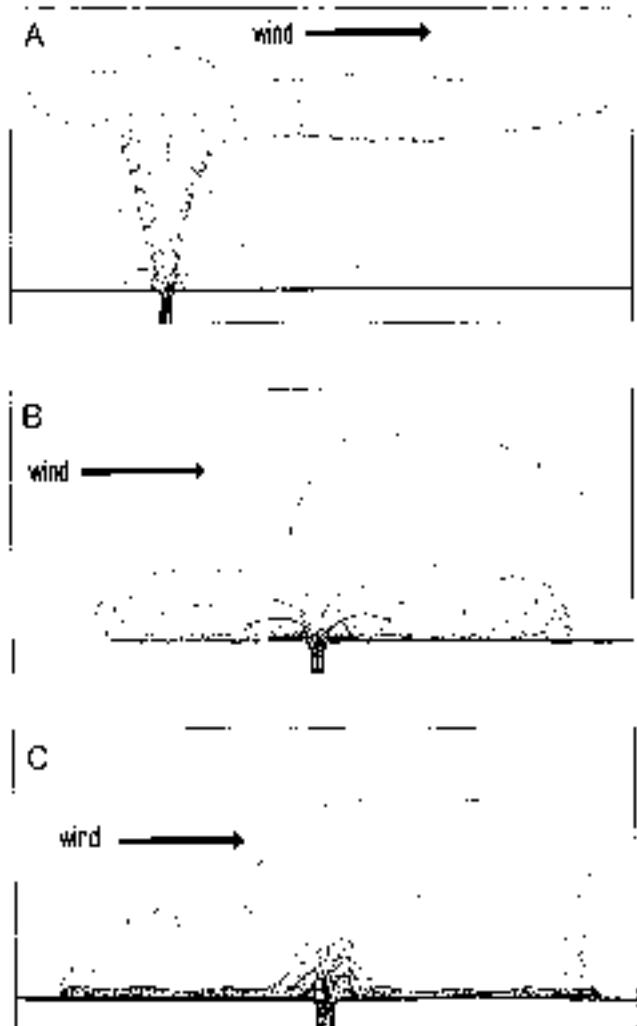

An additional complexity arises in the proximal environment where large clasts, which are little affected by interaction with the atmosphere, follow ballistic trajectories that are controlled by their initial velocities and ejection angles. Ballistically emplaced materials form a second category of fall deposit, but are normally a small proportion of the total volume of ejecta. They vary in nature from isolated individual clasts in otherwise conventional plume-deposited fall deposits to the situation (in hawaiian and strombolian activity) where the emerging jet consists mostly of large clasts forming a fountain around the vent. In this instance clasts accumulate to form a spatter or scoria cone or recombine to generate a lava flow (see Scoria Cones and Tuff Rings).

### B. Pyroclastic Density Currents

Two end-member types of pyroclastic density current, dilute and concentrated, are recognized from observations of historical eruptions and studies of historic and prehistoric deposits (Figs. 1 and 2). The dilute end-member is commonly referred to as pyroclastic surge and the concentrated end-member as pyroclastic flow. There is considerable ongoing debate about the boundaries between these end-member types, particularly with regard to the nature of the high-velocity density currents (*blasts*) generated in historic eruptions such as Mont Pelée 1902, Bezymianny 1956, and Mount St. Helens 1980.

#### 1. Dilute Currents/Surges

These have been observed to travel at speeds of typically tens of meters per second, but blast-like phenomena,

**FIGURE 1** Schematic diagram to illustrate the three main end-member transport systems for the emplacement of pyroclastic deposits. (A) Fall: high buoyant plume carrying all except coarsest particles to heights of kilometers to tens of kilometers above the surface; particles sedimented from plume to form deposit; plume dispersal controlled by wind direction and strength. Coarsest clasts (arrows) follow ballistic trajectories and fall within 3–5 km of vent regardless of wind. (B) Surge: ground-hugging relatively dilute density current with gradual (exponential?) downward increase in density; not influenced by wind, but generating a secondary buoyant plume that is wind affected. (C) Flow: ground-hugging, clearly defined, concentrated density current with accompanying dilute overriding cloud; not influenced by wind, but generating a secondary buoyant plume that is wind affected.

which share many characteristics of end-member surges, have propagated at 100–300 m/s. Eyewitness accounts, theoretical modeling, and the products of prehistoric eruptions imply that these transport systems

- (1) contain less than 0.1 to 1% by volume of solids even close to the ground surface,
- (2) are density stratified with the highest particle concentrations close to the ground surface, and
- (3) transport material primarily by turbulent suspension, with a lesser population of coarser clasts moving as a saltating and/or sliding traction carpet.

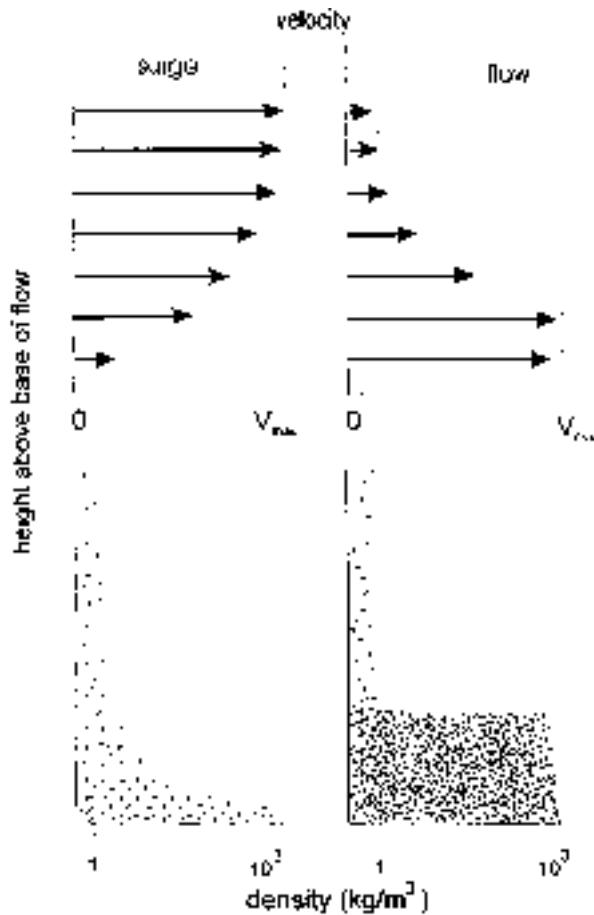

Surges have been modeled by considering their dynamics to be controlled by the loss of particles by sedimentation into the deposition system (from which the particles eventually come to rest), thus depleting the transport system of mass. Therefore, the surge terminates where it becomes positively buoyant with respect to the ambient atmosphere and lifts off to form a buoyant plume. The density contrast between surges and the ambient atmosphere is relatively low, and surge dynamics can thus be modeled to some degree using relationships derived for aqueous, pure-liquid or sediment-bearing liquid gravity currents.

## 2. Concentrated Currents/Flows

These have been observed to travel at a range of speeds similar to that of surges, i.e., from a few meters to several tens of meters per second. Velocities much greater than this (to 200–300 m/s) have not been observed but are inferred from the heights of obstacles climbed or overcome by some flows. Eyewitness accounts, theoretical modeling, and records of historic eruptions imply that flows

- (1) have solids concentrations of the order of tens of volume percent,
- (2) have a free surface, above which the solids concentration diminishes sharply, and
- (3) transport material by a combination of support mechanisms, including particle–particle contact, fluidization support, matrix support, dispersive pressure and buoyancy (i.e., of large, low-density pumice clasts in the concentrated matrix). Turbulence may or may not be present, but is not dominant as a particle support mechanism, unlike in surges.

Although moving flows and surges look superficially similar from the outside, there is a fundamental contrast between their structures (Fig. 2). In flows, almost all the

**FIGURE 2** Schematic cross-section through end-member dilute (surge) and concentrated (flow) density currents to show the differences in structure. Values of  $V_{\max}$  can vary from a few meters per second up to ca. 300 m/s in surges and flows; note that the arrows represent time-averaged trajectories and neglect the short-order turbulent fluctuations. Density values shown are indicative only. In their basal few meters to tens of meters, surges show a gradual downward increase in density due to sedimentation and a decrease in mean velocity due to ground friction; deposits are generated by sedimentation through this basal zone in a deposition system. Solids concentrations in the moving surge are a few percent or less, and the deposition system controls how material is converted into the final deposit. In contrast, flows in their basal few meters to tens of meters are concentrated, with rapid decreases in concentration and mean velocity across an upper interface to the overriding cloud. Flow deposits represent, at one extreme, portions of the flow, slowed by ground friction and left behind, or, at the other extreme, the flow itself which has come to rest; however, differences in particle concentration between the moving flow and the stationary deposit are relatively small.

mass and lateral momentum is concentrated in the basal undercurrent (the flow proper), and the overriding cloud, although visually impressive, is dynamically insignificant and derives its existence and momentum only from the passage of the flow. In surges, the mass and momentum are more evenly distributed in the current; any basal concentration of material is derived by sedimentation from this current and hence is traveling slower than the bulk of the current due to ground friction.

### III. DEPOSITION SYSTEMS

#### A. Introduction

Every clast involved in an explosive eruption has a period of transport, yet ends up as a stationary object in a deposit. The processes whereby this happens are often complex and controversial. The *deposition system* has been proposed as a concept to emphasize that the features of the deposit reflect processes operating only in the latest stages of movement, but the applicability of this is clearly different between fall, surge, and flow deposits. For example, coarse (plinian style, see Fall Deposits) fall deposits are observed to form by the grain-by-grain accumulation of individual clasts, and a separate deposition system as such does not exist. In contrast, clasts supported by turbulent suspension in a dilute current must go through some kind of discrete deposition system as they slow and are deposited. The concept of a separate deposition system is important, because it limits which features can be inferred for the transport system from the deposits themselves, and the nature of explosive eruptions makes direct measurements of transport system properties often difficult or impossible. Here we introduce a simple approach that can be used as a field-based criterion to understand the processes leading to the main features seen in pyroclastic deposits.

#### B. Simple Controls on Deposition Mechanics

On a broad scale there are four fundamental controls active during the deposition of pyroclastic deposits (Fig. 3):

- (1) The *trajectories* of the clasts as they are being deposited, which can vary from vertical to horizontal.

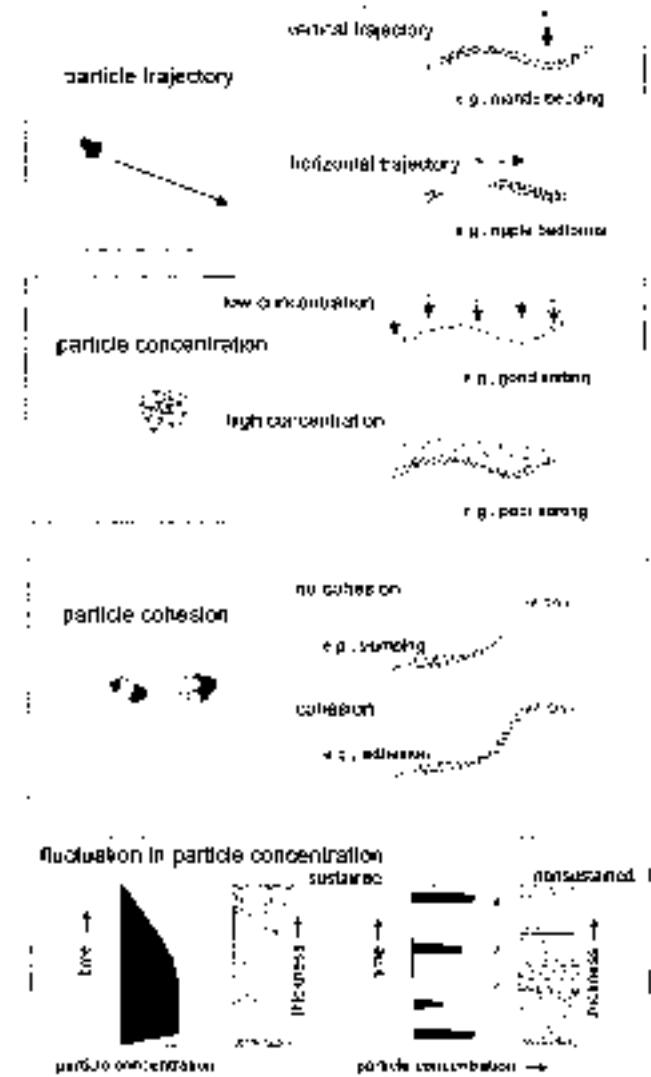

FIGURE 3 Schematic diagram of the four major controls on deposition processes during the formation of pyroclastic deposits: particle trajectory, particle concentration, presence or absence of cohesion, and fluctuations in particle concentration with time.

These trajectories will control the extent to which clasts mantle the ground surface or show evidence for lateral emplacement, for example, unidirectional bedforms.

(2) The *concentration* of particles in the depositing material, ranging from low (discrete particles) to high (dense-packed assemblages of particles). The volume concentration of solids in the depositing material will determine to a large extent the degree of sorting and the scale of the bedforms that can be formed.

(3) The presence or absence of particle *cohesion*. Particle cohesion will cause deposition to tend to be more

rapid and irreversible, as well as increasing the maximum slope angle on which deposition can occur.

(4) The presence or absence of *fluctuations* of particle concentration with time, that is, is the deposition system steady or unsteady, sustained or nonsustained. This will determine whether deposition produces a single uniformly graded bed or a succession of beds of contrasting character.

The first two controls are considered by us to be the most important and vary between absolutely definable limits that can be quantified to a greater or lesser extent with present technology and understanding. The third and fourth controls vary more widely, exert a primary control only in a minority of cases, and at present are mostly treated qualitatively.

### C. Fields of Pyroclastic Deposition

Setting aside particle cohesion (Section III,E, below) and the effects of fluctuations (Section III,F), we can draw up a diagram that plots particle concentration against particle trajectory (Fig. 4). We can then outline three fields corresponding to the archetypal kinds of pyroclastic deposit:

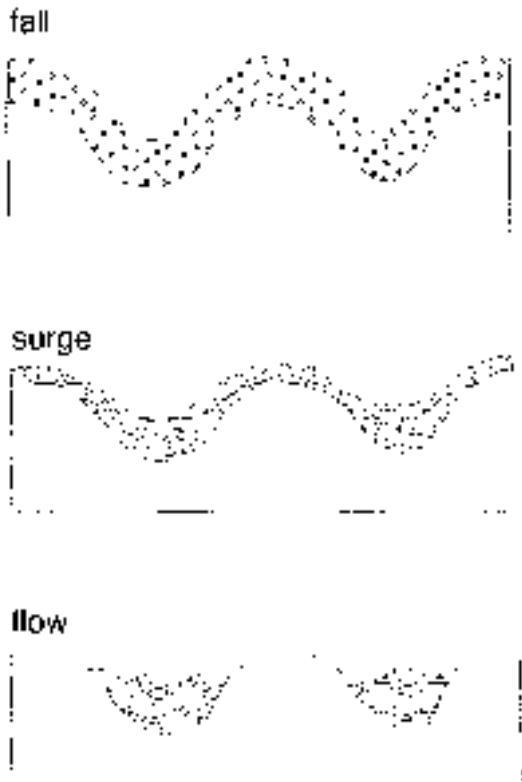

*fall*: vertical trajectory, low solids concentration,  
*surge*: horizontal trajectory, low solids concentration,  
*flow*: horizontal trajectory, high solids concentration.

These fields, to a first order, can explain the fundamental characteristics of the great proportion of pyroclastic deposits (Fig. 5).

Archetypal *fall deposits* drape the landscape and lack evidence for lateral emplacement, such as cross-bedding or wave bedforms. In the absence of particle cohesion (Section III,E), they are well sorted and can be bedded on a scale down to millimeters because they are gradually

FIGURE 4 Sketch diagram of the particle concentration in the depositing material versus the trajectories of depositing clasts to show the end-member fields of fall, surge, and flow deposition.

**FIGURE 5** Schematic diagram of the archetypal characteristics of the three main pyroclastic deposit types. Fall—mantle bedding, with plane parallel beds and no internal erosion, good sorting (except where water is present; see Section III,E), juvenile clasts with angular to ragged shapes. Surge—nonmantling beds, thickening into low-lying areas, with cross-stratification, pinch-and-swell bedding and scoured contacts, moderate sorting, juvenile clasts with some degree of rounding. Flow—landscape-filling units, generally poorly bedded to nonbedded, poor sorting, rounded juvenile clasts.

deposited at low particle concentrations. Evidence for high temperatures, except for welding in extreme proximal areas, is scarce because of strong cooling of clasts during transport and relatively slow deposition rates.

Archetypal *surge deposits* do not evenly drape the landscape but pinch and swell, reflecting limited control over their travel paths by gravity. They show evidence for lateral transport in the form of basal scouring, unidirectional bedforms such as megaripples, and internal cross-bedding. The deposits vary in their sorting characteristics from good to poor. Evidence for transient high temperatures is common, in the form of burns suffered by victims, or by carbonized vegetation, but sustained temperatures high enough to cause syn- or post-emplacement particle cohesion are rare.

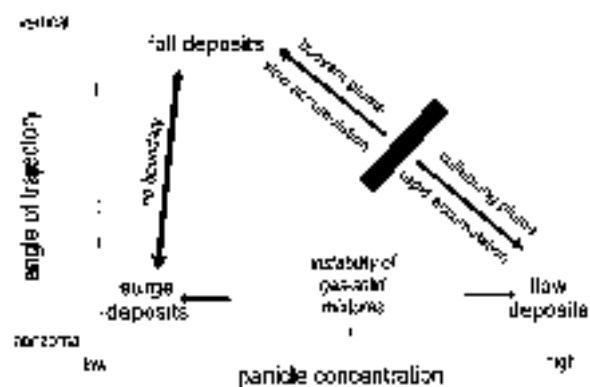

Archetypal *flow deposits* do not drape the landscape, but thicken into or are confined to valleys, reflecting the control of gravity over their travel paths. They show other evidence for lateral transport in the form of basal scouring, but lack internal bedforms, and their sorting is usually poor. Indications of high temperatures during deposition are the norm, ranging from carbonized vegetation and thermal oxidation colors to post- (and less often syn-) eruption welding and cohesion of clasts. The ubiquity of welding in pyroclastic flow deposits has often been taken to indicate a thermally efficient transport mechanism for flows, that is, one that does not involve much mixing with air.

#### D. Boundaries between Fields of Pyroclastic Deposition

As well as defining the end-member deposit types, it is appropriate to consider the nature of the boundaries between them (Fig. 6).

##### 1. Fall:Surge

There are no grounds for supposing there is any clear boundary between these two end-member styles. Consider a fall deposit; if it is being deposited in windless conditions, then there is no mechanism for accumulating the deposit other than vertically, except for slumping or tumbling of grains down steep slopes. However, in the presence of wind, the horizontal component of the particle trajectory due to the wind may be comparable or greater than the vertical component due to gravity,

**FIGURE 6** Sketch diagram of the particle concentration in the depositing material versus the trajectories of depositing clasts showing the inferred boundaries between the three main depositional regimes that lead to the three main types of pyroclastic deposit. See text for discussion.

especially for finer material (Fig. 7). The particles are thus depositing at an angle, exactly analogous to snow drifting in wind. If the wind velocity is strong enough, material on the ground surface may be picked up, saltated, and redeposited by wind, to produce bedforms that should be, in principle, identical in many respects to deposits laid down by a surge traveling at the same velocity. Examples of wind drifting are very common in reports of modern eruptions, but rare in documented prehistoric deposits. In part this is due to a bias toward study of plinian fall units that are coarse enough to have required unusually strong winds to modify, and in part because the presence of cross-bedding and ripple waveforms is taken automatically to indicate either reworking or surge deposition. The latter distinction is important in delineating the associated hazards (a wind-driven fall may be unpleasant, but a surge is most likely to be fatal) and to understanding and interpreting the dynamics of surge emplacement.

## 2. Fall:Flow

There are good grounds for thinking there is normally a clearly definable threshold between these styles of deposition (Fig. 8). To generate a pyroclastic flow from material accumulating about a vent requires that material to trap gas. Fall end-members accumulate at rates that are low enough such that interparticle gases can escape easily; consideration of observed or inferred accumulation rates for proximal to medial fall deposits suggests that these will rarely exceed 0.01–0.001 m/s, which

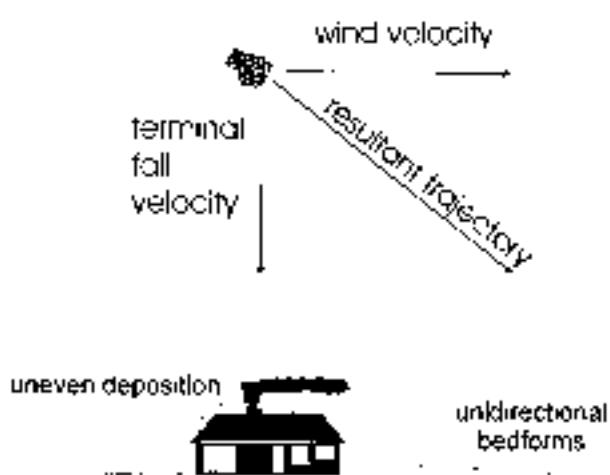

FIGURE 7 Sketch of a single clast being deposited from a buoyant plume in a strong wind; the inclined trajectory is the sum of the wind velocity and the terminal fall velocity vectors. The lower part shows some of the resulting effects on the deposition patterns of fall deposits.

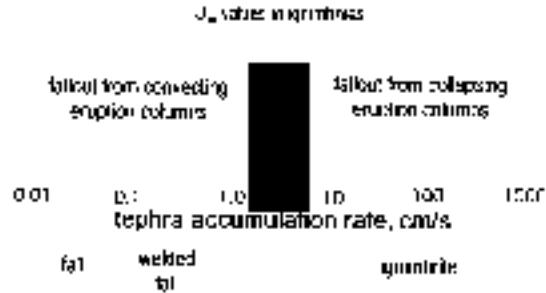

FIGURE 8 Graph illustrating a concept of the boundary between flow and fall activity, based on the different depositional regimes of material in the area immediately around the vent. The range of  $U_{mp}$  values in ignimbrites represent the maximum velocities (values refer to air at room  $T, P$ ) at which gas can pass through poorly sorted material representative of the grain-size characteristics of typical pyroclastic flow deposits and inferred to be similar to the composition of the material being delivered to the surface beneath a collapsing eruption plume. With a stable, buoyant plume, the depositing material is generally coarse and well sorted, with  $U_{mp}$  values in excess of 100 cm/s; deposition rates are thus too low to initiate mobilization of depositing tephra, because there is enough time for interstitial gas to drain out. With a collapsing plume, accumulation rates are so high that gases cannot escape and the accumulating material is mobile and moves off as a flow.

are several orders of magnitude too low to trap gases in depositing material of the appropriate grain size characteristics. In contrast, any pyroclastic flow generated by column collapse (as is often the case; see Volcanic Plumes) will involve the sedimentation of material around the vent at rates of  $>1$  m/s. At what threshold of accumulation rate will interstitial gases be trapped? In fluidization experiments, the maximum velocity at which gas can escape through a particulate material evenly (i.e., without channeling or forming bubbles) is, for poorly sorted materials, of the order 0.01–0.1 m/s. Thus in the area beneath a collapsing eruption column, material is accumulating far faster than the interparticle gases can escape, the material will have essentially all of its weight supported by the interstitial gas, and it will flow and deform under stresses like a conventional liquid. Therefore it seems that there is an effective demarcation between fall and flow, largely due to the huge differences in accumulation rates around the vent generated by sedimentation from a high buoyant plume versus a collapsing column. Fall depositional systems that approach the accumulation rates required for particulate flow do occur, but are almost invariably associated with the low fountaining of fluid magmas (i.e., hawaiian style,

characterized by a decoupled gas phase) and result in lava flows, not a particulate flow.

### 3. Surge:Flow

The relationships between archetypal surge and flow modes of transport and deposition are the areas of greatest interest and controversy. Recently the term *pyroclastic density currents* has become popular to refer to all laterally moving currents, regardless of their solids concentration, and *flow* and *surge* are used to refer to concentrated and dilute currents, respectively. There are two divergent schools of thought. One treats flows and surges as the end-members of a completely variable spectrum of currents with all variations of particle concentrations possible in between. The other believes there to be some variation within both flows and surges but that they are fundamentally distinct phenomena, separated by a hiatus that reflects the difference between the mechanics of the transport processes (Section II,B).

In part confusion has arisen in the literature over the terms *flow* and *surge* because of differing opinions over what is the most important characteristic to define each phenomena and explain their patterns of transport and deposition. The two parameters considered most important are solids concentration and the presence or absence of turbulence (or some other kind of unsteadiness). Different groups of workers emphasize one or the other of these as the most important criterion for labeling deposits and inferring their transport mechanics. Here we infer solids concentration to be the key criterion. A second source of debate has been the extent to which subaqueous liquid or liquid/particle gravity currents, the physics and sedimentological consequences of which have been extensively studied, can be used as analogs for gas/particle gravity currents in subaerial settings.

As a contribution to the debate over whether flows and surges form a continuum it should be noted that some kind of phase instability is characteristic of those particulate systems where the interstitial medium is a gas. This instability arises primarily from the high density contrast between the particles and interstitial fluid; it is seen in gas–solid systems (e.g., sand in air), but is very noticeably absent in liquid–solid (e.g., sand in water) systems. This phase instability is seen in fluidized systems, where excess gas, beyond that needed to fluidize the material, passes through the system as bubbles that rise through a concentrated matrix that has not expanded beyond its state when bubbles first appeared. In contrast, the same particles, if fluidized by a liquid will evenly expand to accommodate the extra liquid flow and bubbles are not seen. The phase instability is also seen, for

example, in vertical and horizontal pneumatic conveying where the solid particles and the carrier gas travel through pipes. In both cases, increasing the solids loading from the end-member pure gas does not result in a gradually increasing solids concentration, but instead at a certain loading (typically  $<10$  vol%) the system breaks down into separate concentrated and dilute phases. Again, such behavior is not seen in liquid–solid systems. It is tempting to suggest that some similar kind of behavior may apply to the gas–solid particulate systems that in nature form subaerial pyroclastic density currents.

### E. Role of Particle Cohesion

Particle cohesion is important in several respects in the deposition (and to a lesser extent transport) systems that generate pyroclastic deposits. Setting aside the effects of electrostatic attraction, which have been observed in historic ash falls (e.g., Mount St. Helens, Sakurajima) but which are poorly documented or undocumented from prehistoric events, the two circumstances where particle cohesion is particularly important occur at two extremes of temperature. These are at low temperatures ( $\leq 100^\circ\text{C}$ ), where liquid water can cause bridging between particles, and at high temperatures ( $\geq 700$ – $800^\circ\text{C}$ ), where juvenile clasts can adhere because they are molten and sticky.

At *low temperatures*, cohesion can occur in both the transport system and on deposition, and preferentially affects fine particles. Accretion and clumping of particles due to water in buoyant plumes has been observed in historic eruptions in the form of ash-bearing liquid drops (rain) and moist accreted aggregates (accretionary lapilli) and is inferred to also occur in cool, wet surges. Such accretion is responsible for the premature deposition of finer particles that would otherwise have been carried farther from the vent by the transport system and causes the resulting fall deposits to be more poorly sorted and have more matrix material than their dry counterparts (see Phreatoplinian). Evidence for water-induced accretion on deposition is preserved as vesicular matrix textures and/or rain-splash bedding, indicating that liquid water was present as the deposits were accumulating, and has been reported from numerous fall and surge deposits, but rarely from flow deposits.

The presence of liquid water at low concentrations imparts a cohesive strength to the material that allows fall and surge-emplaced deposits to adhere to surfaces much steeper than the dry angle of repose. However, at higher concentrations, water will allow soft-sediment

deformation or syndepositional removal of material as ash-laden slurries. In surge or wind-driven fall deposits, any cohesion will alter the geometry of bedforms by inhibiting the subsequent reentrainment of material back into the transport system, but such effects have not been systematically documented.

At *high temperatures*, cohesion caused by plasticity or fluidity of pyroclasts occurs in two main environments, in both cases preferentially affecting coarser clasts (as these retain heat the longest). First, in extreme proximal areas (i.e., within hundreds of meters of the vent) where clasts have short travel times with limited opportunity for cooling, cohesion of hot clasts is important in building oversteepened pyroclastic structures like spatter cones or ramparts (see Strombolian and Hawaiian Eruptions). Second, in medial to distal areas, high temperature cohesion can only occur in systems where minimal mixing has occurred with the atmosphere, that is, in pyroclastic density currents. In these cases, the role of particle cohesion in influencing transport and deposition conditions is controversial (see Ignimbrites and Deposits of Block-and-Ash Flows), partly because of uncertainties in the relative timescales for cohesion of viscous clasts versus the transport history and partly because of limited data on the viscosity and effective stickiness of clasts.

The most extreme cases involve pyroclastic material that has coalesced on deposition back into a coherent liquid that may retain momentum from the transport system (especially in pyroclastic density currents) but subsequently flows down slope under the influence of gravity. Units formed by this mechanism include fountain-fed lavas (in proximal areas, i.e., within kilometers of vent) and rheomorphic flow deposits (in medial areas, i.e., to distances of tens of kilometers from the vent). Such rheomorphic materials can be difficult to distinguish from conventional lavas, and welded falls may be hard to separate from high-grade ignimbrites; debates over the origin of documented examples are ongoing.

#### F. Role of Fluctuations in Particle Concentration

All the pyroclastic transport and deposition systems outlined in this chapter show fluctuations, effectively of particle concentration, with time. Such fluctuations are instrumental in generating many of the outcrop-scale features that contribute to the recognition and interpretation of fall, surge, and flow deposits. With fall deposits, fluctuations serve to create a first-order subdivision between the products of accumulation from (i) sustained,

relatively steady eruptions and (ii) nonsustained, discrete explosions of fluctuating intensity. This *steady* versus *unsteady* character is reflected in the bedding and grain size properties of fall deposits (see Fall Deposits). In pyroclastic density currents, many authors lay emphasis on the inherently fluctuating nature of transport and deposition in dilute currents (surges), versus a more steady-state mode for transport and deposition in concentrated currents (flows). This contrast is interpreted to reflect both the contrasting momentums of the transporting systems (i.e., for a given velocity, a flow has a higher momentum due to the greater particle concentration) and the length scales over which deposition occurs (e.g., thinner beds or laminae from surges versus thicker beds or individual flow units from flows).

---

#### IV. SUMMARY

Pyroclastic deposits are the end product of complex phenomena that are still poorly understood but frequently deadly to observers. The overall morphologies and internal characteristics of pyroclastic deposits reflect phenomena associated with both transport and deposition systems. Many features of pyroclastic deposits can be documented and interpreted within a simple framework of four parameters, namely, the trajectories of the depositing clasts, the concentration of particles in the depositing mixture, the presence or absence of particle cohesion, and the extent and timescale of fluctuations in transport and/or deposition systems.

Fewer than 10% of the explosive eruptions of the present century have been reasonably well documented scientifically, and few volcanologists have the opportunity to observe more than 3 or 4 large explosive eruptions in their lifetime. It is not difficult however for one person in a year to measure the deposits of several large eruptions of the past, and the volume of data forthcoming from such measurements is enormously greater than that forthcoming from observations on current activity.

## GLOSSARY

**componentry** Study of the abundances of different individual particle types in a pyroclastic deposit

**dispersal index ( $D$ )** A measure of the extent of a pyroclastic fall deposit, specifically the area enclosed by an isopach drawn at 1/100 of the maximum extrapolated thickness of the deposit.

**external water** Any water (e.g. seawater) involved in explosive volcanism that was not originally dissolved in the magma.

**fragmentation index ( $F$ )** A parameter measuring the grain size of a pyroclastic fall deposit, specifically the percentage of ash finer than 1 mm at the point on the dispersal

axis corresponding to 1/10 of the maximum thickness of the deposit.

**grain size half-distance ( $b_c$ )** The “average” distance over which the maximum clast size in a pyroclastic deposit halves.

**isopach** Line joining points of equal thickness in a deposit.

**isopleth** Line joining points where the sizes of the largest clasts (pumice or lithic) are the same.

**pyroclastic fall** The rain-out of clasts through the atmosphere from an eruption jet or plume during an explosive eruption.

**thickness half-distance ( $b_t$ )** The “average” distance over which the thickness of a pyroclastic deposit halves.

**P** YROCLASTIC FALL DEPOSITS are produced by the rain-out of clasts through the atmosphere from an eruption jet and/or plume during an explosive eruption. Fall deposits are the simplest of pyroclastic products, and their value within physical volcanology lies in this simplicity and in the ease with which

their properties can be used to infer eruption parameters. Fall deposits result from both “dry” magmatic and “wet” phreatomagmatic eruptions, and the “whole deposit” grain size distribution and morphology of the pyroclasts reflect principally the nature of the fragmentation process. Falling pyroclasts are fractionated during their transport through air (and sometimes also through water). Aerodynamic properties of the clasts, the vigor of eruption, and the nature of the transport process impart distinctive thinning and fining characteristics to the beds.

## I. INTRODUCTION

We here describe the properties of fall deposits on three scales:

- Large scale:* Those properties that may be inferred only from examination of the entire deposit
- Medium scale:* Those features that may be observed and used on outcrop scale
- Small scale:* The properties of the particles that make up fall deposits

Large-scale features include the rates at which fall deposits thin and fine away from source and the grain size properties of the entire deposit. Bedding and grading, absolute grain size, and sorting and welding are medium-scale properties. The morphology and vesicularity of juvenile clasts and the content and nature of foreign (wallrock) clasts are small-scale features.

## II. LARGE-SCALE PROPERTIES

Fall deposits are generated from three mechanically distinct but spatially overlapping regions during an explosive eruption (see the chapter entitled “Volcanic Plumes”):

1. The *jet* or *gas-thrust* region where the material first emerges from the vent at high velocities
2. The *plume* region where the mixture rises buoyantly in the atmosphere to a height determined by the thermal flux
3. The *umbrella-cloud* region where the eruption plume spreads laterally, in response to atmospheric stratification and the wind

Fall deposits form concave-upwards cones of tephra that thin away from a point of maximum thickness that is usually close to or coincident with the eruptive vent (Fig. 1a and 1b). Isopach and isopleth maps of the distribution of tephra thickness and maximum grain size, respectively, are used to quantify the thickness and coarseness of the deposits. The individual isopachs/isopleths usually form more or less regular ellipses (Fig. 1c) that are elongated in the downwind direction; the direction of elongation away from the vent defines the *dispersal axis* of the deposit. Complexities, such as (1) secondary thickening of the deposits due to the aggregation and early fallout of fine particles, (2) elongation of the umbrella cloud in different directions at different levels in the atmosphere, or (3) changing wind directions during the course of an eruption, can be recognized sometimes in isopach and isopleth maps of well-preserved deposits (Fig. 2).

### A. Thinning of Fall Deposits

The thickness and maximum grainsize of proximal to medial fall deposits decay exponentially, or nearly so. Exponential decay of thickness can be recognized by a straight-line relationship on a plot of the (natural) logarithm of thickness ( $\ln T$ ) versus the square root of the corresponding isopach area ( $\sqrt{A}$ ). The rate of thinning can be described by a simple parameter, the “half-distance” ( $b_t$ ), which is the distance over which the thickness halves (Table I), analogous to the half-life in radioactive decay. The extrapolated value of the thickness to  $\sqrt{A} = 0$  yields a maximum thickness value,  $T_0$ . For any deposit that shows an exponential decay of thickness, the volume of the deposit ( $V$ ) can then easily be estimated from the empirically derived equation

$$V = 13.08T_0b_t^2.$$

In practice, there are departures from simple exponential decay shown by many fall deposits (Fig. 3), which result in deviations from straight-line relationships on diagrams of  $\ln T$  versus  $\sqrt{A}$ . There are three fundamental causes for this, ultimately related to the grain size distribution of the erupting mixture and its influence on eruption column behavior (see the chapter entitled “Volcanic Plumes”):

1. Changes in transport mode between the regions of the eruption column. In those eruption styles dominated by coarse clasts (e.g., strombolian, hawaiian), much of the material is too coarse to be carried up in the buoyant plume region, but instead is distributed in

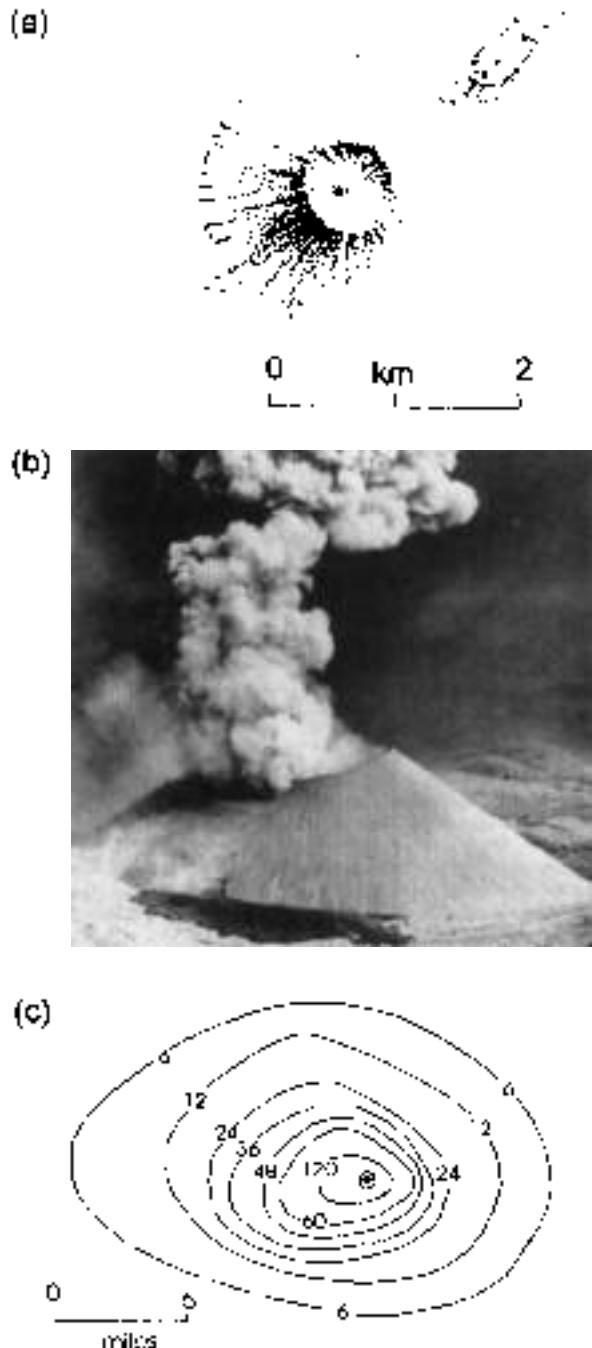

FIGURE 1 Sketch and photograph of Paricutin scoria cone, Mexico and isopach map for the distal fall deposit (reproduced from Krauskopf, K; McWilliams, H. (1946). The activity of Paricutin during its third year. *American Geophysical Union Transactions* 27, 406–410). The main cone of Paricutin formed between 1943 and 1944 in a series of strombolian and subplinian eruptions.

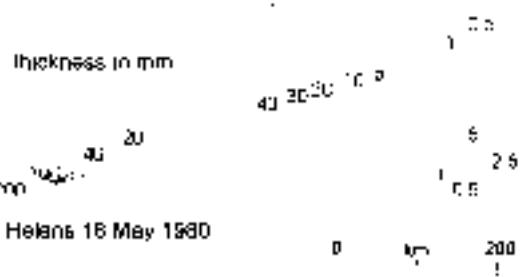

FIGURE 2 Isopach map for the 18 May 1980 Mt. St. Helens fall.

ballistic fashion around the vent. Where the slope of the cone of accumulation exceeds the angle of rest ( $\sim 35^\circ$ ), slumping will generate a cone of uniform slope rather than an exponentially decaying sheet. In the rare cases where the extreme proximal regions of widespread ("plinian") deposits are preserved, there is usually evidence also for accumulation of a thick pile of material around the vent that represents a steep, "ultraproximal" segment on a plot of  $\ln T$  versus  $\sqrt{A}$ , with  $b_t$  values on the order of tens to a few hundreds of meters. In addition there are many examples known where there is an inflection point in a plot of  $\ln T$  versus  $\sqrt{A}$  a few kilometers to tens of kilometers from the vent (Fig. 3b); this change is attributed to the differing transport regimes in the buoyant plume versus the umbrella cloud region. Typically,  $b_t$  ranges between 1 and 10 km for the proximal portion, and can range from 20 to 100 km, or more, over the distal portion.

2. Changes in the fall behavior of clasts with differing grain sizes. The size and density spectra of clasts carried into the umbrella cloud region are equivalent to a wide range of particle fall velocities. Differences in these fall rates (controlled by the particle Reynolds number,  $N_{Re}$ ) are sufficiently large that the finest fragments (chiefly vitric ash) that settle under Stokes' law conditions at low  $N_{Re}$  are carried significantly farther and generate a distal segment on a plot of  $\ln T$  versus  $\sqrt{A}$ .

3. Complex sources of pyroclastic material. In eruptions where a buoyant vent-derived plume coexists or is interspersed with buoyant portions of pyroclastic density currents (see the chapter entitled "Volcanic Plumes"), the fall deposits may show complex thinning relationships and mixing of material from different sources. In part this is driven by the dominance of fine ash in the second of these sources, which causes the bulk of the combined fall deposits to be transported farther from the vent, and, in part, it is related to the fact that the "source" of any plume coming from a

pyroclastic density current may be geographically detached from the primary vent, as was observed with the May 18, 1980, Mt. St. Helens eruption.

Many fall deposits, especially those for which data are not available in the most proximal or distal areas, show a single straight-line relationship on a plot of  $\ln T$  versus  $\sqrt{A}$ , and the method of volume calculation just given provides a useful minimum volume estimate. The proportion of this volume that is enclosed within the final mapped isopach depends on the ratio of the thickness of the last mapped isopach ( $T_{last}$ ) to the extrapolated maximum thickness,  $T_0$ :

$$V/V_{total} = 1 - (T_{last}/T_0)(1 - \ln(T_{last}/T_0)).$$

So as long as  $(T_{last}/T_0)$  is less than 0.05, at least 80% of the calculated volume will be enclosed within the final mapped isopach. Other deposits are known for which there are three or even four straight-line segments; volumes can still be calculated, but these have to be integrated separately for each segment. There is no simple

relationship between maximum thickness and dispersal (Fig. 4a).

## B. Dispersal Indices of Fall Deposits

The thickness half distance may be used to separate classes of fall deposit with differing dispersal characteristics (e.g., Fig. 3a). An alternative method for quantifying how widespread is a fall deposit is the dispersal index ( $D$ ), introduced by G. P. L. Walker. This index is defined as the area enclosed within the  $0.01T_0$  isopach, and it ranges from  $<1\text{ km}^2$  in small, cone-dominated deposits to  $>2 \times 10^6\text{ km}^2$  in some phreatoplinian fall deposits (see the chapter entitled “Phreatoplinian Eruptions”). Walker later suggested that a more rational index of dispersal might be the area that enclosed half of the volume of the deposit, but this requires the fall deposit volume to be accurately known (see Section II,C). If a fall deposit is a simple exponential cone the dispersal

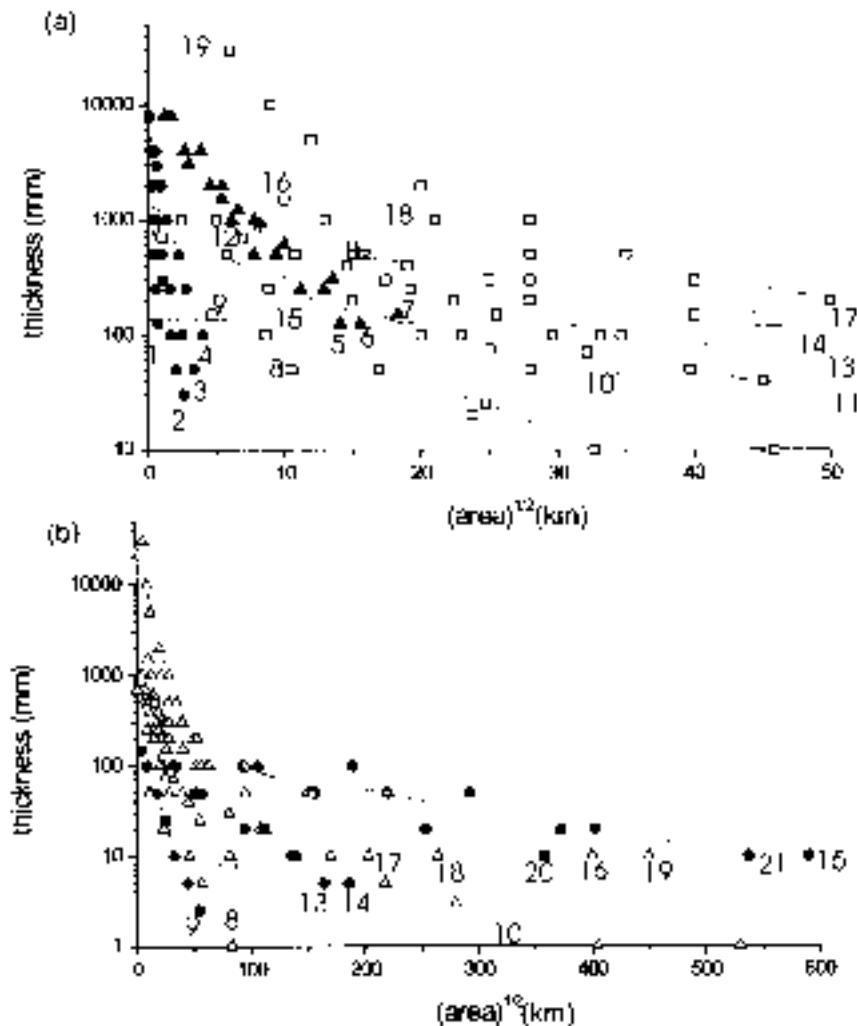

FIGURE 3 Plots of  $\ln T$  versus  $\sqrt{A}$ . (a) Plot of proximal thinning relationships for representative hawaiian/strombolian (solid circles), subplinian (solid triangles), and plinian/phreatoplinian (open squares) tephras. (b) Similar plot at expanded scale for the plinian (open triangles; solid line) and phreatoplinian (solid circles; dashed line) units.

index is proportional to  $b_t^2$ ;  $D = 138.7b_t^2$ , and the area within the  $0.01T_0$  isopach encloses 94% of the erupted volume. The area of the same deposit that encloses half of the volume of the deposit is marked by the isopach with  $T = 0.186T_0$  and encloses an area of  $18.4b_t^2$ .

### C. Fining of Fall Deposits

All fall deposits show some diminution of grain size between proximal and distal areas. For many purposes (especially modeling of plume dynamics, and comparing the "power" of eruptions), the maximum grain size is

the key parameter that is measured. Various workers have used different techniques; for example, averaging lengths of the longest, or all three, axes of the 3, 5, or 10 largest clasts at any exposure, or measuring in similar fashion but only over a defined area ( $1\text{ m}^2$ ,  $10\text{ m}^2$ ) at any exposure.

The decay of the maximum grain size of fall deposits is also often exponential, or nearly so, and can also be described by a "half-distance,"  $b_c$ , over which the maximum grain size (however measured) diminishes by half. The grain size half distance is principally influenced by the energetics of the column and ranges up to 18 and 40 km, respectively, for the most energetic "dry" (plinian) and "wet" (phreatoplinian) eruptions known.

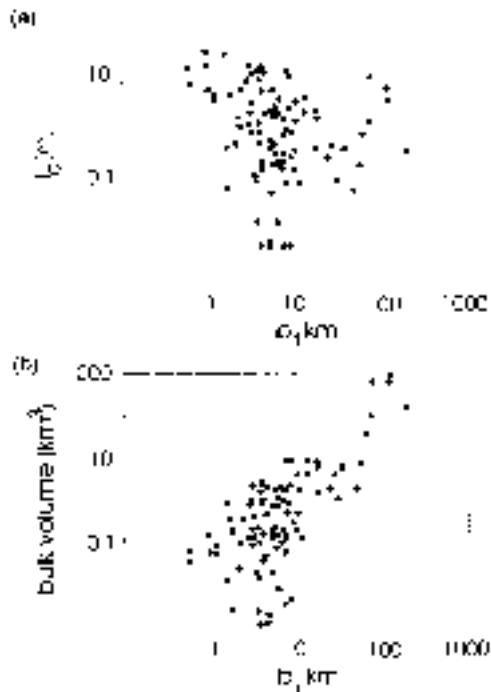

FIGURE 4 Plots of bulk volume and extrapolated maximum thickness against thickness half-distance.

Two parameters, the inferred maximum clast size and the mean grain size, can be used to define a "size half-distance." The latter has not been widely used, and its full significance remains unexplored.

The ratio of thickness and maximum grain size half-distance ( $b_c/b_t$ ) is principally controlled by the grain size

characteristics of the erupting mixture at the vent. There is a wide variation of values,  $b_c/b_t$  being lower for deposits dominated by finer-grained clasts, but most deposits have  $b_c/b_t$  between 0.5 and 1.5 (Fig. 5).

#### D. Volume

Two methods are widely used for determining bulk volumes of fall deposits. The first uses the observed (or inferred) exponential decay of thickness with area and integrates under the lines of  $\ln T$  versus  $\sqrt{A}$  to obtain a volume estimate. This method is dependent on accurate measurements (or assumptions) to extrapolate values of  $\sqrt{A}$  as  $T$  approaches 0. The second method estimates the total mass of magma erupted by comparing the measured mass proportions of loose crystals in the fall deposit with the mass ratio of phenocrysts to glass in pumices from the deposit. It assumes that the crystals have a narrow size distribution and hence that they are all deposited and preserved in proximal to medial areas, then uses the phenocryst:glass mass ratio in pumices to estimate masses (hence volumes) of the "missing" finer-grained vitric ash deposited in inaccessible distal environments. This method is dependent on accurate knowledge of the phenocryst:glass ratios in the pumices and deposit (in an eruption where the magma was zoned with respect to phenocryst content, this may be effectively impossible) and is unusually labor-intensive. Volumes estimated from the former method yield values that are as low as one-third to one-half of volumes for the same deposits estimated using the latter method.

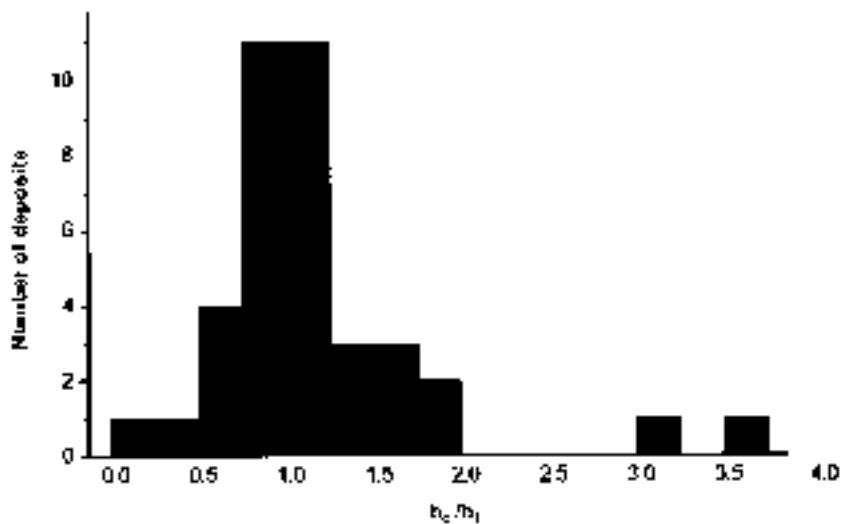

FIGURE 5 Frequency plot for deposits with a given ratio of thickness and grain size half-distances ( $b_c/b_t$ ).

In large part, conflicts between these methods for estimating fall deposit volumes exist because of uncertainties in estimates of the volume of distal-deposited fine ash fall associated with eruptions, especially those where large-volume pyroclastic density currents are generated. However, another reason for conflict is because theoretical models for deposition from eruption plumes and umbrella clouds predict deposition in terms of mass per unit area, whereas this parameter is largely ignored in field measurements in favor of simple thickness measurements. The two can be compared only if accurate measurements of *in situ* pyroclast mass (or dry bulk density) are available and/or data on pyroclast mass per unit area are collected. With the notable exception of the Mt. St. Helens 1980 fall deposits, both forms of data are sparse, and rectification of this is important for future studies.

The most voluminous fall deposits tend to be those that are the most widely dispersed (Fig. 4b). This relationship is correlated over 3–4 orders of magnitude (eruption rates of  $\sim 10^6$  to  $10^9$  kg/s; deposit masses  $10^{11}$  to  $10^{15}$  kg) and implies that the magma discharge rate is related in some fashion to the size of the magma chamber being tapped.

### E. Whole-Deposit Grain Size

The grain size characteristics of entire fall deposits (whole-deposit grain size) reflect only processes of fragmentation and eruption, not transport. As such they hold real potential as a parameter for classification of fall deposits and comprehension of eruption dynamics. Unfortunately, few sets of data exist, and most of these are for relatively small historical eruptions. The diffi-

culty lies in (1) the low potential for preservation of deposits beyond the 1-cm isopach in subaerial environments, and (2) the fact that the distal portions of many fall deposits are deposited offshore. In prehistoric fall deposits, where distal deposits are not preserved, only crude estimates of the whole-deposit grain size can be made in most cases. Techniques applied include one or more of (1) integration of relative abundances for individual size fractions using a plot of  $\ln(\text{mass per unit area})$  versus  $\sqrt{A}$  for each size fraction, (2) using broad constraints on the abundance of fine distal ash fractions (estimated using the crystal measurement method described in the previous section) to control the fine “tail” of the whole deposit, and (3) using grain size populations in syneruptive water-flushed fall or pyroclastic density current deposits where the particles are less widely segregated and dispersed.

---

### III. MEDIUM-SCALE PROPERTIES

#### A. Stratification and Grading in Fall Deposits

The nature of the stratification and the fluctuations in grain size in fall deposits offer insight into the changing intensity of the parent eruptions, particularly for very proximal sections. Most fall deposits consist of an alternation of coarser and finer grained intervals (Fig. 6). Sharp bedding planes, dividing units of contrasting grain size, imply spasmodic, nonsustained eruption (Figs. 6a, 7); sustained events produce deposits lacking well-defined bedding planes (Figs. 6b, 7). The absolute grain

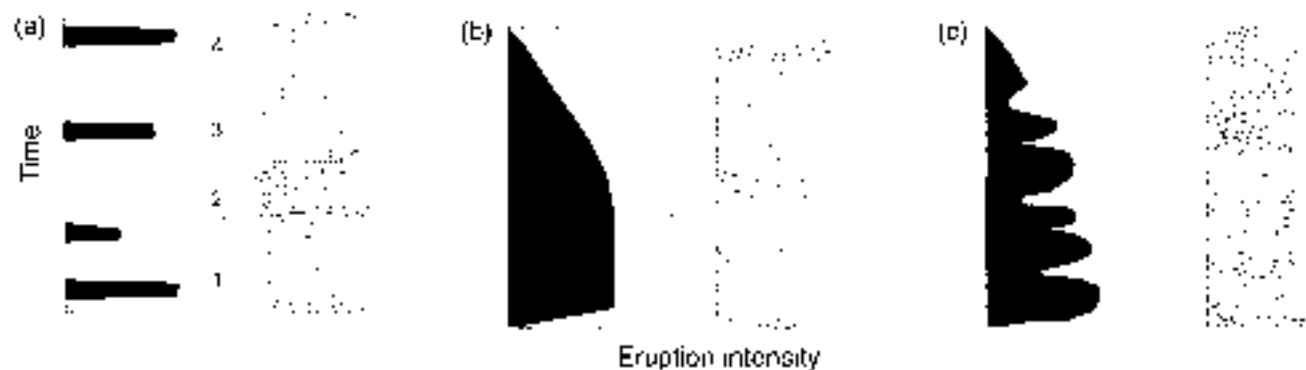

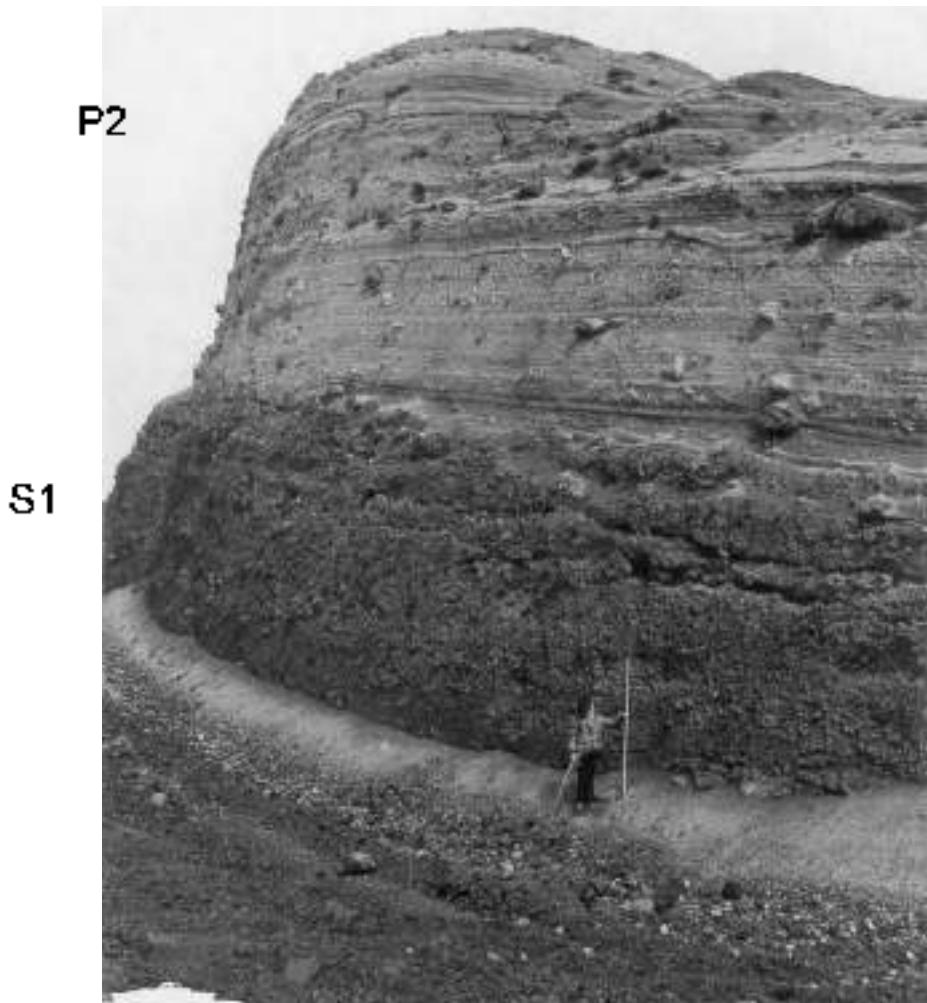

FIGURE 6 Schematic cartoon of the relationships between eruptive intensity, the development of bedding, and the maximum clast size for a given component.

**FIGURE 7** Contrasting bedding and grading in sustained Strombolian and episodic phreatomagmatic pyroclastic deposits at Rothenberg scoria cone, Germany. The darker lower Strombolian S1 beds show cryptic fluctuations in grain size (shower bedding) interpreted as due to sustained eruption with fluctuating intensity of the type sketched in Fig. 6c; the upper lighter phreatomagmatic P2 beds were produced by multiple discrete explosions (see Fig. 6a). Note also the greater abundance of lithic blocks (light-colored) in P2. Photograph by Paul van den Bogaard.

size of the finest ash “partings” in a deposit gives some estimate of the duration of pauses in the eruption; for example, 10- $\mu\text{m}$  sized ash can persist in the atmosphere for 2 to 3 days so that beds of this grain size in a sequence imply breaks of at least this duration (provided that flushing of this ash by moisture and/or electrostatic attraction has not occurred). Conversely, small amounts of very fine ash erupted in early phases of a prolonged “dry” eruption may not settle until after the close of the last phases of eruption, as has been proposed for the 1912 A.D. eruption of Novarupta in Alaska. Passing away from vent the definition of partings in a deposit may fade, as the period of plume transport becomes

significantly longer than the duration of fluctuations in the intensity of the eruption.

Progressive vertical changes in particle size or composition within a bed are known as *grading*. Density grading is a progressive change in particle density with or without a change in grain size. Density grading is a more common feature of flow deposits, whereas size grading is typical of all pyroclastic deposits (Fig. 6b), but can be expressed in very subtle fashion. Both normal and inverse size grading are common in fall deposits. Grading is most commonly interpreted in terms of fluctuating vigor of the eruption (Figs. 6b and 6c), but can also be produced by wind shifts and/or alteration in the

inclination of the eruption column or jet. *Shower bedding* is a term given to gradual fluctuations in grain size within a fall deposit (Fig. 7).

Fall deposits tend to lack the internal unidirectional sedimentary structures that characterize the deposits of vent-fed pyroclastic density currents, although near-surface winds and coeval plume-fed density currents occasionally create cross bedding and pinch-and-swell structures in fall deposits. Mantle bedding (Fig. 8a) is a

classical feature of fall deposits—plane-parallel fall units drape and follow preexisting relief on slope angles up to 25° to 30°. On steeper surfaces material may roll, slide, or avalanche down slope and, in extreme cases, form better-sorted lensoid inverse-graded units on or below any steep slope (Figs. 8b, 9b).

### B. Absolute Grain Size and Sorting

The behavior of particles that form pyroclastic fall deposits is strongly influenced by their terminal fall velocities. The residence time of any clast in an eruption plume is inversely proportional to its fall velocity ( $V_t$ ), which increases with clast diameter ( $d$ ) and density ( $\rho$ ) as

$$\begin{aligned} V_t &\approx (3.1 gpd/\sigma)^{1/2} && \text{for Reynolds numbers } > 500, \text{ or} \\ V_t &\approx gpd^2/18\mu && \text{for Reynolds numbers } < 0.4, \end{aligned}$$

where  $\sigma$  is the density of air and  $\mu$  the dynamic viscosity.

George Walker recognized, at a very early stage, a crude correlation of absolute grain size with eruption style. Fall deposits of very wet eruptions are typically very fine-grained, whereas deposits of dry eruptions are coarse-grained (Fig. 9a). This correlation was originally linked to a greater efficiency of phreatomagmatic explosions. However, the possibility arises that part of the differences between wet and dry fall deposits is due to the effect of liquid water in causing premature flushing of fine ash from the eruption column. Absolute grain size can be described in terms of either maximum clast size (as in the construction of isopleth diagrams) or some measure of average clast size. The two commonly quoted parameters are  $Md_\phi$  ( $=\phi_{50}$ ) and  $M_z$  ( $=[\phi_{16} + \phi_{50} + \phi_{84}]/3$ ), where the numbers refer to percentiles coarser than the phi-size stated and  $\phi$  is the negative log to the base 2 of the grain size in millimeters.

There is considerable overlap between the grain size of dry or “magmatic” fall deposits and that of phreatomagmatic deposits from eruptions with low water/magma ratios (Figs. 9b and 9c). In contrast, many deposits of phreatomagmatic eruptions involving abundant water typically have  $\sigma\phi$  values of 2 or higher.

The size of juvenile particles in a deposit is a measure of both the efficiency of the fragmentation processes and the vigor of the eruption. It is important to realize that these factors are not always coupled. For example, hydrothermal explosions (see the chapter entitled “Surface Manifestations of Geothermal Systems”), powered by flashing of superheated water to steam, produce highly fragmented assemblages of clasts, because they utilize the available thermal energy very efficiently

**FIGURE 8** The response of fall deposits to preexisting topographic relief. (a) Mantle bedding in Quaternary fall tephrae of Tenerife, Canary Islands. (Photo reproduced from Fisher, R. V., and Schmincke, H. U. (1984). “Pyroclastic Rocks.” Berlin. Copyright © Springer Verlag.) (b) Lensoid slope-affected bedding in a strombolian phase of the Harry Johnson Road basalt deposit, Taupo Volcanic Zone. The slope-affected beds are significantly better sorted (data from these beds defines trend C in Fig. 9c) than the primary strombolian fall deposit.

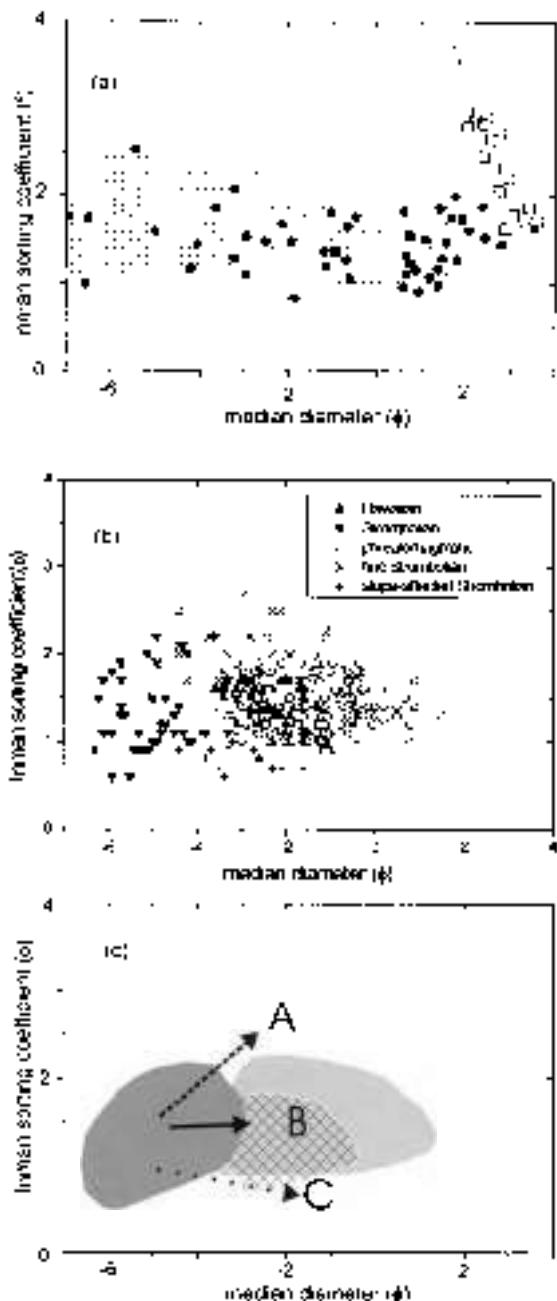

FIGURE 9 Contrasting grain size properties for a variety of pyroclastic fall deposits from eruptions involving widely different water/magma ratios. (a) Dry (plinian) and wet phases of the 1875 A.D. eruption of Askja caldera, Iceland, after Sparks, R. S. J., Wilson, L., and Sigurdsson, H. (1981). The pyroclastic deposits of the 1875 eruption of Askja, Iceland. *Phil. Trans. Roy. Soc. London A* **299**; 241–273. The phreatoplumian phase C at Askja was characterized by relatively high water/magma ratios when silicic magma interacted with abundant external water, and the contrast in deposits to the associated plinian phase D is clear. (b) Dry (strombolian and hawaiian) and wet phases of basaltic volcanism.

(down to  $\sim 100^{\circ}\text{C}$ ). However, they are generally rather weak, as the total energy available to eject and transport clasts is constrained by the low preeruptive temperature of the systems (typically only 230–300°C).

There are some tricks in interpreting particle size distribution:

1. The size of lithic clasts is not always a measure of the efficiency of fragmentation, especially in deposits rich in foreign lithics. In the case where such clasts are derived from a preexisting unconsolidated tephra or sediment, their particle size distribution may be effectively inherited from this predecessor, and very large or very small clasts may be absent from the lithic population. Many very fine grained but lithic-rich phreatomagmatic falls should not be interpreted as representing highly efficient fragmentation for this reason. Likewise, recycling of clasts through the vent (see later discussion) can also promote an unusually fine grain size distribution.

2. One process that can complicate interpretation is if apparently juvenile clasts fall back into or close to the source and then are recycled through the vent. The grain size and also morphology of these clasts then has no relationship to the eruptive conditions at the moment when they finally leave the vent. These clasts share a transport history with truly juvenile clasts in the same deposit but may have been fragmented under very different conditions and indeed refragmented several times.

3. Another process leading to an apparent reduction in the grain size of a deposit is the breakup of large clasts in flight or, more commonly, on impact. The latter

---

The phreatomagmatic units were all linked to low water/magma ratios as basaltic magma contacted limited quantities of ground water and thus the contrasts in sorting and absolute grain size are less marked than in (a). Data are from our research on numerous deposits from Taupo Volcanic Zone and the Eifel and Auckland volcanic fields. (c) Summary of data from (b). Hawaiian fall samples (cross-hatched) in particular show a strong overlap with the coarse-grained phreatomagmatic deposits (pale gray). Three processes operating during Strombolian volcanism also produce deposits whose grain size characteristics also mimic the associated phreatomagmatic fall deposits:

- A: Partial blockage of the vent by wall collapse or formation of lava ponds, (which produces fine-grained and relatively poorly sorted beds)
- B: Size fractionation and fining with distance from vent (distal samples are finer grained but similar to proximal samples with respect to sorting)
- C: Rolling, sliding, and avalanching of material down slope (leading to finer grained and better-sorted deposits)

TABLE II Typical Foreign Lithic Contents of Some Basaltic Fall Deposits<sup>a</sup>

<sup>a</sup> Illustrates the general contrast in lithic content between magmatic ("dry") and phreatomagmatic ("wet") fall deposits. "Wetter" phreatomagmatic fall deposits show evidence for abundant liquid water at the time of deposition, such as mud lumps, soft-sediment deformation, and deep bomb sags. "Drier" phreatomagmatic fall deposits are relatively well sorted and do not contain accretionary lapilli or mud lumps.

<sup>b</sup> Represents a Strombolian eruption through soft, hydrothermally altered host rock.

process can often be inferred from the jigsaw fit of adjacent clasts in a bed.

The combination of sorting and grain size parameters was used at an early stage to define fields for "wet" and "dry" fall deposits. Where clasts are deposited from "dry" plumes (see chapters entitled "Plinian and Subplinian Eruptions" and "Volcanic Plumes") there is minimal interaction with neighboring clasts and marked size and density fractionation develops in the plumes; this is reflected in the deposits. The resulting deposits show both a marked decline in clast size with distance from vent and good sorting throughout. Certain components with fixed (or restricted) ranges in size and density will be concentrated at specific distances from the vent; for example, free crystals commonly form girdles of maximum abundance some tens of kilometers from the vent in plinian deposits. A general improvement in the degree of sorting beyond the near-vent region is a common feature of many dry fall deposits.

In contrast, if aggregates of ash form in moist plumes, through collision and binding of particles, then the aggregates will fall with greater velocities than the terminal velocities of their component particles. This process of ash aggregation results in the "premature" removal ("flushing") of ash-sized ejecta from the plume and simultaneous deposition of a wide range of grain sizes. Many such "wet" deposits are poorly sorted and fine-grained even close to the vent (see the chapters entitled

"Surtseyan and Related Phreatomagmatic Eruptions" and "Phreatoplhinian Eruptions"). Figure 9a shows contrasts in grain size and sorting for alternating wet and dry phases of the 1875 A.D. Askja eruption.

The originally defined fields now seem rather too restrictive, but use of the  $Md$  versus  $\sigma\phi$  diagram in a more subtle way for considering the distinction between different units in one eruptive sequence and particularly trends within a sequence is still extremely valuable. It is possible to use sorting values to distinguish sequences in which contrasts in grain size reflect changing vigor of the explosions or wind shifts, for example (sorting remains constant or improves with decreasing grain size) from those where finer grained beds are the result of weak magma–water interaction or conduit wall collapse (marked decrease in sorting efficiency with decrease in grain size).

Submarine and sublacustrine fall deposits are distinctive in their stratification and in their grading patterns. Settling through water enhances size and, particularly, density fractionation. Pumice lapilli and blocks will only sink once they become partially water-saturated; thus, proximal pumiceous subaqueous fall deposits have concentrations of lithic clasts at their base followed by sharply inverse-graded pumice. Distal water-laid ashes commonly have sharp bases and diffuse tops due to bioturbation and mixing with nonvolcanogenic sediment. In both environments sorting is enhanced relative to subaerial tephra.

### C. Thermal Effects

One natural consequence of the mode of formation of fall deposits is that there is substantial interaction between pyroclasts and air that involves transfer of large amounts of thermal energy to the air and cooling of the pyroclasts. Thus, in comparison with many pyroclastic density current deposits (notably ignimbrites; see the chapter entitled “Ignimbrites and Block-and-Ash Flow Deposits”), fall deposits show less abundant thermal features. These features form an overlapping spectrum from thermal coloration through welding to agglutination.

The most common and widespread manifestation of high-temperature thermal effects is in coloration of pyroclasts, principally controlled by the growth or alteration of iron-oxide mineral species, especially as microscopic crystals. In mafic to intermediate deposits where the background color is black, such thermal oxidation results in the characteristic red color frequently seen in scoria cones and other proximal fall deposits. Such coloration tends to be pervasive throughout the deposits. In more evolved compositions, where the unaltered color of pyroclasts is pale gray to white, a wide range of hues from orange through pink, red to purple, or black to brown are reported from proximal deposits. Commonly these colors are preferentially developed in larger clasts (though pervasive coloration of deposits is also known), this being interpreted to reflect greater retention of heat by the larger clasts during flight.

At higher retained temperatures than those causing coloration are the effects caused by viscous deformation and flow of pyroclasts after landing forming an overlapping suite of effects. *Welding* is represented by the slow-scale deformation of individual pyroclasts together with interclast cohesion under the influence of load stresses induced by accumulation of further material. Factors that promote welding are the retention of heat in individual clasts (e.g., coarse clast size, short flight time, and high initial temperature) and high accumulation rates (to cause rapid burial and loading). The role of the load stress caused by overlying deposits is to make clast viscosity less of a factor in initiating welding than it is in causing agglutination (see later discussion). Welded fall deposits are commonest in deposits of peralkaline or intermediate composition, but are also known from highly silicic compositions. *Agglutination* is the process by which individual pyroclasts, which are still sufficiently hot and fluid, deform and flow on impact under their own momentum. The degree of agglutination varies with the clast viscosity and size and the flight time, and hence is an important process in deposition from low,

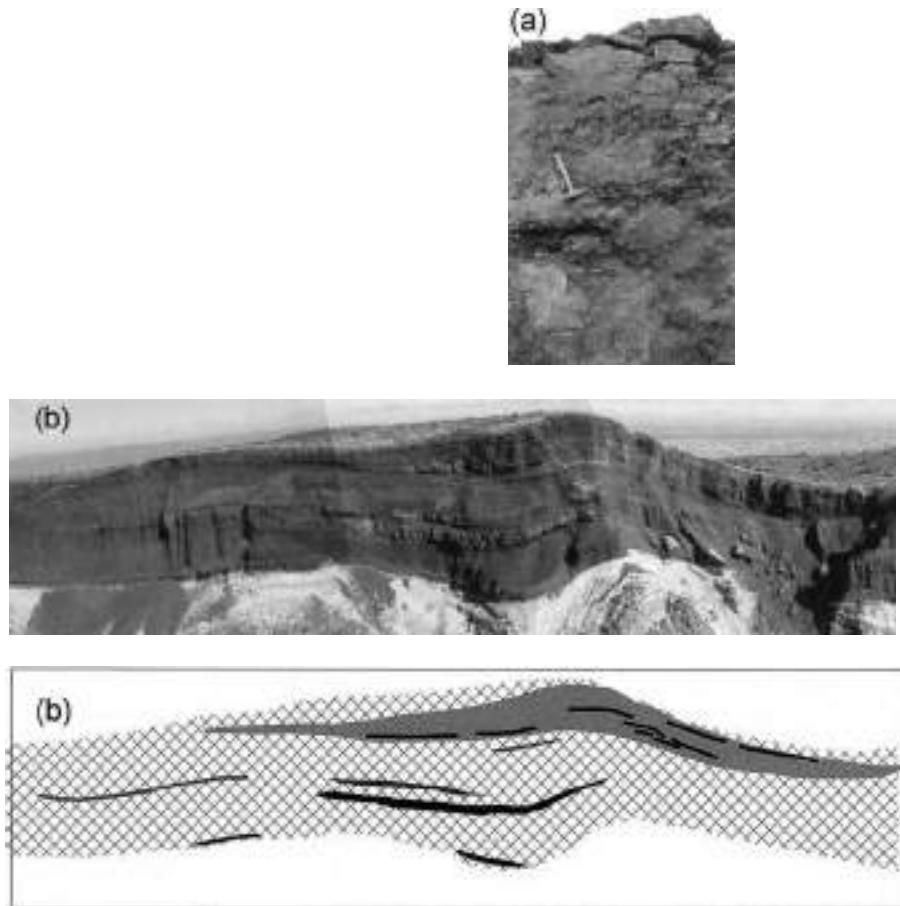

fountaining eruption columns of low-viscosity magmas, such as Hawaiian fire fountains (see the chapter entitled “Hawaiian and Strombolian Eruptions”). Agglutinates are also common in intermediate and peralkaline fall deposits, but rare in silicic compositions (see later discussion).

These thermal phenomena form a series of facies, with a regular increase in thermal intensity toward the vent; this contrasts with thermal effects in ignimbrites that vary more with deposit thickness, which in turn often varies nonsystematically with distance from source. Welding and agglutination in fall deposits are an especially useful indicator of proximity to vent, but some such deposits merge genetically and in time and space with welded ignimbrites and clastogenic lavas. In proximal areas, the distinction between welded deposits of fall versus flow origin is based on the lack of an ash-grade matrix (Fig. 10a) and rapid (decimeter- to meter-scale) vertical variations in welding intensity in the former (Fig. 10b). Clastogenic lavas are abundant at basaltic volcanoes, common in intermediate/peralkaline ones, but scarce among the products of silicic eruptions. This reflects a trend of increasing volatile content (hence explosivity, which controls the clast size population and extent of cooling by interaction with air in the eruption column) and magma viscosity. In the case of highly silicic magmas, clastogenic lavas are either the products of unusually high-temperature melts that were relatively dry or of hydrostatically suppressed eruptions in which retention of volatiles caused low viscosities and limited transport minimized the opportunity for cooling.

---

### IV. SMALL-SCALE PROPERTIES

Many small-scale properties of fall deposits relate to the nature of individual clasts or the abundance of contrasting types of clasts. The study of these properties, componentry, is a technique developed for one purpose but now used more widely for a second. George Walker, who first applied componentry to understand processes of column transport and density fractionation of clasts, used a simple threefold split into pumice, crystals, and lithics (dense clasts). More recently, componentry has been recognized and used as a powerful tool in understanding fragmentation processes. Use for this end requires more subtle division into component classes on the basis of the vesicularity and morphology of juvenile clasts and the lithology of wallrock clasts.

**FIGURE 10** Welding textures in pyroclastic fall deposits. (a) Partially welded agglutinate, Ohakune craters, New Zealand showing (i) the presence of “ghost” boundaries between bombs, and (ii) the absence of abundant fine matrix. (b) Lenses of welded scoria of variable intensity within the deposits of the 1886 A.D. eruption of Mount Tarawera, New Zealand. The deposit formed from the mingling of ejecta from numerous point sources along a 17-km fissure and increasing welding intensity (shown as increasingly darker gray tones) is correlated with increased accumulation rate during periods of vigorous fire fountaining from adjacent vents.

#### A. Juvenile Clast Morphology

Juvenile pyroclasts have shapes that are related to their origin and their transport history. Large clasts can be examined directly; the morphology of fine particles is best studied using a scanning electron microscope.

Magmas that erupt in a hot, fluid condition will fragment to form droplets or spray and hence fluidal clasts. *Achneliths*, *Pelée’s tears*, and *spatter* are products of such behavior. In contrast, material fragmented in a brittle state is markedly angular and the resulting clasts have blocky planar and curviplanar surfaces. Brittle fracture is often a result of quenching by contact with external water or very high strain rates during fragmentation. Quenching leads to the production of cooling cracks and “breadcrust” texture, hydrated and/or chilled rinds

and adhering coats of ash or sublimates on the surface of clasts and in vesicles.

Transport of pyroclasts may modify the original morphology of particles. Chipped or rounded edges and corners and hackly fracture surfaces are features of transport in a concentrated medium and so may help to distinguish clasts in pyroclastic flow deposits from those of fall deposits.

#### B. Juvenile Clast Vesicularity and Crystallinity

The vesicularity of the juvenile clasts highlights the role of degassing in explosive fragmentation. Vesicle popula-

tions in juvenile clasts from plinian (large dry) eruptions are strikingly uniform, indicating fragmentation of relatively homogeneous foam, a reflection of the high viscosity of plinian magmas. Simple, small, dry eruptions (hawaiian, strombolian) are characterized by a similar clast population, but most small dry eruptions show a wider range of vesicularities corresponding to the decoupling of the more fluid magma and volatiles, and progressive degassing of magma remaining in the vent. Because of the decoupling and streaming of the magmatic volatiles through the silicate liquid, there are progressive changes in the portion of the magma that remains in the vent. There are two end members to this process. The first is where magma at shallow depths is well mixed throughout and the result is a progressive decrease in the vesicularity of juvenile clasts with time. In the second extreme, a discrete degassed crust develops on top of the magma pond, and this crust must be passively disrupted by the explosions in order for explosive volcanism to continue. More silicic magmas that undergo slow ascent may also undergo vesicle collapse and syn- and intraeruptive passive loss of volatiles, often accompanied by microlite nucleation (see later discussion), leading ultimately to a population of predominantly dense juvenile clasts.

Clasts from wet explosive eruptions (see the chapters entitled "Surtseyan and Related Phreatomagmatic Eruptions" and "Phreatoplinian Eruptions") show complex patterns with two extremes represented by fragmentation by magma–water interaction alone and fragmentation by magma–water interaction boosted by rapid vesiculation (Fig. 11).

The phenocryst content of juvenile clasts is related to residence time and conditions in the magma chamber, and glass inclusions within phenocrysts may be used to estimate the preeruptive volatile content of the magma. The microlite content of juvenile clasts is linked to the extent of subsurface cooling and volatile loss from the magma while in the conduit. This, in turn, has a strong influence on eruption dynamics. Quantitative measurements of microlite size and shape can be coupled with vesicularity data, and grain size and bedding information to understand the nature of eruptive pulses in complex eruptions such as Pinatubo in 1991.

### C. Wallrock Lithics

The content of wallrock (foreign) lithics is a sensitive indicator of the competence and stability of the rocks forming the conduit walls, as well as the extent of inter-

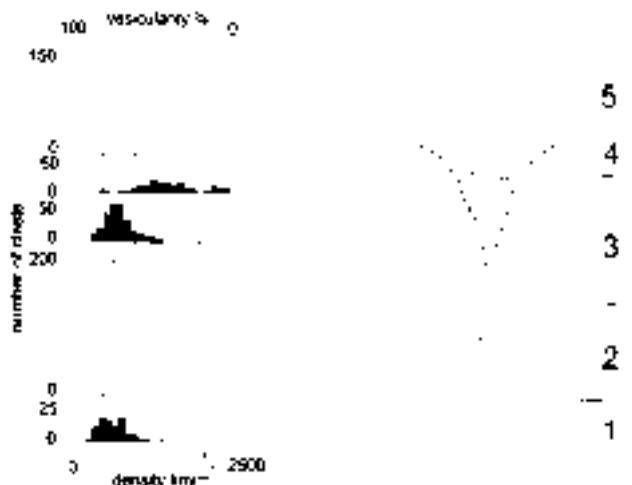

FIGURE 11 Contrasting patterns of density/vesicularity in clasts from "dry" (plinian) and "wet" (phreatoplinian) phases of the 181 A.D. Taupo eruption, New Zealand. Units 1, 3, and 4 show two contrasting patterns of vesicularity. Units 1 and 3 are "wet," yet are dominated by uniform populations of highly vesicular pumice, suggesting that the magmatic phase was a vesiculated foam at the moment of fragmentation. Unit 4 contains a broad mode of much less vesicular juvenile clasts, suggesting that rapid vesiculation was not occurring during fragmentation.

action of the rising magma with groundwater in aquifers. The content of foreign lithics also correlates with eruptive intensity; thus, Hawaiian fall deposits have probably the lowest lithic content (<1 wt%) of all types of pyroclastic deposit. Plinian and phreatoplinian deposits where magma interacts with lake or sea water typically have foreign lithic contents of 3 to 20 wt% but many phreatomagmatic deposits associated with aquifer systems have lithic contents of >50 wt%. The contrast is most striking where such deposits are interbedded with strombolian or plinian phases from the same volcano (Fig. 7).

The lithology of wallrock lithic clasts can help both to locate vent position and to constrain the depth over which fragmentation occurs. In wet explosive eruptions, the nature of the wallrock clast can help "fix" the hydrology of the vent region. For example, an abundance of well-rounded wallrock blocks may correlate with a gravel aquifer, or faunal assemblages in blocks of unconsolidated marine sediments may help fix water depth for submarine vents. If the basement geology is well constrained, then changes in the lithic assemblage with time may record either the opening of new vents in areas of contrasting basement lithology or drawdown of the fragmentation region to deeper levels. Extremely detailed studies of historical eruptions at Vesuvius (see

the chapter entitled “Plinian and Subplinian Eruptions”) enabled a close match to be made between lithic lithology and the basement stratigraphy. Marked increases in wall rock lithic content accompany the transitions from dry to wet behavior at Vesuvius, and the nature of the lithics enabled identification of the aquifer supplying external water to the eruption. Pulses of shallow-derived lithic fragments in the fall deposits accompanied intervals of vent widening.

## V. DISCUSSION

### A. The Role of External Water and Indicators of Magma/Water Interaction

External water flashing to steam is a very efficient way of utilizing magmatic heat to “fuel” an explosive eruption. The inferred effects of this thermodynamic efficiency on the resulting grain size of the deposits is the basis for suggesting that absolute grain size might be used to infer the water/magma ratio for prehistoric pyroclastic fall deposits. There are at least three important caveats. First, it is clear from historical eruptions that in many phreatomagmatic eruptions the extent of mixing and heat transfer is very incomplete, and there may be portions of the magma ejected in a phreatomagmatic explosion that never contact external water and vice versa. Second, magma–water interaction can occur at any point in the degassing history of a batch of magma. If magma encounters external water at the peak of vesiculation, then both volatile exsolution and flashing of external water may operate simultaneously and combine to boost further the efficiency of the fragmentation. Third, there is some evidence that the critical role of external water in inducing poor sorting and fine grain size in fall deposits is not simply at fragmentation, but also during transport and deposition, where water scavenges fine ash from eruption plumes and promotes the formation of accretionary lapilli and other ash aggregates.

Grain size measures have been used with great success (e.g., Fig. 9a) to separate the products of completely dry or “magmatic” fragmentation (plinian, strombolian etc.) from eruptions involving ample amounts of external water (surtseyan, phreatoplinian). However, there exist classes of other phreatomagmatic fall deposit where there is direct (observational) or indirect (textural) evidence for limited magma–water interaction but whose grain size is identical to that of purely dry fall deposits.

In these situations, other quantitative parameters linked to componentry, such as the abundance of foreign lithics or vesicularity of the population of juvenile clasts, are more effective.

In situations where magma has come in contact with groundwater, changes in the foreign lithic content are often much more precise indicators of slight changes in the water/magma ratio than any grain size parameters.

### B. Spectra versus Pigeon Holes

Pyroclastic fall deposits naturally form continua rather than “end-member” clusters, and any one parameter or pairing of two parameters will be inadequate to form a comprehensive classification system for pyroclastic fall rocks. The most widely used classification of deposits, pioneered by George Walker (the “F–D” plot) separates adequately (1) all deposits on the basis of their dispersal, and (2) products of dry magmatic fragmentation from phreatomagmatic deposits characterized by high water/magma ratios. It does not separate the products of phreatomagmatic eruptions where fragmentation was boosted by release of magmatic volatiles from those that were not, nor does it delineate phreatomagmatic deposits characterized by a low water/magma ratio from strombolian or plinian deposits. For any new classification to be more effective it will need to incorporate new parameters related to deposit componentry while being sufficiently flexible to apply to both modern and ancient fall deposits.

## GLOSSARY

**base surge** A turbulent density current that flows outward from the base of a partially collapsing vertical eruption column derived from a hydrovolcanic (phreatomagmatic) eruption; a type of pyroclastic surge.

**bed form (or bedform)** The surface configuration of a bed; also the three-dimensional configuration of groups of strata having geometric shapes that repeatedly occur in nature such as ripples, dunes, and plane beds.

**bedset (or bedding set; also bed set)** A sequence of beds with distinct internal structures, textures, colors or compositions that sets them apart from other sequences, usually bounded by unconformities, or by fallout layers.

**blast** A sudden, violent, overpressured explosion projected laterally or vertically. At Mt. St. Helens the blast was directed laterally and produced a high-velocity dilute pyroclastic density current, or pyroclastic surge.

**blocking** Deflection of the lower, denser parts of a pyroclastic density current (PDC) by a topographic barrier while

the low-density upper parts of the PDC continue to travel over the barrier.

**flow regime** Hydraulic conditions of noncohesive flow of sand and silt that develop ripples, dunes, plane parallel beds, and antidunes. Progressive changes in bed forms occur as flow regime increases. Low-flow regime conditions form small scale ripples that progress to dunes; high flow regime conditions form plane beds and then antidunes.

**flow transformation** Reversible changes (in sediment gravity flows) between turbulent and steady flow related chiefly to particle concentration, thickness of flow, and flow velocity.

**hydrovolcanic** All volcanic activity resulting from the interaction between meteoric or connate water and lava, magmatic heat, or gases at or near the earth's surface (also *phreatomagmatic*).

**pyroclastic surge** Low concentration, turbulent pyroclastic density currents (PDCs). Two kinds of pyroclastic surges are *wet surges*, having temperatures less than 100°C where steam condenses and the surge is a three-phase system with water drops, solid particles, and gas; and *dry surges*, which have mean temperatures greater than 100°C and form by (1) hydrovolcanic eruptions with a low water/magma ratio, or (2) by magmatic eruptions that are driven solely by volatiles. Also see **base surge**.

**transport and depositional system** The transport system carries particles from source to area of sedimentation. The depositional system deposits particles and includes

local movement of particles, such as movement of a mass of particles down a steep slope, after being carried to a particular locality by the transport system.

**T**HE RECOGNITION THAT volcanic explosions could produce density-driven currents that flow rapidly away from the vent, devastating the landscape and leaving thin pyroclastic deposits and ash dunes, was an important step toward our current understanding of volcanic systems. Deposits left by these *pyroclastic surges* are a key in interpreting the eruptive history of a volcano and in predicting the hazards a volcano might pose for the future.

## I. INTRODUCTION

Pyroclastic surges are a type of pyroclastic density current (PDC) that produce relatively thin, bedded and cross-bedded to massive deposits. PDCs are laterally moving gas-particle mixtures with density greater than that of the surrounding atmosphere; original energy sources may be from gravitational potential energy or from a laterally directed explosion (blast). Two main factors profoundly influence type of flow and therefore physical features of the deposits. First is the bulk particle concentration; second is steadiness, or variation in time, of the currents.

Rapid fluctuations in velocity and particle concentration can occur during movement of pyroclastic surges, whereas movement of high-concentration PDCs is relatively steadier. Particle concentration greatly affects the transport mechanism of pyroclasts within a PDC. In a pyroclastic surge, low particle concentration allows turbulence to be the dominant transport mechanism. In contrast, high concentration PDCs (also termed pyroclastic flows) support particles mainly by particle collisions.

A precise quantitative criterion to distinguish high-concentration PDCs from low-concentration PDCs is lacking. We believe that a transition occurs over a range of concentration values rather than a single value, resulting especially from effects of grain size distribution and particle shapes. We expect that the switch from one transport mechanism to the other occurs through a range of particle concentrations around 0.1 (by volume), but this should be viewed only as an estimate until experimental and theoretical work further quantifies the transition.

During a single eruptive event there can be a range of PDC-generating processes that produce temporal variations in the initial grain size distributions, mass fluxes, and energy of PDCs. The topography over which a PDC moves can cause transformations from low to high concentration transport (and/or turbulent to non-turbulent) conditions. Even without fluctuations in PDC generation and the presence of a complex terrain, particle concentration varies vertically within a current, and laterally as particles sink in the current. These factors contribute to the possibility for flow transformations to occur, which ultimately may be recorded in the deposits left by the PDC.

Pyroclastic surges are generated by several mechanisms.

- Collapse or fountaining of an eruptive mixture from a vertical eruption column. This is the mechanism for the classic “base surge” that was also observed in the ejecta clouds from large man-made explosions (see later discussion).

- Rapid expansion (decompression), or blast, of an eruptive pyroclastic mixture into the atmosphere. The 18 May 1980 Mt. St. Helens eruption is an excellent example of a directed blast from the side of a volcano. We also expect that vertically directed explosions can produce shock waves strong enough to pull eruptive debris along the ground as they expand away from a vent, as suggested in numerical models.

- Collapse of a steep surface of a growing lava dome can generate pyroclastic surges as the chunks of material from a dome fall, break explosively, and generate dust. The small and large particles together form dilute PDCs as they flow along the ground.

- Interaction of a dense pyroclastic flow with rough substrate or valley margins, producing a turbulent boundary layer.

- Lateral flow of low-particle-concentration (dilute) ash clouds generated from moving pyroclastic flows, and in regions where pyroclastic flows accelerate down steep slopes or where a hydraulic jump occurs at a break in slope.

The distribution of the most commonly observed pyroclastic surge deposits indicates that in most cases surge run-out extends from only a few hundred meters (e.g., at tuff rings and tuff cones) to about 10 km (e.g., from sub-Plinian to Plinian eruptions) from their vents. However, some surge deposits can extend tens of kilometers, even more than 100 km, from their vents. Examples of far-traveled pyroclastic surges, probably generated by blasts, include the 18 May 1980 Mt. St. Helens surge (~35 km), those from the 1883 eruptions of Kra-

katau (~80 km), and surge deposits associated with the widespread Peach Springs Tuff, California and Arizona, USA (>100 km; we note that interpretations of these deposits are somewhat controversial).

---

## II. HISTORICAL PERSPECTIVES

In July 1946, the United States military establishment conducted a crude experiment to determine the effects of an atom bomb attack on a fleet of ships. They detonated two atom bombs, one 160 m above Bikini Lagoon, and one 30 m beneath the water. The underwater explosion created a short vertical explosion column consisting of an aerosol of gases from the nuclear explosion and water droplets from the lagoon. The water-drenched explosion cloud was too heavy to rise far into the atmosphere. It collapsed and created a turbulent density current cloud that moved away from the base of the explosion column over the surface of the lagoon at about 100 kilometers per hour, drenching the ships with a pervasive radioactive fog. Physicists at Bikini named it a *base surge*.

In 1962, the U.S. government exploded a 100 kiloton atomic bomb at a depth of 194 meters in alluvial deposits at the Nevada Test Site. The explosion excavated a man-made crater 370 meters in diameter and 98 meters deep. The fallback of its explosion column, a mixture of gases from the atomic explosion mixed with dust and sand of the alluvium from the desert floor, produced a base surge with an initial velocity of over 50 meters per second as it spread across the desert floor, leaving a carpet of deposits with an undulating dunelike surface.

In 1965, eruptive activity at Taal Volcano (Philippines) began as a strombolian eruption with an incandescent lava fountain. Were it not for the water mixing with magma, a scoria cone would likely have been constructed. But a crack that opened allowed water from the lake surrounding the volcano to pour into the vent and interact with the magma. This radically changed the behavior of the eruption from strombolian to highly explosive hydrovolcanic. Pyroclastic surges were produced, sweeping out over the landscape like hurricanes, tearing trees from the ground and sandblasting the trunks of those left standing. As the surges moved across the landscape, they left a deposit of cross-bedded, dunelike bed forms. It was recognized that the pyroclastic surges at Taal were the volcanic equivalent of the base surge from nuclear explosions. This link represented a major step in our understanding of the mechanisms and

driving forces of pyroclastic surges and the origin of bedded and cross-bedded deposits around volcanic vents (formerly they were thought to be wind-blown dunes).

In the late 1960s it was discovered that maar volcanoes, constructed of tephra produced by hydrovolcanic eruptions typically display low-angle cross beds and dune structures that record currents moving radially away from the vent. This showed that pyroclastic surges as observed at Taal are a common eruption phenomenon at such volcanoes. In the 1970s, comparison of wavy and bedded pyroclastic deposits genetically associated with thick, massive ignimbrite deposits led to the realization that turbulent, hot, dilute pyroclastic surges could form during magmatic explosive eruptions, along with hot, magmatic high-density pyroclastic flows.

---

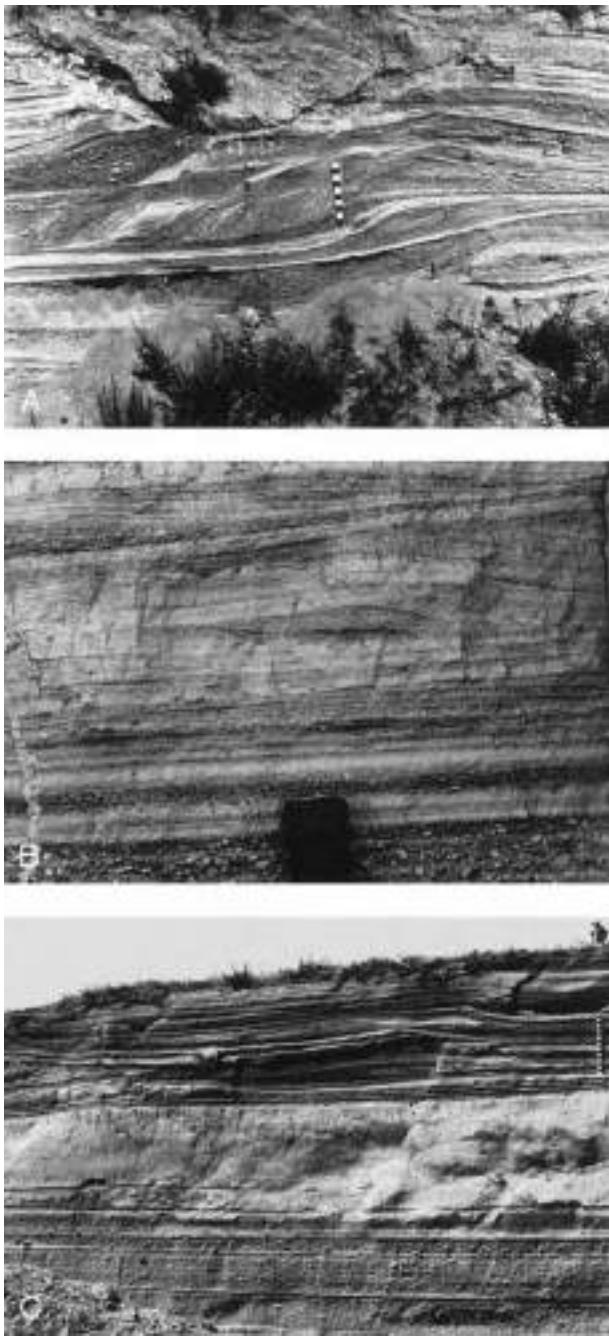

## III. DEPOSIT CHARACTERISTICS

### A. Bedforms

Pyroclastic surge deposits are most easily identified in the field by the occurrence of cross bedding including thinly bedded (centimeter to decimeter), low-angle cross beds (Fig. 1) and slightly wavy bedded structures to relatively large dune forms. They are characteristically associated with planar beds, and in some instances only planar beds are present. Ash-poor planar base surge deposits are granulometrically similar to fall deposits, making them difficult to interpret. Large ballistic fragments deform surge beds by impact to form bedding sags. Large fragments that rest on underlying beds without deforming them can be interpreted as having been emplaced by a laterally driven current rather than ballistic flight.

Different kinds of cross beds in surge deposits may be related to regimes of flow, a concept originally developed for fluvial sands. Flow regimes are defined by bed forms such as ripples, dunes, and antidunes, which are related to hydraulic conditions of flow. Important hydraulic conditions are velocity, shear stress imparted to the underlying bed by the flowing medium, and grain size of the material being carried.

Ripples and small dunes are classified as lower flow regime bed forms. Plane parallel beds, antidunes, and chute-and-pools are upper flow regime bed forms. Preservation of bed forms in pyroclastic surge deposits requires rapid deposition without erosion, because changing conditions of flow regime governed principally by concentration factors erase bed forms that are not in

**FIGURE 1** Photographs of common bed forms in pyroclastic surge deposits. (A) Chute-and-pool structure in deposits of the Laacher See volcano (Germany). 1-m-long measuring stick for scale, marked in 10-cm increments. (B) Thin-bedded deposits with small-scale cross laminations, Ubehebe Crater (USA). Bottom of rock hammer handle, ~2 cm wide, for scale. (C) Planar, massive, and sandwave bed forms at Laacher See volcano; 2-m-long measuring stick for scale, marked in 10-cm increments. (From Fisher and Schmincke, 1984.)

equilibrium with flow conditions. Within the transition from low to high flow regime, previously formed ripples and dunes are destroyed and the bed becomes flat. If deposition occurs at this stage, internal laminations are parallel and are called plane parallel bed forms, or planar beds, even though subtle cross-bedding features may be internally preserved. Plane parallel beds resemble fallout tephra, but are clearly surge deposits if they grade laterally into cross-bedded layers or if they have very subtle, low-angle cross laminations.

At higher regimes of flow, the planar beds can change to a dune or antidune shape, which is roughly symmetrical in cross section; they may also migrate upstream or downstream, or remain stationary.

### B. Granulometry

Granulometric analyses consist of two major kinds of data: (1) sizes of maximum fragment (mainly lithic and pumice) or the average of 3, 5, or 10 such measurements, and (2) statistically generated size distributions.

Plots of maximum average size of three or more measurements are conducted on selected layers and then plotted and contoured over the unit's distribution area. Contoured isopleth maps of average maximum size can be used to estimate eruption energy and carrying capacity of pyroclastic surges, to determine direction toward the source, and to determine wind directions during eruptions or directions of angled eruption columns (e.g., during the 1957–58 Capelinhos eruption, wind directions affected flow directions of some base surges).

Size distribution curves of bulk samples give median and mean size values as well as values of sorting and skewness. These parameters can be used to interpret eruptive energy, height of eruption columns, mechanisms of transport or deposition, and kinds of transport systems and environments of deposition. Care must be taken in sampling surges because many have multiple layers of different grain sizes and sorting parameters.

Median diameters of pyroclastic surges range from  $-3.0$  to  $+4.0\phi$ , but most occur within the  $1.0$  to  $2.0\phi$  range. Inman sorting values range from about  $1.0$  to  $4.0\phi$  with most at about  $1.5\phi$ . Sorting values of surge deposits are intermediate between flows and fallout, but there is wide overlap (Fig. 2). Surge deposits lack the very fine and the coarse size fractions, and therefore typically have a more restricted grain size than pyroclastic flow deposits. Pyroclastic surge deposits are better sorted and contain smaller maximum clast sizes than

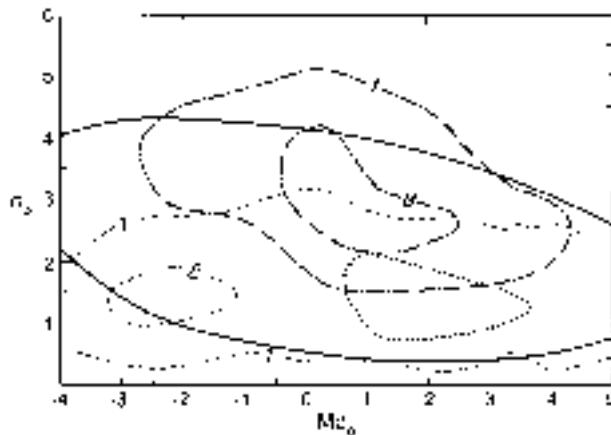

FIGURE 2 Diagram showing Inman sorting values versus median diameter ( $\phi$  units) for surge deposits from around the world. Solid line encloses most surge samples; dotted line encloses examples of cross-bedded deposits from Ubehebe Crater (USA) and Taal Volcano (Philippines). (Modified from Fisher and Schmincke, 1984.)

high concentration pyroclastic flow deposits. Sorting becomes better with distance from source in all pyroclastic surge deposits.

### C. Facies Variations

Pyroclastic surge deposits commonly have systematic facies variations laterally and vertically as functions of distance from vent, pre-eruption topography, eruption processes, and condensed water content. A *facies* is defined by a set of shared characteristics of deposits, such as grain size, sedimentary structures, and local deposit geometry.

#### 1. Proximal to Distal Variations

In 1979 K. H. Wohletz and M. F. Sheridan published a detailed analysis of proximal-to-distal facies variations at several tuff rings and maars in the southwestern United States and northern Mexico, and in surge deposits associated with the large-volume Bishop Tuff in California (note that the interpretation of the latter deposits has recently become controversial). They determined that these deposits include three main facies. In *sandwave facies* the dominant bed forms are sandwave bed forms (dunes, antidunes, ripples, and cross laminations) and massive beds that have little or no internal structure. *Massive facies* is defined by significant occurrence of three types of beds: massive, sandwave, and planar (the latter

have generally planar geometries but may exhibit some cross stratification and pinch and swell features that are transitional to sandwave beds). Finally, in the *planar facies*, the dominant bed forms are massive and planar. In the deposits studied by Wohletz and Sheridan, which, except for the Bishop Tuff example, had lateral extents of  $\sim 1$  km from their crater rims, there was a consistent pattern of sandwave facies in proximal areas, massive facies in medial exposures, and planar facies in distal reaches of the deposits.

Wohletz and Sheridan attributed this variation to progressive deflation of an initially well-mixed, turbulent, low particle concentration surge near the vent. In these proximal locations particles are transported along the ground by saltation and form dunes and other sandwave features, with transient periods of less turbulent transport and deposition of massive beds. In distal areas particles that are remaining in the surge are carried along the ground in traction carpets to form planar, inversely graded beds. The massive facies, in medial locations, represents a transitional zone between sandwave and planar deposition mechanisms. A likely additional effect is the increasing particle concentration (and thus bulk density) gradient at the bottom of a pyroclastic surge as it moves away from its source. As such a gradient becomes stronger, it will progressively damp turbulence and the formation of related bed forms, which would also favor the facies variations observed by Wohletz and Sheridan.

Y. K. Sohn and S. K. Chough conducted further detailed facies analyses of pyroclastic surge deposits associated with tuff rings on Cheju Island, Korea. As with most of the deposits studied by Wohletz and Sheridan, the surge deposits on Cheju Island have lateral extents on the order of several hundred meters. Particularly in the Suwolbong tuff ring, variations in individual beds or bed sets could be traced laterally from proximal to distal locations. Lateral facies variations in these studies are illustrated in Fig. 3. General trends are for the proximal deposits to be relatively unbedded, massive, and disorganized, grading laterally into ill-defined massive beds, to sandwave beds, and finally to planar or sandwave, thinly bedded/laminated tuffs in the most distal reaches.

Sohn and Chough explained these lateral variations as resulting from high particle concentration, highly turbulent flow near the vents, resulting in a sufficiently high rate of fallout of particles from turbulent suspension that no tractional processes could occur to form bedding structures. With increasing distance, the parent surges became more dilute and the suspended-load fallout rate decreased so that tractional bedding processes became increasingly dominant. Detailed studies of lat-

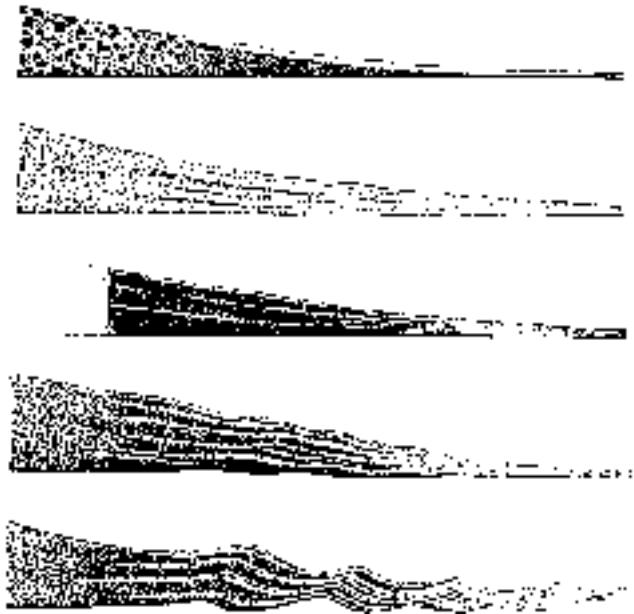

FIGURE 3 Examples of lateral facies variations in pyroclastic surge deposits of the Suwolbong tuff ring (Korea), deduced from facies studies. Lateral distances are at or near crater rim (left side) to several hundred meters from the rim (right side). Dark dots are used to indicate stratification of coarse clasts (lapilli and blocks) relative to ash (white). Wavy forms indicate chief types of bed forms at a given location. (Modified from Sohn and Chough, 1989.)

eral facies variations in deposits of the 18 May 1980 Mt. St. Helens lateral blast by T. H. Druitt indicate that proximal-to-distal variations are dominated by a decrease in particle concentration and sedimentation rate with increasing distance from vent, consistent with the Sohn and Chough interpretations.

Wavelengths of sandwave features in surge deposits commonly decrease with distance from the vent. This, plus the transition from sandwave to planar or laminated beds in all the studies, is consistent with the effects of increasingly strong density stratification near the base of the surges as they traveled away from their vents. At first glance the observations of Sohn and Chough may seem to be at odds with those of Wohletz and Sheridan, but the apparent differences may result from different definitions of bed types, or may simply be differences between the studied deposits, or different initial particle concentration.

## 2. Topography-Induced Variations

Superimposed on proximal-to-distal facies variations are variations due to local topography. When ridges and

valleys are roughly parallel to flow, deposits on valley floors tend to be thicker, coarser-grained, and more massive in texture than those on ridges that are thin, relatively finer grained, and exhibit more bedding and cross bedding (e.g., surge deposits at Ubehebe Craters, California). The primary reason for these differences are that the part of a pyroclastic surge that is at or above ridgeline level is inferred to have a lower particle concentration and carries smaller particles than the lower-elevation parts of a surge; this promotes, obviously, finer grain size in deposits, and stronger turbulent fluctuations, giving rise to abundant bedding. Obstacles such as ridges that are oriented at higher angles to flow direction tend to produce similar facies variations, with relatively massive and coarse deposits at the foot of the obstacle and thinner, more bedded and finer grained deposits at the top. The mechanism for this is referred to as "blocking." In a density stratified surge encountering such an obstacle, a parcel of the flowing mixture from low levels in the surge will have to overcome a density gradient in order to rise up into lower-density regions of the surge and pass over an obstacle. The level in the surge below which a mixture cannot rise over the obstacle, in other words is blocked, and above which it can, is called the "dividing streamline" (Fig. 4). Blocked portions of a surge then produce the facies found at the bottom of such an obstacle.

Important for understanding pyroclastic surge deposits is the interpretation that they form by the combined action of a *transport system* and a *depositional system*. This concept was emphasized in R. V. Fisher's studies of the Mt. St. Helens blast surge deposit, where direct observations of the lateral spread of the blast were combined with descriptions of the effects of rugged topogra-

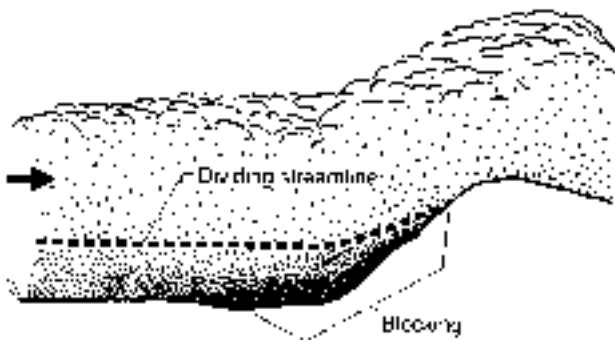

FIGURE 4 Illustration of the effect of blocking in a stratified pyroclastic surge, flowing from the left, encountering a ridge. The dividing streamline represents the level below which material is not able to surmount the ridge. (Modified from Valentine, 1987.)

phy on deposit facies. The transport system, regional in scale, is responsible for general trends such as fining and thinning of deposits away from the vent. The depositional system, at the base of a moving surge, is very local in scale with characteristics determined by the rate of material supplied by the transport system and the influence of local terrain. In some cases at Mt. St. Helens, the local depositional system formed thick (several meters), massive, deposits from high-particle concentration flows in valley bottoms. These deposits were developed directly in the valleys from blockage and diversion by terrain, or from flow off valley walls too steep to retain rapidly depositing debris. In this case the depositional system locally decoupled from the transport system, flowing independently down valleys, regardless of the orientation of the valleys, for perhaps hundreds of meters, while the overriding transport system flowed (mainly) radially away from the vent. On flatter terrain, recent granulometric studies by M. I. Bursik and colleagues have shown that movement of particles in the basal depositional system was limited to distances of ~1–10 m, parallel to the transport system.

### 3. Vertical Variations

Vertical variations in pyroclastic surge deposits can be quite extreme owing to the rapid fluctuations of surges. Sohn and Chough observed several vertical facies variations at the Suwolbong tuff ring (Fig. 5). Vertical variations differ in detail, but all share a common trend in becoming finer grained and thinner bedded upward, as the surges wane and sedimentation rates decrease with time. A common vertical sequence developed from a blast-driven pyroclastic surge is as follows: A coarse, fines depleted, massive basal layer overlain by a finer grained, massive layer with crossbeds at the top, and an ash fall layer at the very top (e.g., deposits of the Mt. St. Helens blast).

### 4. Variations due to Condensed Water Content

In addition to proximal-to-distal, topographic, and vertical variations, a fourth factor influencing surge facies is the relative abundance of condensed water in the blast surge. There are several sources of water in surges: water exsolved from the parent magma during its ascent, groundwater that mixes with the rising magma, surface water (e.g., lakes, oceans) through which an eruption occurs, and atmospheric water vapor entrained into the surge. In dry pyroclastic surges with temperatures greater than 100°C, most or all of the water will be in vapor form; therefore, the sand- and silt-size pyroclasts

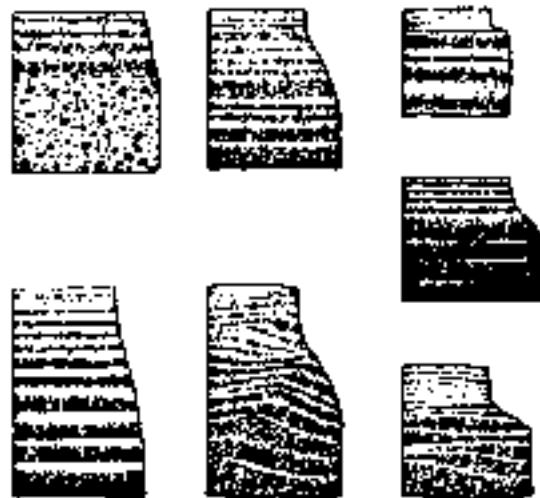

FIGURE 5 Schematic examples of vertical facies variations in surge bed sets of the Suwolbong tuff ring (Korea), deduced from facies studies. Dark dots are used to indicate stratification of coarse clasts (lapilli and blocks) relative to ash (white). Columns represent variations over decimeters to a few meters height in the deposits. Wavy forms indicate chief types of bed forms at a given height. (Modified from Sohn and Chough, 1989.)

are generally not cohesive. Also, particles depositing from the bottom of a dry surge are capable of moving in traction carpets and by saltation, similar to wind-blown sand and dust. They produce bedforms with relatively low angles that resemble eolian deposits in many ways (although important differences are caused by the poorer sorted nature of surges and by their relatively higher sedimentation rates compared to eolian processes). In wet surges, having temperatures less than 100°C and typically produced by explosive magma/water interaction, ash particles may stick together because of cohesion. In such cases, ash may enter the depositional system as clusters rather than as individual particles, and the aggrading bed tends to behave plastically. Deposits of such wet surges tend to have steep-sided bed forms that may exceed the angle of repose of the dry material, be more poorly sorted than their dry equivalents, commonly contain accretionary lapilli, and behave plastically when impacted by ballistic fragments.

There has been debate about the relative importance of cohesive aggradation versus flow regime in determining the migration direction of dune forms in surge beds. Recent studies support the dominating role of flow regime in migration of surge bed forms.

The presence of liquid water in wet basaltic surges and their fresh deposits facilitates alteration of glassy material to palagonite, a combination of hydrous glass,

zeolites, and clays. Palagonite commonly appears in the field as a yellow, brown, gray, or greenish waxlike substance. The color and texture of individual beds in wet surges may vary considerably owing to different eruptive conditions of each surge event, resulting in spectacular multicolored outcrops.

#### D. Association with Other Pyroclastic Deposits

Pyroclastic surges occur alone or in association with both of the other two main types of pyroclastic deposits: fallout and pyroclastic flow. Surge and fall deposits of hydrovolcanic origin are the main “building blocks” of tuff rings and tuff cones. Larger volume eruptions that produce ignimbrites also produce pyroclastic surges that occur at the bases and tops of pyroclastic flow units (or packages of flow units). Pyroclastic surge deposits that underlie pyroclastic flow units are interpreted as forming from unsteady explosive activity during the transition to relatively steady pyroclastic flow eruption and/or the relatively dilute leading edges of pyroclastic flows. Surge deposits on top of flow units record deposition from the dilute ash cloud (ash cloud surge) that develops from an underlying pyroclastic flow. Ash cloud surges may extend considerably farther from the vent than less mobile, parent pyroclastic flows. Ash cloud surges result from differential settling of clasts in a pyroclastic current, from mixing between the top of a pyroclastic flow and the atmosphere, and from interclast abrasion in a pyroclastic flow. A pyroclastic surge deposit on top of a pyroclastic flow unit may also reflect a period of unsteady eruptive activity as well. Pyroclastic surge beds are sometimes interbedded with sub-Plinian to Plinian fallout deposits or vice versa and represent brief periods of column collapse or unsteady explosions. Finally, deposits of blast surges are commonly associated with debris avalanche deposits; this reflects the relationship between collapse of an unstable volcanic edifice and resulting explosive relief of pressure within a volcano.

#### E. Distinguishing between Surge, Eolian, and Water-Lain Sediments

Cross bedding and dune forms can be developed by surge, wind, or water flow, but there are several features that allow one to distinguish between these mechanisms. This is important for establishing the history of a vol-

cano from its geologic record and for predicting potential future hazards.

One of the most obvious differences is general sorting features. Eolian material is commonly very well sorted sand; wind cannot pick up and carry larger particles in suspension. Ordinary water currents (not in flood stage) carry mainly sand, but can also move larger particles ~2 or 3 cm by traction. Fluvial sands are commonly well sorted, though not as well as wind-blown sand. Pyroclastic surge deposits can carry particles  $\geq 10$  cm in proximal localities and remain much more poorly sorted than wind or water sorted materials to distal localities.

Bed forms of pyroclastic surge deposits differ from wind- and water-deposited material in some striking ways. Dune bed forms in dry surge deposits, for example, can show wavelengths of 20 m and wave heights up to 2 m thick—relatively low-angle features compared to eolian and water-lain dune forms. Wet surge deposits can, on the other hand, have relatively steep dune sides compared to eolian and water-lain examples due to cohesion between wet ash particles. Unlike ripples and dunes in water or wind transported materials, the angle of backset beds of surge dunes are commonly steeper than foreset beds. G. A. Smith and D. Katzman show how vertical sequences of dunes produced by pyroclastic surges tend to preserve both lee- and stoss-side layering and often the dune crests as well. This differs from eolian sequences where typically only lee-side structures are well preserved and dune crests are truncated by planar erosional surfaces. Individual strata within dune forms produced by pyroclastic surges are commonly relatively massive and poorly sorted compared to their counterparts in eolian deposits. In addition, pyroclastic bed sets are commonly capped by fine-ash fallout layers, often containing accretionary lapilli.

Another set of criteria for distinguishing between pyroclastic surge, eolian, and water-lain deposits are their overall geometric relationships. For pyroclastic surge deposits, there will be systematic variations in facies, maximum grain size, sorting, thickness, and dune wavelength away from a central location (the vent). Dune migration directions and other flow direction indicators will show radiating patterns from the vent location, although local complications resulting from pre-eruption topography need to be accounted for. The nature of these proximal to distal variations in surge deposits has already been discussed in this chapter. In contrast, the geometry of water-lain deposits will generally be constrained by drainage channels or basins; dunes will show migration directions generally along these channels or basins, and thickness and grain size will also vary in the

same direction (accounting for cross-channel variations). Wind-blown deposits will also show dune migration and facies variations in directions that do not radiate from central locations and that are unrelated to any volcanic structures.

Deposits from laterally directed eruptions such as the 18 May 1980 Mt. St. Helens blast may not have such radial variations, although there will be systematic variations from the source vent. However, in the case of such blast surges, the vertical stratigraphy described earlier makes them easily distinguishable from eolian and water-lain deposits.

Pyroclastic surges that travel over vegetated and forested areas commonly incorporate plant fragments. An observation of downed tree casts in a bedded deposit of pyroclastic material is a strong indication of surge origin. In deposits of dry, hot surges it is common to find charred wood and other plant fragments (note that in ancient deposits these may be difficult to recognize).

earlier. A second consequence is the role of turbulence near the base of a surge where deposition results in an aggrading bed. If the density gradient becomes strong enough at the base, boundary layer turbulence will be retarded, which in turn affects the nature of the deposits. Since it is likely that the density gradient will become more pronounced with increasing distance from vent, because of downward migration of particles with time, lateral facies variations will in part reflect this stratified flow process. Another consequence of stratified flow is its effects on the Froude number of the base of the flow. The Froude number is the ratio of flow speed to gravity wave speed, the latter of which is determined by the density gradient in the flow. For Froude numbers less than 1, surge bedforms will migrate downstream, while for values greater than 1, upstream-migrating antidunes will form. Finally, the density gradient influences the frequency and wavelength of waves in the flow—steeper gradients will result in shorter wavelengths, which may relate to decreasing dune wavelength with distance from vent that is observed in many deposits.

---

#### IV. PHYSICAL PROCESSES

Pyroclastic surges and blasts, like most other explosive volcanic phenomena, have three characteristics that challenge understanding from a theoretical standpoint. First, they are multiphase flows, with particles of a variety of sizes and densities dispersed in a gas. Furthermore, phase changes from steam to liquid water droplets are important multiphase aspects for many pyroclastic surges (e.g., wet surges). Second, they are strongly turbulent; turbulence not only is a major particle transport mechanism, but also results in complicated interactions with the surrounding atmosphere. Finally, velocities of tens to hundreds of meters per second mean that surges are compressible flows; the effects of compressible flow on the final deposits are not known.

A consequence of the multiphase, turbulent nature of pyroclastic surges is that they are density-stratified, meaning that there are vertical variations in the bulk density (gas plus particles) of the current. This arises because particles tend to settle according to their size and density, although this is counteracted by the mixing action of turbulence. There are several important ramifications from density stratification that all arise from the fact that the higher-density mixture from low in the current will be retarded from moving upward because of the density contrast with material higher in the current. One consequence of this is the process of blocking when a surge encounters rough terrain, as described

---

#### V. FUTURE RESEARCH DIRECTIONS

Research on pyroclastic surge mechanisms has greatly progressed from Fisher's discussion in the early 1960s of qualitative flow dynamic principles but without recognition of a partitioning of flows and surges, which began with discovery of volcanic base surges in the late 1960s. In the past two decades eruptions of Mt. St. Helens, Mt. Pinatubo, Mt. Unzen, and Montserrat have provided impetus for accelerated research in volcanic hazards, transport and depositional mechanisms, and eruption predictions. Volcanic processes are increasingly being investigated by laboratory experimentation and numerical modeling. Paralleling the research on flow dynamics of pyroclastic flows have been investigations of granular flow by the engineering profession. Within the 1990s, the two approaches have begun to converge.

In our view, the following are key issues deserving focused research over the coming years.

- *Critical particle loading.* An open question that remains to be answered definitively is, What is the particle loading in a PDC that separates the regime of dominantly turbulent transport from that of dominantly particle-collision transport? How broad is that "transition" zone in terms of particle loading? What are the quantitative relationships between the rate at which particles

sediment out from the transport system into the depositional systems, and the resulting deposit characteristics?

- *Bed form regimes.* It would be useful to generate, from a combination of experiments and field observations, a “phase diagram” that defines the characteristics of pyroclastic surge bed forms as functions of the eruptive conditions and flow regime of the parent surges. Such diagrams have been developed for fluvial and eolian systems and have proven extremely useful for both predicting behavior and for interpreting the geologic record.

- *Compressible flow effects.* Most of our deposit-based inferences about pyroclastic surges are extensions of our knowledge from incompressible flow systems such as wind-driven and fluvial sediment transport. The effects of shock waves and supersonic flow, such as occur in many pyroclastic surges, on resulting deposits is largely unknown.

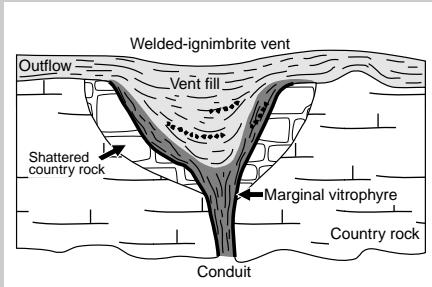

- *Risk assessment.* An ultimate goal of volcanologists is to minimize loss of life and property from explosive eruptions. Risk assessment, which accounts for both the probability of an event and its consequences, is an important step in attaining that goal. The ability to recognize pyroclastic surge events in the geologic record of a volcano is key in establishing probabilities of surge events. An area that needs particular focus is constraining the effects, or consequences, of pyroclastic surge events. This will involve predicting the dynamic conditions within surges and the responses of structures and people to those conditions.

## GLOSSARY

**ash flow/ash-flow deposit or ash-flow tuff** Deposit of pyroclastic density current(s) consisting predominantly (>50 wt%) of ash-size material. In practice, *ash-flow tuff* is used for moderate- to large-volume ignimbrites in the U.S. literature.

**block-and-ash flow deposit** Small-volume pyroclastic flow deposit characterized by a large fraction of dense to moderately vesicular juvenile blocks in a medium to coarse ash matrix of the same composition.

**ignimbrite** Welded or unwelded, pumiceous, ash-rich deposit of pyroclastic density current(s). This term was formerly used for strongly welded deposits only.

**pyroclastic density current** A particulate gaseous volcanic

flow moving along the ground. This term includes both *pyroclastic flows* and *pyroclastic surges* but has no connotation of particle concentration or flow steadiness.

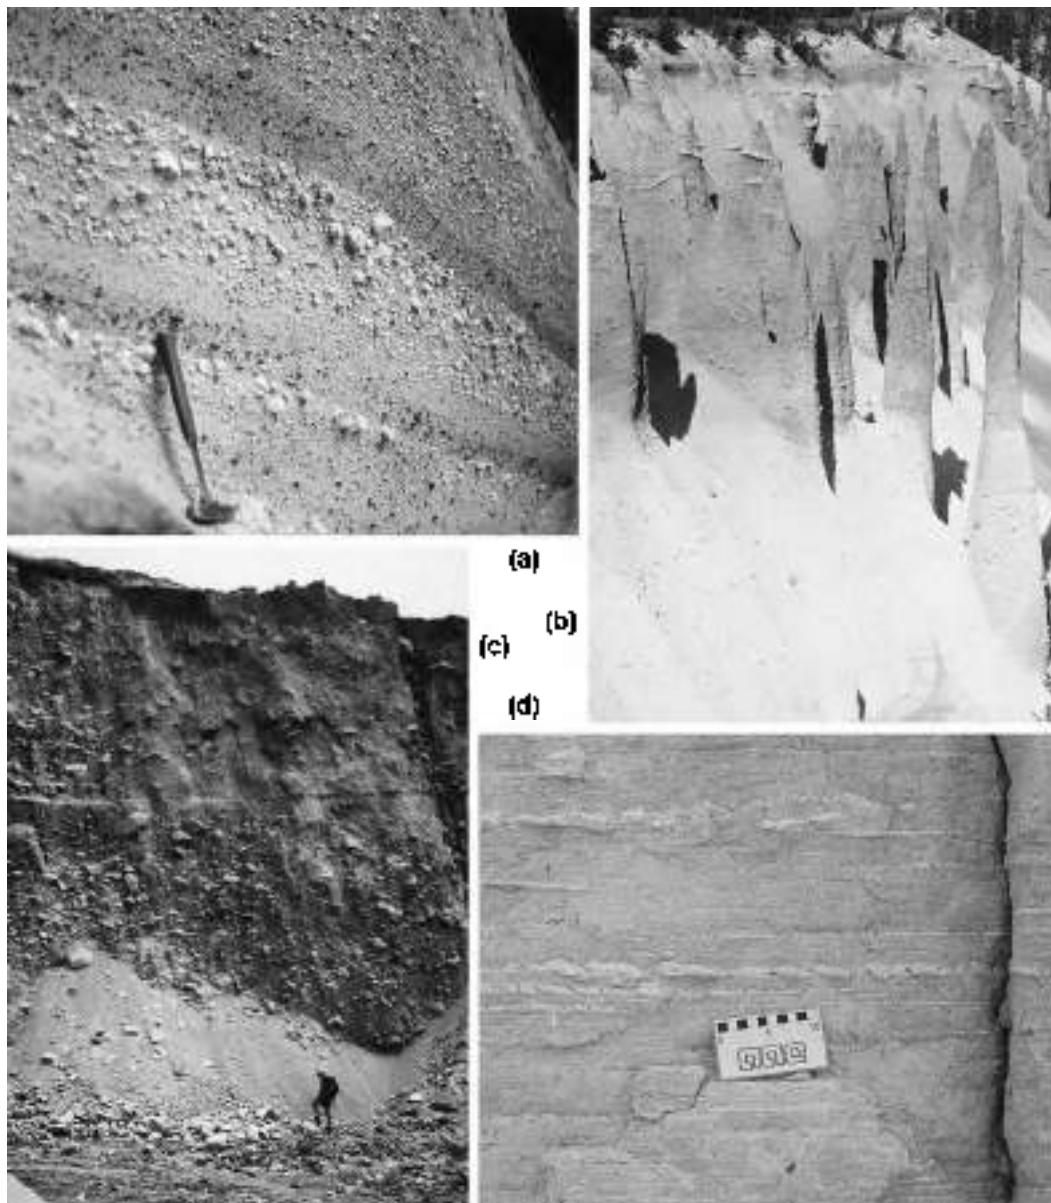

**pyroclastic flow deposit** Predominantly massive, poorly sorted, ash-rich deposit laid down by a particulate gaseous flow. This term is mostly used to imply a depositing flow of high particle concentration (tens of volume percent) in contrast to a low particle concentration pyroclastic surge.

**pyroclastic surge deposit** Strongly bedded (laminated, low-angle cross-bedded) deposits laid down by fast-moving gaseous flows of low particle concentration.

**T**HE PERCEPTION OF pyroclastic flows as a highly dangerous and devastating type of explosive volcanic activity was brought about dramatically by the 1902 *nuee ardente* (glowing cloud) of Mt. Pelée, Martinique, which killed 30,000 people. Studies of recent historic eruptions facilitated the recognition of abundant ignimbrites in the geological record, many of them orders of magnitude larger in volume. It took until the 1960s, however, before large welded ignimbrites with lavalike field characteristics but a clearly fragmental texture became widely accepted as deposits of pyroclastic

flows. The deposits of pyroclastic flows are highly variable in bulk volume (<0.1 to >1000 km<sup>3</sup>), runout distance (<1 to >100 km), deposit geometry and response to topography (channel confined to radially symmetrical), internal structure (massive through layered; Figs. 1a–c), degree of welding (unwelded to lavalike; Fig.

1d), clast type and size (wall rock lithic- to pumice-dominated, ash- to block-rich; Figs. 1a and 1c; see also color inserts), and chemical composition (mafic through felsic, often compositionally zoned; Fig. 1b). Gradations, rather than sharp boundaries, for all these characteristics occur between different ignimbrites and

**FIGURE 1** (a) Flow units near canyon wall in Laacher See ignimbrite. Sharp boundaries between lower lithic-rich and upper pumice-rich, reversely graded zones reflect local detachment of respective zones in the flows. (See also color insert.) (b) C. 60-m-thick section of ignimbrite at Crater Lake, Oregon, compositionally zoned from lower rhyodacite (white) through upper mafic andesite (gray) with pink oxidation zone near top. Pinnacles are cemented fumaroles that resisted erosion. (c) Two depositional units of block-and-ash flows at Mt. Merapi, Indonesia. Note meter-sized blocks. Person for scale. (See also color insert.) (d) Densely welded ignimbrite from Gran Canaria with highly flattened and sheared fiamme, some pulled apart and rotated.

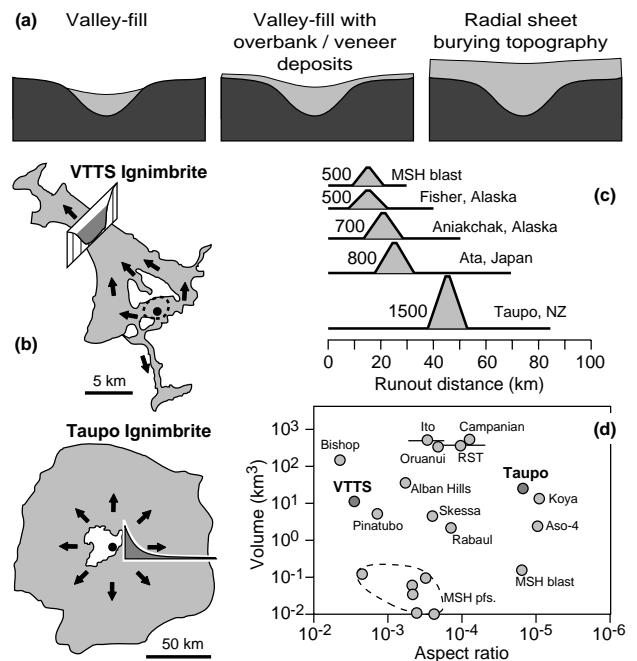

between different facies within one ignimbrite. Furthermore, there are transitions between pyroclastic flow and pyroclastic surge deposits. Such diversity in the deposits has caused a similar diversity in the inferred transport and emplacement processes. Most authors use the term *pyroclastic flow* to imply a current of high particle concentration as opposed to *pyroclastic surge* of low particle concentration. We use the term *pyroclastic density current* here to avoid specific implications on the nature of the flow other than that it was a gas–pyroclast mixture moving along the ground driven mainly by gravity.

## I. GENERAL FEATURES OF IGNIMBRITES

### A. Areal Distribution

Moving pyroclastic density currents are gravity-controlled and preferentially follow basins and channels. This topographic control shows in the areal distribution of ignimbrites (Fig. 2a), which typically pond to great thickness in valleys and grade into thin deposits or disappear on topographic highs. Large ignimbrites can, however, form extensive radial sheets that completely bury the pre-eruptive topography (Fig. 2b). Many ignimbrites were emplaced by pyroclastic currents that were able to surmount high topographic barriers at tens of kilometers distance from the vent (Fig. 2c). On the other hand, small pyroclastic flows moving across a plain can confine themselves by forming lateral block levees, similar to lava or debris flows, and terminate in lobes with steep levee fronts (e.g., Mount St. Helens post-May 18 flows; also typical of many block-and-ash flows).

The dimensions of pyroclastic flow deposits vary greatly, and the maxima for any parameter are still being extended. Distances traveled range from a few hundred meters for small block-and-ash flow deposits (Section III) to ca. 200 km for the most widespread ignimbrites. Areas covered are from a few hundred square meters to 45,000 km<sup>2</sup>, and volumes from a few thousand cubic meters to about 5000 km<sup>3</sup>. The three-dimensional geometry of ignimbrites has been little documented, in part because erosion since deposition has often removed large amounts of material, especially in thinner deposits. A simple quantitative descriptor of the overall shape of a deposit is the aspect ratio, defined as the ratio of the average thickness to the diameter of a circle equal in area to the deposit. Aspect ratios range from  $<10^{-5}$  (low-aspect-ratio ignimbrite) to  $>10^{-2}$  (high-aspect-ratio ig-

**FIGURE 2** (a) Illustration of cross-sectional patterns from strictly valley-confined to topography-burying ignimbrites. nimbrite). Extreme examples are the high-aspect-ratio VTTS and low-aspect-ratio Taupo ignimbrites (Fig. 2d). Documented deposits have average thicknesses that range over about 2 orders of magnitude and are not simply related to either the volume or the welding state of the deposit. For example, the 30-km<sup>3</sup> Taupo ignimbrite has an average thickness of 1.5 m whereas the 150-km<sup>3</sup> Bishop Tuff is about 100–150 m thick, i.e., having about 5 times the volume yet 100 times the thickness of the Taupo ignimbrite. Thickness of more or less radially distributed ignimbrite sheets diminishes with distance from vent in an approximately exponential fashion (Fig. 2b); the thickness–decay pattern of small channelized pyroclastic flow deposits can be complex, depending on topography.

## B. Composition and Componentry

Ignimbrites are composed of juvenile pyroclastic material, represented by pumice or scoria in the block-lapilli fraction and by glass shards and crystals in the ash fraction, and of foreign lithic fragments derived from the conduit walls or picked up from the surface. Juvenile pyroclasts are commonly moderately to highly vesicular but can be poorly vesicular to dense in ignimbrites generated by phreatomagmatic eruptions. The chemical composition of juvenile pyroclasts in small- to intermediate-volume pyroclastic flow deposits ranges across the entire compositional spectrum (basaltic to rhyolitic) of tholeiitic, calc-alkaline, and alkaline magmatic series whereas large ignimbrites mostly have highly evolved compositions. Many ignimbrites are vertically zoned or mixed in chemical composition, providing insight into magma chamber structures. Corresponding with composition, ignimbrites occur in all geotectonic settings on land. Ignimbrites generated on land have been emplaced in the sea and some even erupted from calderas in shallow waters of a few hundred meters depth. We are not aware of any ignimbrite generated in deeper seawater ( $>1$  km).

The relative proportions of components vary between grain size fractions as well as with distance from the vent or height within a single ignimbrite, and they vary between ignimbrites as a function of magma composition and mode of pyroclastic flow generation. For example, pyroclastic flow deposits generated during phreatomagmatic eruptions are generally richer in wall rock lithics than those produced by magmatic eruptions. Highly welded ignimbrites are generally poor in lithics probably because lithic fragments incorporated at the vent can drastically cool the pyroclastic mixture and thus inhibit welding. Lithic fragments in ignimbrites may be basement rocks entrained in the magma chamber or conduit or surface rocks entrained during passage of the pyroclastic currents. Wall rock lithics can be useful to constrain magma chamber depth or conduit position, indicate the former presence of a hydrothermal system, or mark major events of vent erosion or caldera subsidence during eruption where they are enriched in particular horizons.

The crystal content of the ignimbrite matrix is often higher than in the juvenile material, implying that some concentration of crystals has occurred during eruption and transport of the currents. The corresponding glass fraction can occur as the distal portions of the same ignimbrite or form co-ignimbrite ash. Rounded pumice clasts, abraded glass rims on crystals, and fine-ash contents increasing with distance from the vent suggest

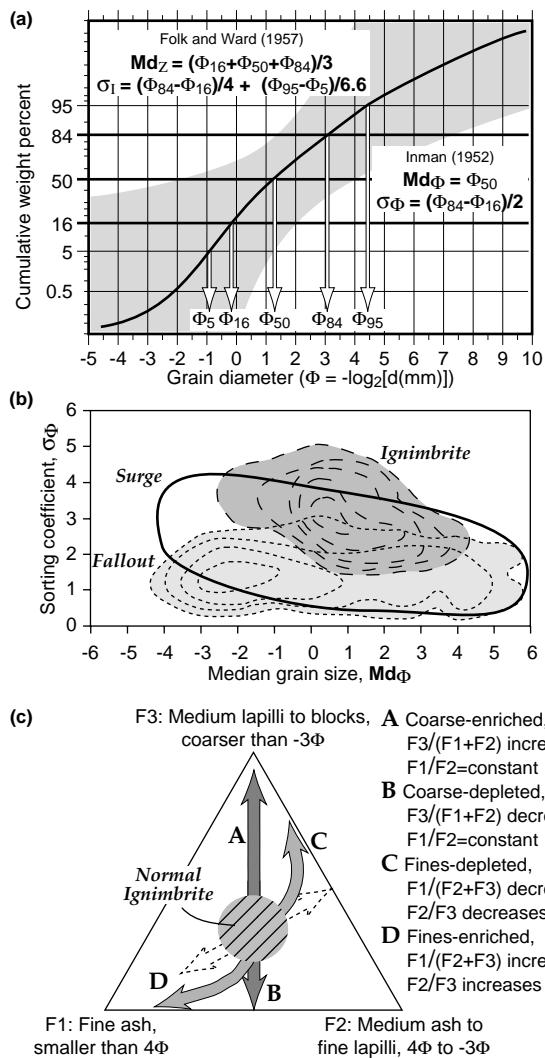

additional vitric-ash formation occurred by abrasion during transport.

Debris from vegetation engulfed by pyroclastic flows is occasionally preserved in deposits emplaced at low temperature; in general, however, finer plant debris is completely destroyed and only thick branches and logs survive transport but become charred. The charred wood can be used to isotopically ( $^{14}\text{C}$  method) determine the age of eruption.

## C. Grain Size, Texture, and Structure

The grain-size frequency distribution of pyroclastic flow deposits is often polymodal and does not follow a single-distribution law (e.g., Gaussian or Rosin-Rammier), although it is common to present distributions on log-normal graphs and employ the Inman descriptive measures that are based on Gaussian distribution (Fig. 3a). The wide range in particle sizes, from micron to meter scale, is reflected in high sorting coefficients (commonly  $\sigma_\phi > 2$ ) of ignimbrites whereas the predominance of ash-sized particles causes the relatively small median size  $Md_\phi = 0$  to 2 (Figs. 3a and 3b), but local facies can show extremely diverging grain-size characteristics. Some ignimbrite facies have been described as “fines-depleted,” by which some authors mean that blocks are enriched relative to ash (case A in Fig. 3c) whereas others imply depletion of ash (case C). We recommend considering the relationships between at least three size fractions (e.g.,  $F_1$ ,  $F_2$ , and  $F_3$  in Fig. 3c) in order to be able to identify coarse-enriched (A), coarse-depleted (B), fines-depleted (C), and fines-enriched (D) facies. This approach is necessary to distinguish size fractions that are actively modified by dynamic processes from those that are passively affected by the constant-sum effect.

The polymodality of ignimbrite grain-size distributions has several causes: (1) fragmentation in the vent, which produces different size distributions for each component (e.g., pumice, wall rock lithics, and crystals), (2) segregation of certain components and size fractions during transport and emplacement, and (3) additions to certain component and size fractions either by fragmentation and abrasion during transport or by entrainment of bed material (e.g., surface lithic fragments and older tuff). Interpretation of ignimbrite grain-size distributions thus must consider variations in componentry between grain-size fractions. For example, a mode in the 250- to 500- $\mu\text{m}$  size range might be attributed to a concentration of crystals in this range. Ideally, then, subpopulations characterized by individual modes may

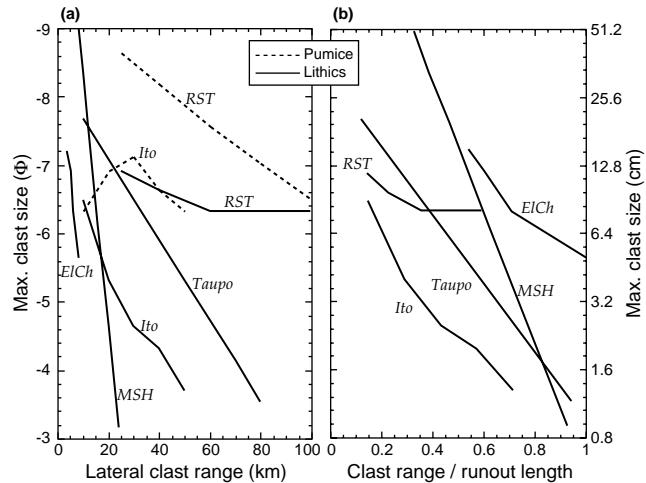

**FIGURE 3** (a) Cumulative grain size distribution and definition of the statistical parameters, median size ( $Md$ ) and sorting ( $\sigma$ ). Gray field includes most “normal” ignimbrite data. (b)  $Md-\sigma$  diagram illustrating different grain size characteristics of ignimbrites and fallout beds, while surge deposits overlap with both. Dashed lines give probability distribution inside fields. Many ignimbrite facies are now known to have grain size characteristics well outside the ignimbrite field and overlapping with the other fields. This diagram should thus not be used to discriminate deposits based on grain size alone. (c) Illustration of selective enrichment and depletion of certain grain size fractions as discussed in the text.

be identified in the bulk size distribution of each component. These can then be interpreted in terms of fragmentation and transport processes.

In general, with distance from source, median grain size decreases, the content of fine ash increases, and size

sorting improves in unwelded ignimbrites. Maximum sizes of vent-derived lithic clasts decrease exponentially with distance from source and may range from meter-sized blocks in proximal outcrops to millimeter-sized lithic particles in distal deposits. Maximum sizes of pumice clasts show more variation in trends with distance from vent; some exponentially decrease outward, others remain high or increase out to an intermediate maximum, and some small-scale historic flows (Komagatake 1929; post-May 18 Mount St. Helens 1980) have carried the largest pumices to the distal tips of the deposits.

The absolute distance from vent up to which clasts of a given size and density (i.e., weight) have been carried is commonly much larger in ignimbrites than in pyroclastic surge deposits (Fig. 4a), suggesting a higher transport capacity of pyroclastic flows compared to surges. On the other hand, the fractional range of clasts, i.e., their absolute distance from vent divided by the runout length of the deposit, is highly variable but generally lower in ignimbrites than in pyroclastic surge deposits (Fig. 4b). This suggests that, with respect to runout distance, pyroclastic flows may lose transport capacity faster than surges.

**FIGURE 4** (a) Distribution of maximum pumice and lithic clast sizes with distance from vent in selected ignimbrites and surge deposits: Ito pyroclastic flow deposit, Japan; Taupo ignimbrite, New Zealand; Rattlesnake Tuff (RST), Oregon; Mount St. Helens blast deposit (MSH); El Chichon 1982 surge deposits (ElCh), Mexico. Clasts of a given size reach farther from vent in large ignimbrites (Taupo, Ito, and RST) than in small pyroclastic flow or surge deposits (MSH and ElCh). Note pumice size maximum about 30 km from vent in Ito ignimbrite. (b) Data in (a) presented with the maximum lateral range of clasts normalized to runout length. Clasts of a given size reach greater fractional distances in surges than in large ignimbrites.

Platy fragments and tree logs, and fluidal deformation textures in welded ignimbrites, as well as elongate microscopic crystals are often oriented in a systematic fashion that indicates flow direction controlled either by local topography or by radial spreading from the vent. As with local thickness changes, interpretation of local flow directions needs to carefully consider that drainage into valleys may have occurred during or immediately after deposition.

Grading textures commonly allow subdivision of an ignimbrite into depositional units, termed *flow units* (Fig. 1a). The *standard ignimbrite flow unit* comprises three layers (Fig. 5), which are now envisioned to represent different regions within a pyroclastic density current:

- Layer 1* Deposit laid down at the flow front during strong interaction with ambient air and ground surface
- Layer 2* Deposit of the main body and tail, i.e., the major portion of the flow
- Layer 3* Deposit from the overriding dilute ash cloud

The association of all three layers is rarely complete; more often, layer 1 or 3, or both, are not present at all or are at least regionally absent.

### 1. Layer 1

A great number of specific varieties of layer 1 deposits have been described, suggesting that layer 1 formation

is strongly controlled by local environmental conditions. *Ground layers* (also coined layer 1(H) or lithic-rich ground layer) enriched in heavy components (lithics, crystals) appear to be the most common type of layer 1 deposit. They range from meter-thick fines-depleted lithic breccias to centimeter-thin ash beds rich in millimeter-sized lithics and are interpreted as segregation bodies sedimented from within the head of a pyroclastic current, which is postulated to be a highly dynamic region where intense mixing with air occurs. *Ground surges* are fines-poor, laminated and cross-bedded layer 1 deposits thought to be emplaced by surges moving ahead of the pyroclastic current. Ground surges can be either lithic- or pumice-rich (layer 1(H) and 1(P) varieties). *Jetted deposits* rich in fine ash and pumice (major layer 1(P) variety at Taupo, New Zealand) are thought to be deposited from concentrated jets ejected ahead of the current. Common to all layer 1 deposits is their production at or in the head of pyroclastic density currents so that they potentially provide insight into how the currents' fronts interacted with the atmosphere, surface water, roughness and shape of the ground, and vegetation.

### 2. Layer 2

Layer 2 is composed of an often reversely graded basal ash *layer 2a* that is variably developed, with sharp contact or gradational transition into overlying *layer 2b*. Layer 2a is thought to form in a lower boundary layer by interaction of the flow with the substratum. The main body of a flow unit, *layer 2b*, is characterized by reverse coarse-tail grading and upward enrichment of pumice clasts and normal coarse-tail grading and baseward enrichment of lithic clasts. The development of grading and segregation structures in ignimbrites varies widely (see Section ID) and is interpreted to reflect vertical motion of clasts according to their density contrast to the current.

Flow units contain *lapilli pipes*, i.e., more or less vertical narrow channels composed of lapilli that are strongly enriched in lithics and crystals but depleted in vitric ash. They form by the localized escape of gas from the compacting deposit that blows out the fine vitric ash. Lapilli pipes preferentially occur in the upper part of layer 2 but also originate from local lithic concentrations or burned logs and can be especially abundant above wet ground. Lapilli pipes are mostly subvertical and formed after emplacement of the flow unit; occasionally, however, lapilli pipes are deformed to sigmoidal shapes by shearing either during flow unit emplacement or during differential compaction. Lapilli pipes may cut

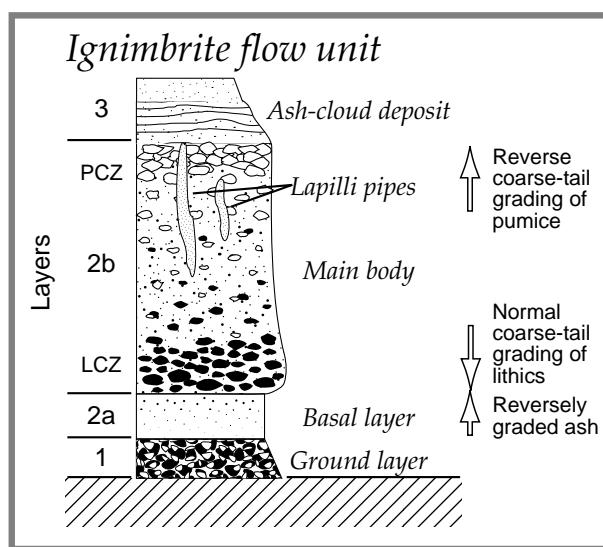

FIGURE 5 Idealized flow unit of ponded ignimbrite. Layer 2 can show a variety of grading structures from no grading to extremely enriched lithic and pumice concentration zones (LCZ and PCZ). Different layer 1 and layer 3 facies are discussed in the text. White particles, pumice; black particles, lithics; dots, ash.

through several flow units and in hot pyroclastic flow deposits may form encrustations by vapor-phase mineralization (*fumaroles*; e.g., Bishop Tuff, and Valley of Ten Thousand Smokes).

### 3. Layer 3

Layer 3 is a deposit of fine vitric ash that is commonly massive with fall characteristics but may also show evidence for lateral transport on the ground, such as miniature flow units, stratification, or even cross-bedding. The ash of layer 3 is believed to have settled from the ash cloud overriding a pyroclastic flow. Layer 3 may not be associated with each flow unit; in fact, layer 3 may only be found on top of the entire ignimbrite if emplacement of the succession of flow units was faster than the settling of fine ash from the overriding ash cloud. Some ignimbrites are associated with very extensive co-ignimbrite ash layers, suggesting that the depositing ash clouds had plinian-like dimensions.

Ignimbrites composed of a single flow unit exist but more often they are composed of flow unit packages. Ideally, a flow unit is envisioned as the deposit of a single pyroclastic current. Flow units have, however, been observed to split into two or more thinner flow units laterally, probably due to splitting into lobes or pulsatory motion of the pyroclastic flow. The number of flow units in an outcrop thus need not be equal to the number of depositing flows. In moderate- to large-volume ignimbrites, and especially in welded ignimbrites, it is often difficult to identify flow units as defined above. This may be due to very thin layers 2a associated with very thick, unstructured layers 2b or to welding compaction and rheomorphic deformation obscuring depositional boundaries. On the other hand, some thick, gradually compositionally zoned ignimbrites do not reveal any clear internal depositional boundaries; this observation provoked the idea that at least some ignimbrites are emplaced by progressive aggradation (grain by grain) from a maintained current rather than layer by layer (flow unit by flow unit) from a number of short-lived flows.

The basal contact of pyroclastic flow deposits is mostly conformable to the preexisting surface but can also be highly unconformable where the pyroclastic currents were able to erode, e.g., close to the vent, on steep slopes, or on soft substrate. Pyroclastic flows of the April 19–20, 1993, eruption of Lascar volcano (Chile) stripped scree and talus from their channels and scratched striae and percussion marks into bedrock; strongest erosion occurred on steep slopes, where flows accelerated through narrow channels and where they already con-

tained abundant lithic blocks. Ash of the strongly welded ignimbrite P1 on Gran Canaria intruded into, completely filled, and welded within (a) void spaces of a canyon boulder bed to several meters depth and (b) tectonic cracks as narrow as a few millimeters and more than a meter deep, indicating great fluidity of the pyroclast–gas mixture.

## D. Facies Variations

Within a single ignimbrite, significant changes in facies can occur on a regional scale, including changes with distance from vent and over areas of different topographic character, and on a local scale, where they are commonly controlled by local topographic features.

### 1. Regional Facies Variations

Many ignimbrites that are massive across intermediate to distal regions contain variably bedded, tractionally formed deposits close to the vent which are associated with erosion and transitional to, or resemble, pyroclastic surge deposits. Such deposits typically show lensoid, wavy, discontinuous bedding, laminations or cross-bedding, with variable grain size and poor to moderate sorting of individual beds, and gradually merge into massive ignimbrite farther from the vent (e.g., Roccamonfina, Italy; Laacher See, Germany; Taupo, New Zealand; Novarupta 1912, Alaska; Pinatubo 1991, Philippines). In addition, cross-bedded pyroclastic flow deposits also occur on steep flow paths, such as at Mount St. Helens, during the 1980 eruptions. The Neapolitan Yellow Tuff (Italy) is an ignimbrite that seems to be characterized by such facies throughout most of its extent. These transitional facies are interpreted to have been emplaced under intermediate-concentration conditions from fast pyroclastic density currents that were evolving from the collapsing eruption column toward higher concentration farther from the vent.

The range of facies developed in ignimbrites is particularly shown by the 30-km<sup>3</sup> Taupo ignimbrite (Fig. 6a), which is interpreted to represent a single short-lived (ca. 400 s) catastrophic outburst of material, i.e., equivalent to a single vent-derived flow unit. These facies are developed in three ways:

First, a spectacular development of layer 1 deposits (as discussed above), which form about 15 vol% of the ignimbrite (Fig. 6b). The exceptional development of layer 1 deposits at Taupo is inferred to reflect the extreme velocities attained by the flow coupled with the abundance of vegetation.

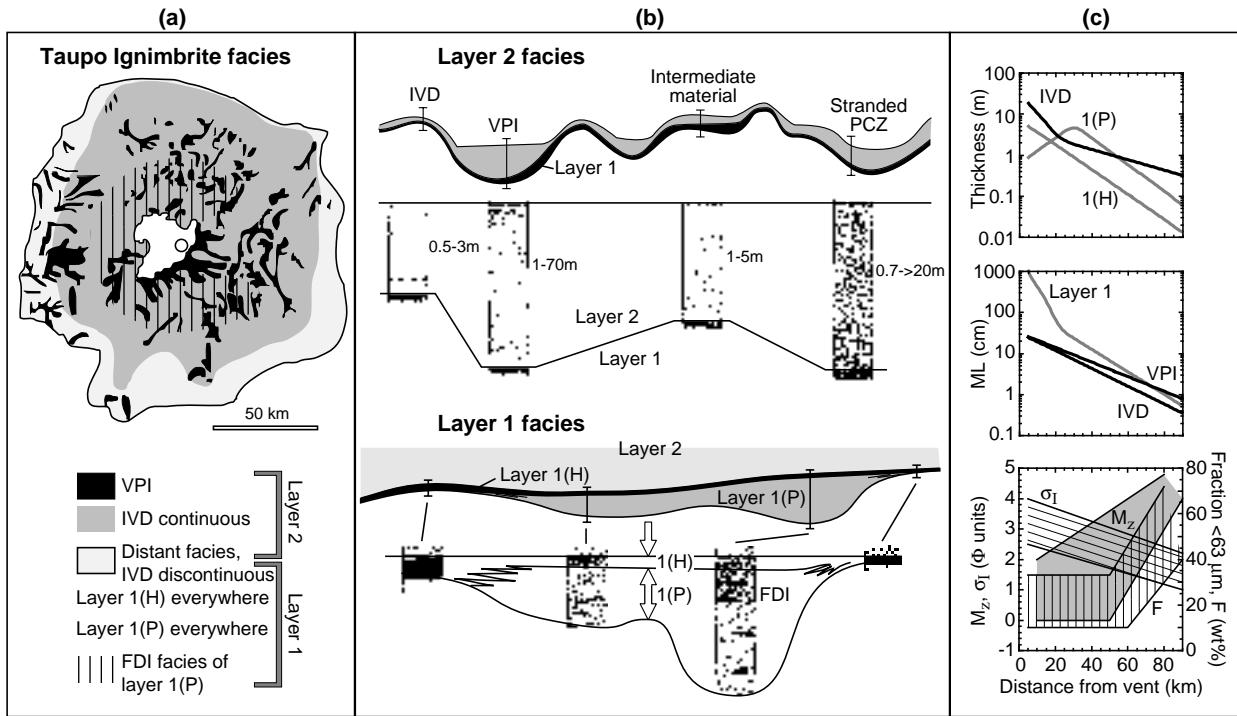

FIGURE 6 (a) Map of facies distribution in the Taupo ignimbrite. VPI, valley-ponded ignimbrite; IVD, ignimbrite veneer deposit; I (H) and I (P), lithic- and pumice-rich layer I; FDI, fines-depleted ignimbrite, a variety of layer I (P). (b) Illustration of layer 2 and layer 1 facies changes across topography. (c) Variation with distance from vent of thickness and maximum lithic clast size (ML) in IVD, VPI, and layer 1 deposits, and grain-size characteristics of layer 2 material.

Second, the reaction of the bulk of the ignimbrite (i.e., layer 2) to the landscape over which it was emplaced. In the Taupo ignimbrite, layer 2 comprises a landscape-mantling *ignimbrite veneer deposit* (IVD) and a landscape-modifying *valley-ponded ignimbrite* (VPI; Fig. 6b), the two merging into each other over distances of decimeters to tens of meters. The relationships between the IVD and VPI are seen in many ignimbrites where the current(s) were able to surmount interfluves partly or wholly.

Third, the Taupo ignimbrite shows spectacular variations (up to 2–3 orders of magnitude) in such parameters as mean grain size, contents of lithics and crystals, fine-ash abundances, and largest clast sizes over the  $80 \pm 10$  km from source to distal limits (Fig. 6c). The scale of the lateral variations at Taupo is again in large part driven by the velocity of the parent current, with the concomitant effective segregation and separation of different fractions.

Facies changes from channel-fill to overbank in the much smaller ( $<1 \text{ km}^3$ ) multiple-flow-unit ignimbrite at Laacher See, Germany, differ from those in the Taupo ignimbrite. Thick flow units in channels taper out to

ash layers on the overbanks that are only a few centimeters thick but flow unit structures, albeit mostly incomplete, persist up to some 300 m out of the channels (Figs. 7a and 7b). Farther out, and with increasing distance from the vent, correlation of gradually thinner overbank ash layers with channel-fill flow units becomes almost impossible. Areal distribution and lateral changes of the overbank facies suggest that the phase segregation into lapilli- and lithic-rich channeled and lapilli- and lithic-poor overbank flow occurred very close to the vent during funneling through passes in the Laacher See basin wall.

## 2. Local Facies Variations

Small-volume pyroclastic flow deposits derived from valley-confined flows terminate marginally against the valley walls. The Valley of Ten Thousand Smokes (VTTS) ignimbrite, with its “high-energy” proximal facies on high ground and perhaps 100-m thickness in upper reaches of the valley, stops dead against a moraine only 15 m high blocking the valley about 15 km from the vent. Apparently, each of the many flows that con-

tributed to the bulk deposit was too sluggish to surmount this small barrier.

At Laacher See, pyroclastic flows funneled through deep, narrow, rough-walled canyons (Fig. 7a) and interacted with canyon walls in a variety of ways, producing marginal flow unit structures that change with travel distance and shape of the valley walls (Fig. 7c). Some flows were not wide enough to touch the canyon walls that are 200–300 m apart. In upstream regions of the canyons, flow units then taper out into thin ash-rich margins, in some places fringed by a carpet of lag-pumice blocks (Fig. 7c, diagram 5), whereas flow units

further down canyon are bounded by steep pumice-block levees (Fig. 7c, diagram 9). Similar marginal structures were also observed at Mount St. Helens. Such rare narrow flows were not accompanied by ash clouds large enough to leave laterally continuous ash layers. In contrast, flows that filled the width of the canyons did have ash clouds depositing on the canyon walls and shoulders but these ash layers were flushed from the steep walls by rain soon after emplacement and are now contained in reworked fine ashes overlying the canyon-fill ignimbrite. The downstream changes (Fig. 7c) from proximal wavy-bedded deposits through flow units containing

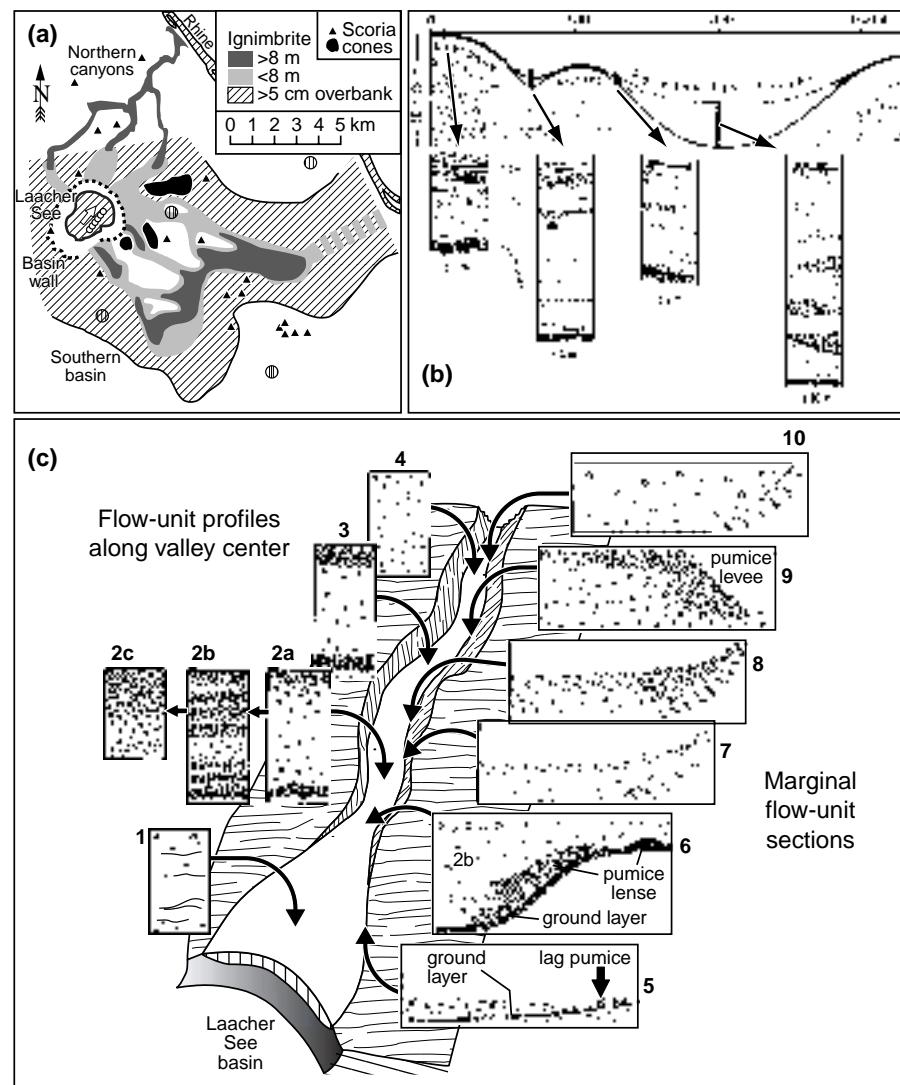

FIGURE 7 (a) Map of ignimbrite distribution around Laacher See volcano. Circle with arrow inside lake indicates vent migration during pyroclastic flow production. (b) Transition of thin overbank ash layers into thick flow units in channels on the smooth topography south of Laacher See. (c) Proximal to distal structural and compositional changes in flow unit sections along valley center (left) and along valley margin (right) in the northern canyons in (a). Diagrams 2a–2c show changes from valley center toward the margin.

abundant segregation bodies and complex marginal structures to distally massive flow units without marginal interaction are interpreted to reflect progressive deflation.

### 3. *Lithic Breccias*

Heavy lithic clasts are most susceptible to changes in the transport capacity of pyroclastic currents, which diminishes with distance from vent as reflected in the decreasing size of lithics in ignimbrites. Local reductions in transport capacity can be inferred from steps in the lithic size vs distance patterns but are most evidently marked by the occurrence of *lithic lag breccias*. These are commonly clast-supported beds of lithic blocks with an ash matrix that may or not be depleted in fine ash compared to the normal ignimbrite matrix. Lithic blocks are rounded in some breccias, yet others contain large fragments of fragile rock types such as paleosols, lake sediments, or diatomite. Lithic breccias occur in proximal settings, where they are dominated by vent-derived wall rocks, or elsewhere in specific paleotopographic settings, where locally derived lithic fragments may be important.

Near-vent, commonly fines-depleted lithic lag breccias lack evidence of ballistic impact of large blocks but may contain degassing structures such as lapilli pipes. Such breccias are either separated from normal ignimbrite by erosional unconformities or laterally merge into either lithic-rich ground layers (layer 1) or lithic-concentration zones of flow unit layer 2. Proximal lithic lag breccias have been left behind by pyroclastic currents that lost their excess load when dynamically adjusting from column collapse to subhorizontal flow.

The formation of more distal local lithic breccias is controlled by specific topographic conditions. Most commonly, local lithic breccias are found at sudden changes from steep to shallow ground slope, where pyroclastic currents possibly passed through stationary hydraulic jumps. Other local breccias occur inside sharp bends of a valley, where large vortices may have formed or where pyroclastic flows entered large bodies of water. Local lithic breccias can also form immediately downstream of topographic settings that favor erosion and massive entrainment of surface clasts by a pyroclastic current, which subsequently dumps this extra load. Local lithic breccias are mostly not depleted in fine ash and laterally merge into layer 2; they are commonly massive and unbedded although some layering, cross-bedding, or stoss-side stacking beds can be developed close to vent and on steep slopes where the pyroclastic currents had a high velocity.

---

## II. WELDED IGNIMBRITES

### A. Introduction

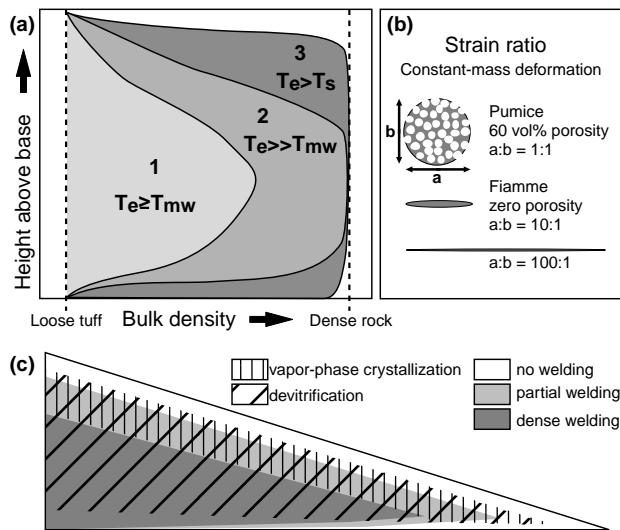

Ignimbrites show textures and structures developed in response to their high postemplacement temperatures and retained volatiles, *viz.*, *welding*, *devitrification*, and *vapor-phase alteration*. The onset of welding in time and space is determined primarily by the magma composition (including retained volatile species that lower glass viscosities), load stresses, and temperature (both the absolute value and the time spent above any given value, *i.e.*, the cooling rate). Typical minimum temperatures for welding are between 500 and 650°C for calcalkaline compositions. Most welded ignimbrites, regardless of temperature, include some material that is nonwelded due to either rapid cooling (*e.g.*, directly overlying a cold substrate) or inadequate load stresses (*e.g.*, the top-most part of a deposit).

### B. Small-Scale Features

Welding is the cohesion, deformation, and eventual coalescence of pyroclasts at high temperatures under loading stress. In hand specimen, welding is manifested in turn by (1) cohesion of clasts across point contacts where load stresses are focused (“sintering”), (2) flattening of pyroclasts under the load stress (Fig. 1d), and then, in the most extreme cases, (3) flow as a coherent liquid (the process termed *rheomorphism*).

In young deposits, the contrast between sintered and nonwelded material may be very clear, but in ancient deposits, sintering cannot easily be distinguished from other diagenetic processes causing induration, and clear welding is seen only in the presence of flattened clasts. The higher the emplacement temperature and the lower the clast viscosity, the more intense is the compaction (*i.e.*, elimination of pore space) under a given load and less load is needed to achieve a certain degree of compaction. In extreme cases, vitroclastic textures can be eliminated in densely welded material.

The degree of welding is measured either by the bulk density (Fig. 8a) or by the horizontal to vertical axis ratio (strain ratio) of vitric shards and *fiamme* (Figs. 8b and 1d), *i.e.*, flattened pumice clasts, which can reach values of 100:1 in densely welded ignimbrites. The vertical variation of the strain ratio often parallels that of bulk density. Strain ratios larger than 10:1 are commonly taken to indicate viscous flow has occurred.

**FIGURE 8** (a) Schematic vertical variation in bulk density of welded ignimbrites emplaced at different temperatures  $T_e$  above that of minimum welding,  $T_{mw}$  (curves 1 and 2). Ignimbrites that are almost entirely densely welded may have been emplaced at above-solidus temperature,  $T_s$  (curve 3), especially if they are thin. (b) Illustration of fiamme geometries. Mass remains constant, but volume decreases during compaction as pore space is eliminated. The strain ratio 10 : 1 is achieved by keeping **a** constant and collapsing **b** until pore space is zero. Higher strain ratios involve flowage in addition to simple compaction. (c) Welding and crystallization zones in a schematic, vertically highly exaggerated section through a welded ignimbrite.

Highly stretched fiamme can be cracked, pulled apart, and rotated (Fig. 1d).

Ignimbrites emplaced at temperatures sufficient to weld commonly cool slowly enough for juvenile glass to devitrify. There is a wide spectrum of effects from microscopic crystallization preserving the original pyroclastic texture, though to total overprinting by a coarse granophyric texture. At one extreme, thick, hot ignimbrites (e.g., caldera-fill deposits) can recrystallize to resemble an intrusive rock. However, minor posteruptive devitrification in ancient deposits can be difficult to distinguish from long-term diagenetic devitrification.

Welding and devitrification release most or all of the residual volatiles from the glass, and these volatiles can cause further vapor-phase alteration of the ignimbrite and/or deposition of further mineral species in pore spaces. Common new minerals are alkali feldspar, silica polymorphs, and hydrous minerals, but a wide variety of more exotic mineral species are also known. In addition, movement of vaporized groundwater or rainwater through the still-hot ignimbrite can cause further transport and deposition of mobile elements. Residual vola-

tiles that exsolve during welding can become trapped in densely welded material and accumulate to form subspherical cavities filled by vapor-phase minerals, called *lithophysae*.

### C. Large-Scale Features

In a welded ignimbrite, there are often systematic arrangements of the various zones of welding, devitrification, and vapor-phase alteration (Fig. 8c). Ignimbrites deposited rapidly at uniform temperature show vertical variations in density (i.e., welding intensity), with a maximum in the lower part of the ignimbrite, due to downward increasing load pressure and nonsymmetric cooling through the upper and lower boundaries (Fig. 8a). For a given emplacement temperature, the zone of dense welding widens with deposit thickness, whereas for a given deposit thickness, the proportion of the deposit that is densely welded increases with emplacement temperature (Fig. 8a). Overlapping with, but displaced vertically from, the welding zones are zones of devitrification and vapor-phase alteration, the upward displacement being due to the transport direction of heat and released volatiles in the cooling rock body. Welded ignimbrites also typically develop prismatic jointing—the spacing of which is widely interpreted to reflect the cooling time—oriented perpendicular to isotherms in the rock mass.

A welded ignimbrite that accumulated so rapidly that negligible cooling occurred (whether composed of one or many flow units), resulting in a simple arrangement of welding zones (Fig. 8c), is a *simple cooling unit*. *Compound cooling units* show departures from the simple profile, most clearly seen in irregular vertical gradients in bulk density and strain ratio, and are widely interpreted to reflect prolonged emplacement with the opportunity for partial cooling to occur between successive packages of material. It is not clear whether the complex density/welding profiles in compound cooling units represent significant time breaks in deposition (which need not be long if intervening heavy rainfall occurs) or variations in emplacement temperatures of successive flows.

### D. Rheomorphism

Ignimbrites on sloping ground may flow rheomorphically as a coherent viscous liquid once dense welding has eliminated intergranular friction. There is a complete spectrum from (1) stretching and boudinage of flattened

fiamme to (2) deformation of internal bedding and welding fabrics into flow folds of tens of meters to millimeters amplitude to (3) wholesale flow of the coherent liquid to produce features similar to those of conventional lavas of the same composition. Ramp structures and shear faults then can severely disrupt the initial stratigraphy.

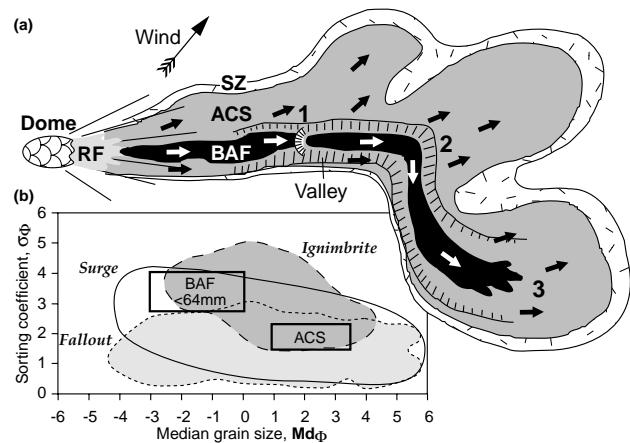

At high temperatures, partially liquid particles may flatten under their own weight (cf. curve 3 in Fig. 8a) and flow downslope as they aggregate on the ground. Welding then is syn-depositional, controlled by viscosity and emplacement dynamics, as opposed to welding after emplacement. Under such conditions viscous flow is a continuation of the particulate pyroclastic current and may follow primary flow directions rather than local slope. Mapping of flow direction indicators and 3-D structural analyses thus provide means to distinguish between syn- and post-depositional welding.

### III. BLOCK-AND-ASH FLOW DEPOSITS

#### A. Distribution and Facies Associations

Block-and-ash flows can form by collapse of vulcanian eruption columns but most historic examples were generated by partial to total collapse of viscous lava domes as they oversteepen at their fronts during growth. Volcanoes producing lava domes and block-and-ash flows are numerous; among the most recent examples are Mount Unzen, Japan (1991), Mt. Merapi, Indonesia (1984, 1994, 1997–1998), and Montserrat (1995–1996). Dome collapse can be gravitational, explosive, or both. At Unzen, a strong explosion was observed to immediately precede the major block-and-ash flow of June 8, 1991. Video recordings show the formation of abundant ash as soon as the lava front collapsed, and small ash puffs from cracks in the dome can be seen before dome-flank failure, suggesting overpressure in the dome as a major cause of fragmentation, although collapse was probably initiated by gravitational instability.

Block-and-ash flows commonly extend up to 10 km from their source at speeds up to 100 km/h and are accompanied by ash cloud surges, which reach a wider areal distribution compared to the valley-confined block-and-ash flows (Fig. 9a). A seared zone where little or no ash is deposited but vegetation is burned fringes the ash cloud surge deposits. The hot ash-cloud surges can knock down trees and destroy houses. They are the most dangerous aspects of block-and-ash flow activity,

**FIGURE 9** (a) Distribution of block-and-ash flow (BAF), ash-cloud surge (ACS; arrows give flow direction), and the seared zone (SZ) below a partially collapsed dome with a rock-fall scree (RF) at its base. Drawn after observations at Unzen and Merapi. Numbers 1–3 indicate enhanced ACS production and detachment where BAF rushes down a waterfall (1), ACS surmounts a bending valley wall that deflects BAF (2), and ACS advances beyond the limit of BAF, coming to rest on lower plain (3). Distribution of ACS deposit can be affected by wind. (b) Range of median size and sorting values for ACS deposits and BAF-matrix material  $<64$  mm; poorly constrained since little data are available.

most of all because they are less controlled by topography and can detach from their associated channelized block-and-ash flows. The formation of ash-cloud surge is, however, strongly influenced by topography (Fig. 9a). Increased ash-cloud production occurred at Mount Unzen, where the June 3, 1991, block-and-ash flow cascaded down two waterfalls, causing a wider spread of the ash-cloud surge downstream. Farther downstream, a sharp bend in the valley was followed by the block-and-ash flow but not by the ash-cloud surge, which rushed straight on out of the valley and killed 43 people.

#### B. Structure and Composition

Block-and-ash flows commonly have basaltic–andesite, andesite, or dacite compositions but may also be rhyolitic. The deposits are usually described as monolithologic but it is commonly difficult to distinguish juvenile and older dome fragments, because vesicularity and crystallinity vary across even single domes. Hydrothermal alteration of clasts can be helpful to identify older dome fragments but is ambiguous.

*Block-and-ash flow deposits* differ from pumiceous ignimbrites by containing little fine ash <1/16 mm (usually <5 wt%) but a large fraction of dense to moderately vesicular, rarely pumiceous, blocks up to several meters in diameter (Fig. 1c) that are derived from the juvenile source dome and possibly from older dome remnants. The deposits are poorly sorted but a complete grain-size distribution (including the block fraction) has not yet been reported (Fig. 9b). Bed structure can be either clast-supported or matrix-supported and generally massive but vague layering may locally occur. Flow unit structures as in ignimbrites are not commonly observed due to the absence of low-density fragments, but a fine-grained (or block-free) basal layer may be present and lapilli pipes are rare. The blocks are either uniformly distributed through the bed or show normal or reverse coarse-tail grading. Large blocks may be carried up to the distal tip of the deposit but the largest block size has been observed to reach a maximum at some intermediate distance, dropping off toward the vent as well as to the flow terminus. Block-and-ash flow deposits are about 1–10 m thick and thin to 1–2 m at their lobate, blunt termini. The detailed variation pattern with distance of both clast size and thickness strongly depends on how the channel gradient evolves. There may be no deposition at all on steep slopes such as immediately below the dome.

*Ash cloud surge deposits* are typically <1 m thick, consist of sand-sized and finer ash with median grain sizes ranging from 500 to <100 microns, and are relatively well sorted (Fig. 9b). Beds are laminated or consist of discontinuous or wavy layers, dune structures occur, and basal layers can be depleted in fine ash while overall fine-ash content increases toward the top. A topmost fine-ash layer may contain accretionary lapilli. Ash cloud surge deposits are exposed on the margin of the block-and-ash flow deposits but may also cover and/or underlie them.

#### IV. PYROCLASTIC FLOWS THAT ENTERED THE SEA

##### A. Flow-Water Interaction

Pyroclastic flows generated at near-shore or ocean-island volcanoes can enter the sea and produce widespread submarine volcaniclastic deposits. There is geologic evidence for a variety of ways in which pyroclastic flows

interact with the sea. Scenarios for pyroclastic flows erupted on land or in shallow water include

1. Pyroclastic flows mix with seawater, causing coastal steam explosions or transformation into debris flows or turbidity currents
2. Pyroclastic density currents travel across the water, dropping sediment into the sea
3. Pyroclastic flows remain intact and either push aside shallow water near shore or flow under deeper waters until they come to rest or transform into debris flows

Evidence for submarine pyroclastic-flow-related debris flows and turbidites is abundant, suggesting that mixing of pyroclastic flows with seawater commonly occurs. That such mixing involved phreatic explosions has been implied by increased crystal/lithic ratios or a shift to finer sizes in the crystal population of the submarine deposits compared to those on land, but evidence for coastal explosions is not commonly reported. Welded ignimbrites in ancient near-shore environments probably displaced the seawater without much interaction except for local breccia pipes at the base of the ignimbrite where water in wet sediment was vaporized. Little convincing evidence exists that primary, hot pyroclastic flow deposits were emplaced in deep waters. There is proof, however, that some pyroclastic currents were able to travel large distances across the sea; the Koya flow in Japan, for example, had to cross 30 km over the deep waters of the Japanese sea to be emplaced on Kyushu and neighboring islands.

##### B. The Krakatau 1883 Example

The 1883 eruption of Krakatau volcano in Indonesia provides an excellent opportunity to examine the effects of pyroclastic flow interaction with the sea. It was a moderate ignimbrite-producing event, which resulted in the formation of a 5-km-diameter caldera that is open to the sea. For 2 days a series of large-volume pyroclastic flows entered the sea around Krakatau. Pyroclastic flow deposits consist of 2- to 4-m-thick flow units and locally have a total accumulated thickness of 60 m. The great thickness of flow deposits directly adjacent to the sea indicates that substantial volumes of flow material must have been discharged into the sea during the eruption.

Outside of the caldera there was significant addition of material to the sea floor as a result of the 1883 eruption (Fig. 10). Coring of the submarine deposits has yielded two distinct facies in water depths less than

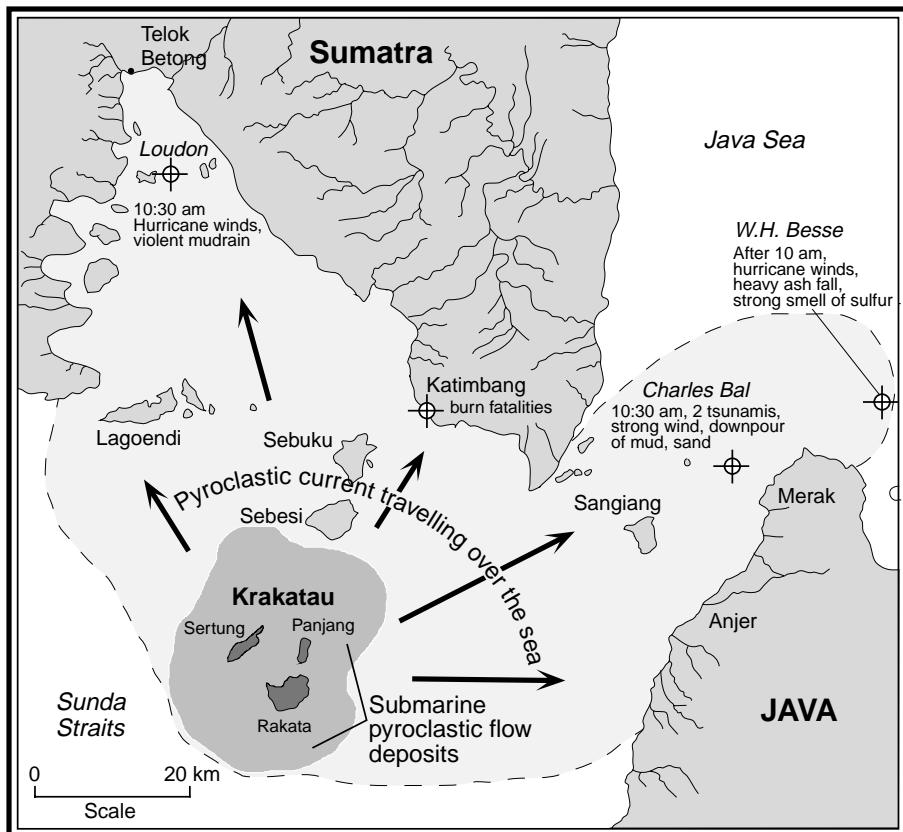

FIGURE 10 Map of the Sunda Straits area showing Krakatau islands surrounded by submarine pyroclastic flow deposits (gray shading) and extent of the pyroclastic current that traveled over the sea (light gray shading), overran the islands of Sebesi, Sebuku, and Lagoendi, and reached the Sumatra coast, leaving deposits described in the text. Locations of ships that recorded passage of the pyroclastic current (and tsunami waves) are indicated.

20 m. The first, and more abundant, is massive and consists of a poorly sorted mixture of pumice and lapilli in a gray, silty matrix of glass shards, crystals, and lithics. The other facies is marked by better sorting, finer grain size, and the presence of parallel and cross laminations. Thermoremanent magnetization studies of samples from the submarine massive facies indicate deposition at temperatures in excess of 450°C. Because of their high temperature and submarine emplacement, these deposits most likely formed from hot flows that traveled under water.

There is also evidence that a hot gas/particle current traveled over the sea surface during the 1883 eruption of Krakatau. The most compelling observation is a large number of burn fatalities (ca. 2000) that took place 40 km from the vent across the Sunda Straits, along the southeast coast of Sumatra (Fig. 10). Ships 65–80 km away from Krakatau were engulfed by ash clouds. Pyro-

clastic deposits on islands provide important information about the nature of the ash currents as they traveled to the north and northwest from Krakatau (Fig. 10). The currents overran all of these islands and most of the vegetation was destroyed, with total loss of life. The deposits consist of three major types:

1. Volumetrically most important, poorly sorted massive beds of angular to subangular dacitic pumice and lithic clasts in a matrix of fine ash with small pieces of charcoal
2. Stratified beds containing pumice and lithic clasts that are more rounded
3. Intercalated layers of pumice lapilli with virtually no dense components, which are attributed to tsunami inundation of the islands

Grain-size characteristics of the massive and stratified deposits support deposition from some type of pyroclas-

tic density current. These distal samples form a continuum in grain-size trends defined by the more proximal subaerial and submarine pyroclastic flow deposits. With increasing distance from Krakatau, there is a systematic decrease in the median diameter and sorting coefficients of the deposits. As the currents traveled across the sea surface, they apparently became cooler and more dilute (surgelike). Eventually, the currents became buoyant, producing a large-scale co-ignimbrite plume rich in moisture. From this plume an episode of mudrain deposition affected a large area of the Sunda Straits.

#### V. IGNIMBRITE SOURCE VENTS

Ignimbrite source vents, especially of large-volume examples, are often hidden by caldera subsidence and caldera fill. Buried vents can be located by mapping regional facies variations in the ignimbrite (thickness, grain size, maximum clast size, degree of welding), by lithic lag breccias, and by the flow-orientation patterns of logs, platy fragments, and crystals. Small- to intermediate-volume ignimbrites are commonly derived from central vents that can be identified by mapping the distribution of associated fall beds. Fall isopachs of Laacher See tephra bracketing the main pyroclastic flow deposits show that these formed during a period of vent migration within the crater basin (Fig. 7a).

Moderate- to large-volume ignimbrites are commonly associated with caldera collapse. Evidence that such ignimbrites erupted through ring fractures rather than central vents has been provided in some cases. In the Bishop ignimbrite, characteristic vent-derived lithic rock types show that earlier fallout and ignimbrite production from a single vent was followed by eruption of middle and upper parts of the ignimbrite from multiple vents along a ring fracture that defined the structural outline of the Long Valley caldera. Sectorial variations in the mixing proportions of rhyolite and trachyte in the composite ignimbrite P1 on Gran Canaria cannot be reconciled with a central vent but require eruption through a ring fissure; there is no associated plinian fall and thus no evidence of previous eruption through a central vent.

During fissure eruptions, activity probably focuses on several sites along the fissure rather than occurring along its whole length. Some ignimbrites have been found not to be associated with any subsidence structure but rather with linear fissures, several to tens of kilometers long,

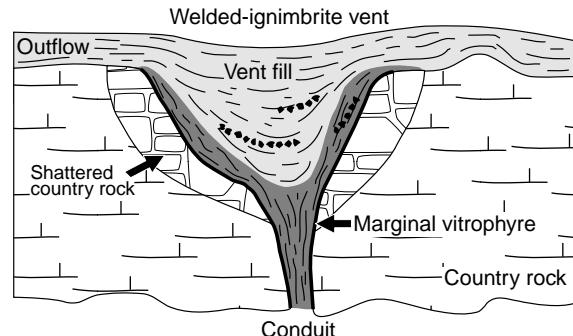

FIGURE 11 Section through a welded-ignimbrite vent showing foliations in marginal vitrophyre and central vent fill and a zone of shattered country rock outside the vent.

and apparently controlled by regional tectonic fault systems, especially in regions of crustal extension.

Exposed sections through ignimbrite source vents not destroyed by caldera collapse, such as the Gabbs Valley vent in Nevada, are rare but share typical zonation patterns. The vent is roughly funnel-shaped, widening dramatically toward the surface, and is surrounded by a zone of shattered country rock that may be 100 m wide but diminishes with depth (Fig. 11). Inside the vent, a vitphyric, paratactic textured zone with foliations (flattened fiamme and flow lineations, local folding) parallel to the wall-rock contact lines the vent walls. The vent interior is filled with welded, devitrified, eutaxitic tuff with more shallowly dipping foliations that may contain zones enriched in lithic lapilli. Deeper into the vent where it narrows, the marginal zones merge to fill the conduit; near the surface, foliation dips decrease and merge with those in the outflow tuff (Fig. 11). Steeply foliated marginal tuff is thought to have agglutinated along the walls during eruption whereas the bowl-shaped interior foliation reflects compaction of vent-filling tuff after eruption.

---

#### VI. PRODUCTS OF SECONDARY PROCESSES

##### A. Compaction and Reworking

The typical concave-up surface of ignimbrite emplaced within valleys or overlying buried pre-eruption valleys

is commonly interpreted to result from postdepositional compaction during escape of gas trapped during emplacement and by densification of the grain framework under load and during welding. Such a surface shape, however, may already be present during emplacement when a horizontal velocity gradient across the flow causes marginal portions from an initially deeper flow phase to lag behind and become emplaced next to deposits from a thinner flow tail in the center of the valley. In addition, remobilization and secondary flow down topographic gradients can change the shape of the deposit.

*Secondary pyroclastic flows* were generated from primary ignimbrite for more than 4 years after the Mount Pinatubo eruption. The secondary pyroclastic flows formed by collapse of primary, largely uncompacted ignimbrite, leaving single or multiple headscarsps, and traveled down valleys for up to 10 km in much the same way as did the primary flows. Deposits of secondary pyroclastic flows are up to 10 m thick and almost indistinguishable in structure and composition from the primary deposits, containing basal lithic and topmost pumice segregation layers and lapilli pipes. Discriminating features include moderate fines-depletion and random thermoremanent magnetic polarity of the secondary deposits, which may also overlie epiclastic deposits (e.g., lahars) formed after primary ignimbrite eruption.

*Phreatic explosions*, which may occur months to years after emplacement, blast craters through pyroclastic flow deposits emplaced on wet ground or trapped water and form laminated to cross-bedded tuff rings on their surface (e.g., at Mount St. Helens).

Heavy rainfall and ice melting on glaciated volcanoes generate floods that easily erode and mix with unconsolidated pyroclastic-flow material to form lahars as, for example, at Mount Redoubt, Alaska. It is often difficult to distinguish primary pyroclastic flow deposits from secondary, reworked material, especially at volcanoes where block-and-ash flow deposits are abundant. Segregation pipes and fragments of charred vegetation are known to occur in secondary, water-reworked deposits, the former due to escape of steam or water and the latter inherited from the primary hot deposit. However, segregation pipes emanating from carbonized vegetation are good evidence for a primary, hot emplacement mechanism, whereas the presence of a vesicular matrix and/or close association with fluvial sediments is indicative of a secondary, wet laharic deposit. In some cases, paleomagnetic techniques (uniformity of magnetization direction, paleotemperature estimates) can also be used to infer a primary or secondary origin.

## B. Alteration and Cementation

During slow cooling of pyroclastic flow deposits, precipitation of iron oxides often creates an upper zone of pink color in unwelded deposits, and precipitation of various minerals from vapor phases (predominantly cristobalite, tridymite, and hydrous minerals) can partially to totally fill interstices between particles. Localized degassing channels, or fumaroles, which can be active for many years as vapor formed by interaction between the hot deposit and rain- or groundwater moves up along preferential channels, develop encrustations of vapor-phase sublimes enriched in trace elements.

A common process of alteration and cementation of pyroclastic flow deposits is zeolitization. The assemblage of zeolite minerals (mostly phillipsite, chabasite, and, at a later stage, analcime, but many other zeolites occur), the extent of zeolite cementation, and the distribution of zeolitized zones in the deposit apparently depend on the spatial and temporal variation of water saturation, which, next to external factors, is controlled by the local grain-size distribution (fine-grained, poorly sorted ash is less permeable but, once soaked, retains water longer), although zeolitization zones commonly cross depositional boundaries. Geologic evidence does not support a significant control of emplacement temperature or even magmatic composition on the degree of zeolitization in most pyroclastic flow deposits. Zeolites form from the alkali elements that become mobile during low (i.e., ambient) temperature hydration ( $\text{Na}^+$ ,  $\text{K}^+ \leftrightarrow \text{H}^+$  ion exchange) of volcanic glass by meteoric water.

---

## VII. GENERATION AND TRANSPORT PROCESSES

Having briefly discussed block-and-ash flow formation in Section III, we here focus on the formation of ignimbrites that, based on historic observations, are believed to form by collapse of eruption columns. Eruption modeling provides some insight into physical conditions of pyroclastic flow formation. The high-speed hot pyroclast-gas mixture leaving the vent has a bulk density of the order of  $10 \text{ kg/m}^3$  but becomes diluted by entrained air that expands upon heating. Sufficient air entrainment facilitates the formation of a buoyant plinian column of lower than atmospheric density, but eruption conditions such as wider vent diameter limit the efficiency of dilu-

tion by entrainment, keeping the mixture denser than air so that it partially or totally collapses back to the surface from the height where initial momentum became exhausted. High mass discharge and wide cross-sectional vent area reduce the collapse height and eventually the pyroclastic mixture may spread sideways shortly above the vent so that the resulting pyroclastic current largely inherits the properties of the mixture at the vent.

However, eruption models are simplified by assuming that the eruption mixture is homogeneous in composition and physical properties across the vent but recent detailed studies of near-vent deposits show that this is not necessarily the case. Column collapse is not irreversible and renewed plinian activity can occur as shown, for example, by multiple flow units intercalated with fallout beds at Laacher See. Furthermore, geologic evidence for simultaneous plinian and ignimbrite-producing activity, such as in the historic 1912 Novarupta and 1991 Pinatubo eruptions and the prehistoric Taupo and Bishop Tuff eruptions, and recent modeling results show that plume buoyancy and collapse are not mutually exclusive. Considering the complexity of natural eruption columns, modeling can only provide a first-order approximation of the initial conditions of pyroclastic currents.

Modeling approaches to pyroclastic density currents employ either a finite-volume, single-pulse release from source or steady-state conditions of maintained material supply during transport. In the first case, the duration of flow generation (or eruption) would be shorter than the duration of lateral transport whereas in the second case, eruption duration would exceed the time needed by the current to reach its runout distance. Eruption durations may range over  $>3$  orders of magnitude from phreatomagmatic discrete explosions through complex collapse patterns of nonsustained eruption columns to more or less continuous long-lived activity and are not simply related to pyroclastic-flow transport times, thus allowing for a wide range of time relationships that must be carefully identified for each deposit and eruption. A pulselike character is attributed to pyroclastic surges derived from instantaneous explosions and to small pyroclastic flows derived from partial column collapse during relatively weak eruptions. At the other extreme, maximum eruption rates of  $<10^{10}$  kg/s, limited by viscous magma flow through reasonable conduit dimensions, require eruption durations longer than the transport times of large ( $>10^{14}$  kg) ignimbrites reaching about 100 km from source. Some large ignimbrites, however, have been emplaced by a succession of ignim-

brite-producing episodes, which may or may not have had a pulselike character, rather than by a single long-lasting eruption.

Much of the present discussion on pyroclastic flow transport relates to whether the presumably low bulk density of the collapsing mixture is maintained for substantial lateral travel distance or the pyroclastic current rapidly deflates to a high concentration mass flow. Generally speaking, deflation will be delayed if the flows are fast and highly turbulent and the grain size is fine. The transport mechanisms of pyroclastic currents are presently being discussed in terms of two extreme models, *dense pyroclastic mass flows* and *dilute pyroclastic suspension currents*, which essentially differ in the factors that control particle support and runout of the flows. None of these models is, as yet, capable of quantitatively predicting both the regional mass distribution and the facies variations of ignimbrites. We will now briefly introduce the physical concepts and then discuss the significance of geologic observations.

The runout of *dense pyroclastic mass flows*, similar to that of avalanches, is controlled by the consumption of initial energy by internal and external friction. A simple (Mohr–Coulomb) model envisions a pyroclastic flow (or avalanche) as a sliding block of some frictional strength that will move on ground slopes  $>\theta$  and reach a distance  $L = H/\tan \theta$ , where  $H$  is the height of origin and  $\theta$  the angle of internal friction of the material. In contrast to cold avalanches, however,  $H/L$  ratios calculated for pyroclastic flow deposits (Fig. 12) suffer from poor con-

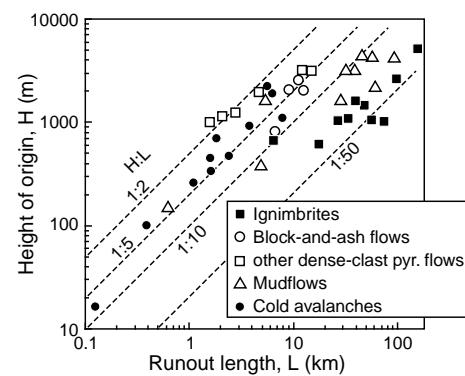

FIGURE 12 Height of origin ( $H$ ) versus runout distance ( $L$ ) of various pyroclastic and other flow deposits. Mudflows have lower  $H/L$  ratios than cold avalanches, and large ignimbrites have lower ratios than small pyroclastic flow deposits, suggesting that both lubrication of the granular material and the mass of flow influence mobility. Note, however, that  $H$  values for pyroclastic flows derived from column collapse are uncertain.

straints on the value of  $H$ ; even during observed eruptions, it is almost impossible to determine a specific collapse height as collapse may occur over a height interval. Furthermore, the Mohr–Coulomb model has proved insufficient to reproduce observed pyroclastic flow velocities, and other friction terms, such as turbulent stresses at high speed, need to be included for more successful modeling. The Mohr–Coulomb model also does not consider flow mass, while it is evident that runout length of ignimbrites generally increases with their mass (Fig. 12). Large runout distances require significant reduction of internal friction. The effect of self-lubrication observed in rapid granular flows, where the bulk of material rides on a highly sheared boundary layer, may be applicable to fast pyroclastic flows on steep slopes. Pyroclastic flow mobility may also be enhanced by fluidization, where an upward-moving gas phase partially supports and unlocks particles. The fluidization concept envisions exsolution of magmatic gas from pyroclasts and entrainment of air, preferentially at the flow front, as sources of gas. Hindered settling of grains through trapped interstitial gas may have similar drag-reducing effects. Inertial granular flows should stop dead and be emplaced en masse when shear stresses drop, e.g., upon meeting a flat ground slope. Some block-and-ash flows effectively meet this condition. Effectively viscous, well-fluidized flows with a laminar velocity gradient should smear out their material over the runout length.

The runout of *dilute pyroclastic suspension currents* is controlled by the balance between initial mass flux and pyroclast sedimentation and entrainment of air, which ultimately dilute the current to below atmospheric density, causing it to loft into the air as a co-ignimbrite ash plume. Sedimentation rates depend on grain size and how well pyroclasts are kept in suspension by flow turbulence. Air entrainment depends on the strength of shear at the flow surface and on engulfment at the current's head. It follows from the balance between mass flux, sedimentation, and entrainment that (a) very slow and coarse-grained currents rapidly sediment most of their load near the vent whereas (b) very fast currents quickly dilute by air entrainment and transform into ash plumes carrying a large fraction of the erupted fine pyroclasts, but (c) deep, fine-grained currents at intermediate speed will reach the greatest runout distance. The deposit of a pyroclastic suspension current will of necessity accumulate progressively but, since suspension currents invariably become stratified with higher particle concentration near their base, the depositional process is probably complex and little can as yet be inferred about the resulting bedforms and grain-size characteristics.

Studies of the Mount St. Helens May 18, 1980, blast deposit and recent observations during the 1995–1996 eruptions on Montserrat promoted the concept that pyroclastic density currents develop a basal depositional system that controls emplacement conditions and is dynamically distinct from the transport system, which controls overall distribution of the material. Deposit characteristics are then believed to reflect the depositional, but not necessarily the transport, system.

Geologic evidence invoked in favor of one or the other model is mostly ambiguous. For example, how much are massive bedforms with floating pumice, commonly used to imply dense flow, influenced by late-stage motion such as drainage into channels rather than by overall transport conditions? How much dilution is really necessary to produce tractional bedforms, or can dilute currents produce massive poorly sorted beds? Most of what we know about bedform development comes from aqueous systems but it is clear that gaseous systems behave in a very different way because of different viscosity, density, and thermal expansion, so that the value of analogies is fairly limited.

Pumiceous ignimbrite has a bulk density close to that of water and little variation in gas content during flow is required to allow for flow either over or under water. The smaller the density contrast, the more efficient the mixing with water should be and, therefore, dilute currents should travel greater distances across water. These relationships have, however, not been explored quantitatively. Large topographic barriers can be surmounted by dilute pyroclastic currents due to their low density and great depth and by dense pyroclastic flows due to large momentum. Similarly, radial flow patterns little influenced by irregular topography would be compatible with both dilute turbulent or dense high-momentum flows. The suspension-current model predicts that a large mass fraction of erupted material can be emplaced as extensive co-ignimbrite ash. Some co-ignimbrite ash layers subequal in volume to the ignimbrite itself would be difficult to reconcile with elutriation from a dense flow but it has also not yet been shown how these ash layers, except for being time equivalents, physically relate to their associated ignimbrites. Many small channeled pyroclastic flows have clearly been emplaced in an almost en-masse fashion with limited lateral shearing. Other flow units grade laterally into thin widespread ash layers that were clearly emplaced by currents much deeper than the deposits. Thick massive ignimbrites that are continuously compositionally zoned were apparently emplaced by progressive aggradation from sustained currents.

---

### VIII. FUTURE RESEARCH

The deadly and destructive nature of pyroclastic density currents makes their study an important and challenging topic in volcanology. As in the past, most of the relevant information has to be inferred from the resulting deposits. There are still major challenges in the documentation and interpretation of ignimbrites in order to be able to reconstruct the dynamics and timings of their parental currents and eruptions. We suggest that studies of pyroclastic flow deposits should continue to focus on facies transitions in response to topographic and other environmental changes, since these changes are most important in inferring changing transport conditions. In particular, an emphasis on obtaining quantitative data is required, as many of the comparisons, which could be made between deposits, lack a suitable quantitative framework. A number of such studies have been made, but more are needed and should be placed in the context of the general eruption conditions of the volcano investigated. Until quantitative data are available for a variety of examples, modeling scenarios of pyroclastic density currents as a basis for hazard assessment and emergency planning during eruptions are still problematic. In part, this arises from controversies over the different natures and significance of the transport versus depositional processes and the ways in which these are interpreted from deposits. One ultimate goal would be to model these processes as a function of both topography and eruption conditions that can be determined from observations such as magma composition, volatile composition and release patterns, vent configuration(s), and overall eruption dynamics. To advance these approaches, however, a fundamental understanding of the compressible flow dynamics of rapidly moving hot gas–particulate currents is necessary, which requires dedicated experimentation and theoretical approaches.

## GLOSSARY

- bulking** The erosion and incorporation of secondary, exotic debris by lahars as they move downstream.
- debris avalanche** A flowing mixture of debris, rock, and moisture that moves downslope under the influence of gravity. Debris avalanches differ from debris flows in that they are not water saturated and in that the load is entirely supported by particle-particle interactions.
- debris flow** A water-saturated mixture of debris and water having large sediment concentration that moves downslope under the influence of gravity. Forces related to both solid and fluid phases act together to drive debris flows and determine their distinctive behavior. A fairly uniform mixture of solid and liquid phases in vertical profiles characterizes debris flows and distinguishes them from more water-rich hyperconcentrated flows. The literature suggests a gradational boundary of 50% to as

much as 60% sediment by volume separating debris flows and hyperconcentrated flows. Sediment concentration is not definitive because behavior also depends on factors such as sediment-size distribution and degree of agitation.

**debulking** A process in which the lahar selectively deposits certain particles, owing to their size or density, as it moves downstream. Debulking differs from the general deposition of bulk sediment in preferentially removing particles, usually large or dense ones, from the flow.

**granular temperature** A measure of degree of particle agitation, usually defined as the ensemble average of the square of the fluctuating components  $v'_s$  of instantaneous grain velocities,  $v_s$ :  $T = \langle v_s'^2 \rangle = \langle (v_s - \bar{v}_s)^2 \rangle$ , where  $\bar{v}_s$  is the mean velocity component. Granular temperature may be interpreted as twice the fluctuation kinetic energy per unit mass of granular solids.

**hyperconcentrated flow** A gravitationally driven, nonuniform mixture of debris and water having water content larger than that of debris flow but less than that of muddy streamflow. Some variation with depth of solids fraction characterizes hyperconcentrated flows and distinguishes their behavior from that of debris flows. The literature reports depth-integrated solids concentrations of between 20 and 50–60% for hyperconcentrated flows. Hyperconcentrated flows possess fluvial characteristics, yet carry very high sediment loads.

**lahar** An Indonesian term that most commonly means debris flow, transitional flow, or hyperconcentrated flow originating at a volcano. Though some floods and muddy streamflows are genetically related to lahar events, most are not, and the term lahar is not generally extended to include such flows. Although many workers use lahar for both the process and the deposits that result from it, it is better to restrict the term to the process.

**muddy streamflow** A flow that essentially transports sediment as normal streams do, with fine-grained sediment in suspension and coarse-grained sediment moving piecemeal along the bed as bedload. Muddy streamflows and floods have smaller sediment concentrations than do hyperconcentrated flows.

**phase (of flow)** The flow type in a lahar wave at some time and place. Phases associated with lahars include debris flows, hyperconcentrated flows, and muddy streamflows.

**stage (of flow)** The height above the channel bottom of the flowing lahar. Examples of lahar stages include the initial rising or waxing stage, the peak-inundation stage, and the final long-duration falling or waning stage.

**turbulence** Chaotic fluid movement [normal to direction of flow], or deviation of flow from laminar. Turbulent flow characterizes streamflows but not debris flows or sediment-rich hyperconcentrated flows.

**L**AHARS OCCUR DURING volcanic eruptions or, less predictably, through other processes common to steep volcanic terrain when large masses of sediment, and water, sweep down and off volcano slopes incorporating additional sediment. Because lahars are water saturated, both liquid and solid interactions determine their unique behavior and distinguish them from other related phenomena common to volcanoes such as debris avalanches and floods. The rock fragments carried by lahars make them especially destructive; abundant liquid contained in them allows them to flow over gentle gradients and inundate areas far away from their sources. People in such distal areas commonly neither expect the danger nor anticipate the destructive power of lahars.

## I. DEFINITION AND SIGNIFICANCE OF LAHARS

### A. Historic and Prehistoric Examples of Lahars

Lahars at volcanoes inundate surrounding areas and damage or destroy nearby communities. Torrential rains

mobilized loose debris and generated hundreds of lahars after Mount Pinatubo in the Philippines erupted cataclysmically in 1991. Although each of the Pinatubo lahars was relatively small, within 3 years, they cumulatively remobilized nearly 3 of the 10 km<sup>3</sup> of juvenile pyroclastic debris emplaced during the eruption. Filling of downstream channels and overbank flow onto surrounding fields and villages inundated more than 400 km<sup>2</sup> and displaced more than 50,000 people. In contrast, the 1985 pyroclastic eruption of Nevado del Ruiz in Columbia was relatively small (0.01 km<sup>3</sup>) but generated much larger lahars (total volume of ~0.1 km<sup>3</sup>). The interaction of hot pyroclastic flows or surges and glacial ice and snow at the summit of the volcano caused these lahars. The lahars flowed up to 100 km down four of five drainages that head at the volcano. These were the deadliest lahars worldwide to have occurred during historic time. They destroyed more than 5000 homes and killed more than 23,000 people. In the town of Armero, 73 km downstream of the volcano, virtually all structures in the path of a lahar were obliterated and three-quarters of the inhabitants killed.

Studies of prehistoric lahar deposits indicate the potential for even greater disasters. About 5600 years B.P., the enormous (3.8 km<sup>3</sup>) prehistoric Osceola Mudflow from Mount Rainier in Washington state began with a debris avalanche that transformed to a lahar as it deformed [and dilated] because of the enormous volume of water contained in pore spaces and in the volcano's hydrothermal system. It filled valleys from depths of 85 m to as much as 200 m, flowed more than 120 km down valleys, and continued for up to 20 km under the water of Puget Sound while retaining sufficient coherence to transport large gravel and wood fragments. It inundated an area in excess of 350 km<sup>2</sup>, which is now populated by hundreds of thousands of people. A large pyroclastic flow that mixed with more than 1 km<sup>3</sup> of glacial ice and snow generated a prehistoric lahar at Cotopaxi in Ecuador that was as voluminous as the Osceola Mudflow. The lahar filled valleys to depths of 80–200 m, flowed more than 300 km to the Pacific Ocean, and covered at least 440 km<sup>2</sup>.

### B. Purpose

Because the timing of lahar events is unpredictable and working with active flows can be hazardous, much of our present knowledge of flow behavior is inferred from study of lahar deposits. Nonetheless, a few key observational and experimental studies have improved understanding of debris-flow processes. The chief purpose of

this article is to summarize what is known about the nature and behavior of lahars on the basis of observations, experiments, and careful examination of deposits and further to describe carefully the nature of deposits derived from such events.

### C. Terminology

Lahar is an Indonesian term that most commonly means debris flow, transitional flow, or hyperconcentrated flow originating at a volcano. Muddy streamflows and floods have lower sediment concentrations than do hyperconcentrated flows and essentially transport sediment as normal streams do, with fine-grained sediment in suspension and coarse-grained sediment moving along the bed. Although some floods and muddy streamflows are genetically related to lahar events, most are not, and the term lahar is not generally extended to include such flows. Although many workers use lahar for both the process and the deposits that result from it, it is better to restrict the term to the process.

---

## II. GENESIS OF LAHARS

Lahars may be primary (syneruptive) or secondary (post-eruptive or unrelated to eruptions). Lahar genesis requires (1) an adequate water source; (2) abundant unconsolidated debris that typically includes pyroclastic-flow and -fall deposits, glacial drift, colluvium, soil, etc.; (3) steep slopes and substantial relief at the source; and (4) a triggering mechanism. Water sources include pore or hydrothermal water, rapidly melted snow and ice, subglacially trapped water, crater or other lake water, and rainfall runoff.

### A. Lahars Induced by Sudden Melting of Snow and Ice, Voluminous Floods, or Torrential Rains

Floods of water moving across the easily erodible loose clastic sediments common on the flanks and aprons of volcanoes easily incorporate that debris and may quickly bulk up to form lahars (Figs. 1A and 1B). Bulking is critical to all lahars that begin with sudden water releases. Lahar formation depends on the right mix of readily available sediment and water discharge. If peak-water discharge is huge, the amount of sediment available for bulking may be inadequate and a flood results

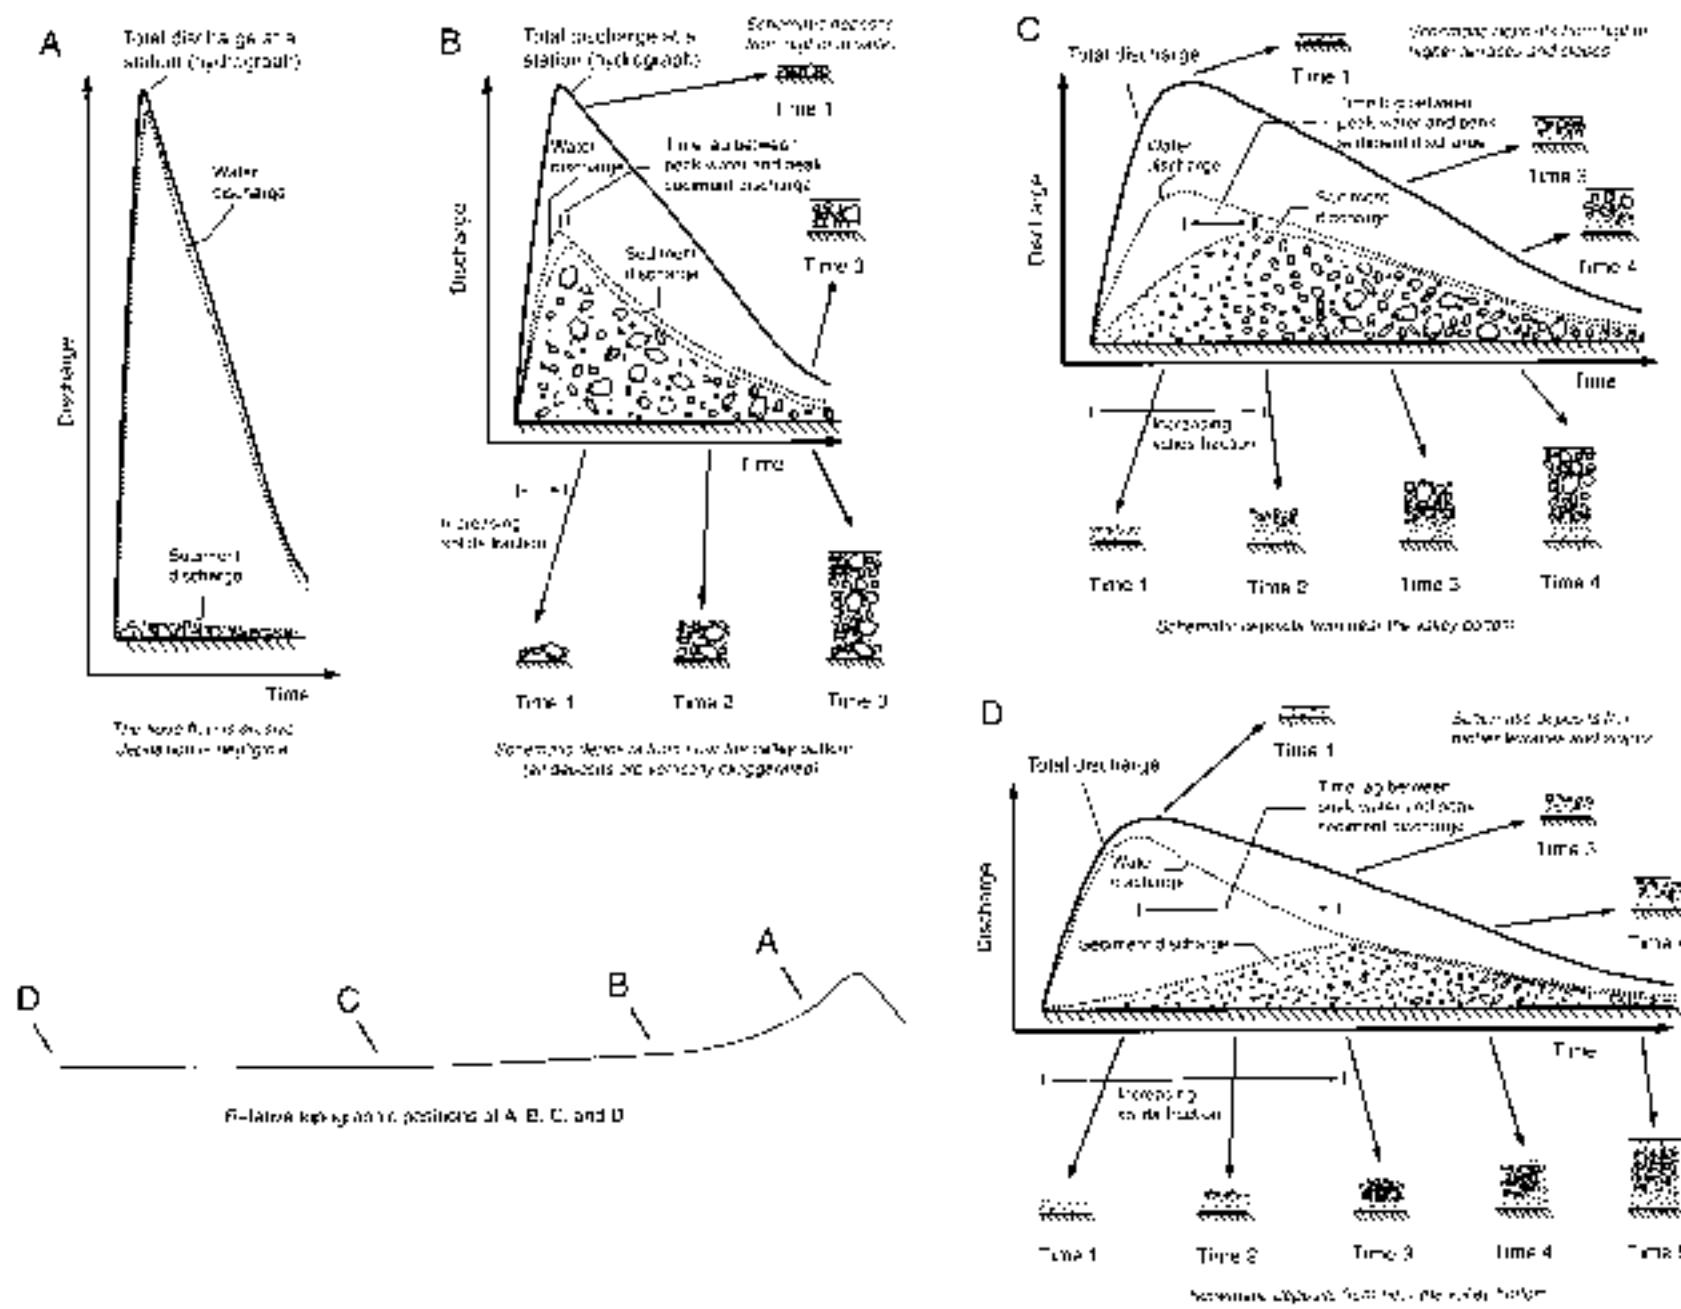

instead of a lahar. Similarly, when high-discharge flow continues for many hours or even days to weeks, as it can during lake-breakout floods, there is not enough sediment available along the drainage system to form lahars. Lastly, in catchments where there is little or no easily erodible clastic debris or soil material, bulking is retarded, and lahars do not occur.

At volcanoes, lahars induced by sudden water release can occur by four principal means. (1) Pyroclastic flows and surges mix with and rapidly melt glacial ice and firn. Generally, such pyroclastic flows come to rest or nearly do, forming meltwater that then runs off, coalesces, and erodes the pyroclastic debris to form water-rich lahars. The lahars continue to bulk up with volcaniclastic debris, glacial drift, alluvium, and colluvium as they flow downstream so that within a few kilometers to several tens of kilometers they become debris flows. Lahars of this type are considered primary. (2) Eruptions can displace large volumes of crater-lake water that form lahars downstream. Crater lakes, caldera lakes, and volcanically debris-dammed lakes can also break out months to years after eruptions. Such delayed breakouts occur when water levels gradually rise and then overtop and rapidly incise fragile debris dams. (3) Subglacial eruptions can form subglacial lakes that eventually break out when a section of the ice cap becomes buoyant and releases the trapped water. Small-scale outburst floods occur as normal glacial processes during periods of ablation. Although huge eruption-driven outbursts cause sediment-rich, water floods called jökulhlaups, small secondary ones commonly bulk up to form lahars. (4) Lahars owing to intense rainfall often occur after pyroclastic eruptions deposit abundant loose debris in the form of pyroclastic-flow or -fall deposits surrounding vents of volcanoes. Lahars of this type are commonly small but frequent in occurrence during rainy periods. Size and frequency of rain-induced lahars may increase in the months or years following the primary pyroclastic eruption and then slowly decrease as drainage networks and vegetation reestablish themselves (e.g., Mount Pinatubo after its 1991 pyroclastic eruption).

Because clay-rich sediment is both uncommon on the flanks or aprons of active volcanoes and resistant to erosion, lahars induced by sudden water release generally appear to be clay-poor (less than about 5% clay/(sand + silt + clay)).

### B. Edifice- or Flank-Collapse-Induced Lahars

Although most edifice collapses behave as debris avalanches, those with sufficient, widely dispersed, pore and

**FIGURE 1** Schematic hydrographs showing how lahars beginning with water floods are initiated and behave when they undergo downstream dilution. Flood phase is shown in A, debris-flow phase is shown in B; and transitional phases are shown in C and D. The diagram also illustrates the progressive-aggradation model of inverse grading in C and D.

hydrothermal water in the precollapse rock liquefy as the material deforms during collapse. The shallow intrusion of magma within an edifice is the likeliest cause of collapse-induced lahars larger than about  $0.2 \text{ km}^3$ . Smaller collapse-induced lahars may have various triggers, including magmatic or phreatic volcanism and volcanic or tectonic earthquakes.

The process of hydrothermal alteration, especially at glaciated volcanoes, increases the probability of edifice-collapse lahars. Acid-sulfate leaching in hydrothermal systems removes mobile elements, adds sulfate, and breaks down framework silicates to form silica phases, such as cristobalite and opal, and clay minerals, such as kaolinite and smectite. This process weakens the rock so that it more readily disintegrates during deformation after collapse. Thus, huge blocks typical of debris avalanches are less common in lahars of this type even though their origin is the same. Abundant alteration minerals, especially clay minerals, increase porosity and decrease permeability of the rock and thus, in combination with the hydrothermal system, trap a widely dispersed reservoir of water within the precollapse mass. Because of its water content and its tendency to disintegrate, hydrothermally altered rock, unlike fresh rock, easily liquefies as it deforms. Collapse-induced lahars are typically clay-rich, and most are observed to have greater than 5% clay/(sand + silt + clay).

Clay-rich, collapse-induced lahars appear to be more common at ice-clad volcanoes than at volcanoes that are free of ice. Glacial erosion tends to expose deeper, potentially more altered, portions of volcanoes by more effectively incising into an edifice. Further, incised slopes in altered rock are more susceptible to failure not only because the rock is weak but also because it is oversteepened. Lastly, melting glacial ice provides a slow-release source of water that is important to the efficient operation of the acid-sulfate leaching process.

At and near some volcanoes, especially tropical ones, tectonic earthquakes cause multiple slope failures that ultimately coalesce and form collapse-induced lahars. Such lahars are unrelated to volcanism but, owing to characteristics of their deposits (commonly clay-rich, hummocky, and voluminous), can be mistaken for lahars generated by major edifice collapse of hydrothermally altered sectors of volcanoes.

---

### III. BEHAVIOR OF LAHARS: DOWNSTREAM PROCESSES

Lahars can change character downstream. Some floods incorporate enough sediment proximally to become

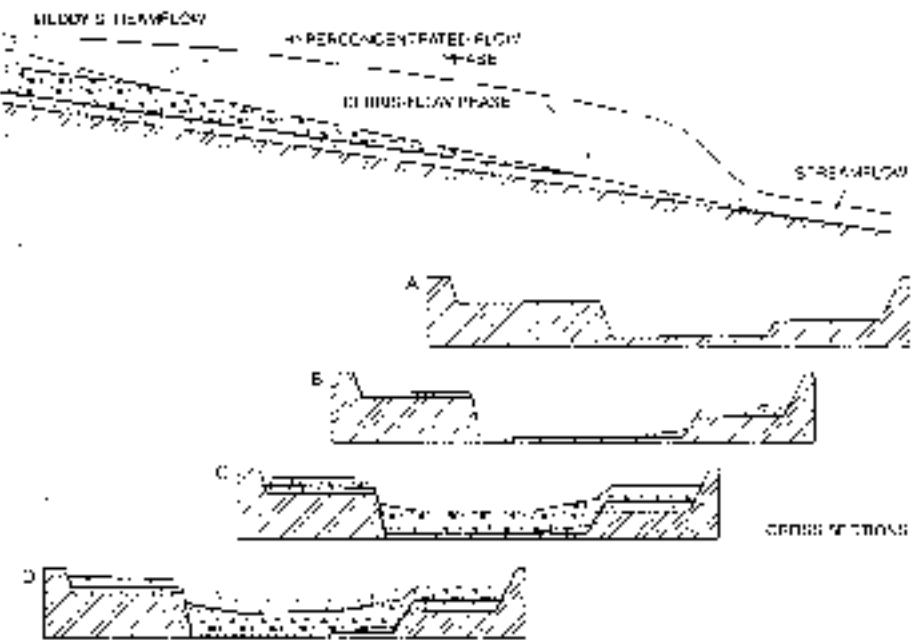

hyperconcentrated flows or debris flows. In medial or distal reaches, debris flows can also transform back to water-rich hyperconcentrated flows or, ultimately, floods. Further, debris avalanches proximal to volcanoes can transform totally to debris flows as they move downstream.

#### A. Erosion and Bulking

Lahars cause erosion by undercutting steep slopes and terrace scarps and by scouring their beds. Erosion is strongest along steep reaches underlain by loose clastic sediment and weakest either along reaches underlain by highly resistant bedrock or along reaches with very gentle gradients. Along any particular reach, water-rich, hyperconcentrated phases are typically more erosive than sediment-rich debris-flow phases (Fig. 2), but local erosion can occur during any flow phase. The waxing stage of a lahar is likely to coincide with the most widespread and voluminous erosion and bulking. The final waning stages of a lahar are also commonly erosive and ultimately result in the incision of channels in fresh lahar deposits.

Erosion at the base of a lahar occurs by piecemeal dislodgment of particles, by undercutting at upstream migrating knickpoints, and by rip up of sediment owing to root heave of falling trees. The presence of undisturbed, delicate, deposits such as tephra layers at the base of debris-flow deposits suggests that piecemeal erosion of particles occurs chiefly during more water-rich hyperconcentrated phases. Piecemeal erosion is probably not an important process outside of active channels. If channel beds comprise erodible sediment, sequences of upstream migrating knickpoints are common during hyperconcentrated-flow phases. Typically knickpoint steps are a few tens of centimeters to a meter or so high and spaced on the order of tens to hundreds of meters apart. During more sediment-rich flows, knickpoints become higher and more widely spaced. Knickpoints may disappear during debris-flow phases, which, in fact, commonly aggrade rather than erode their beds. Lahars voluminous enough to escape channels knock trees down and incorporate them. Root balls of falling trees drag considerable sediment into the active flow and loosen even more sediment that is then available for erosion. Voluminous lahars that inundate large areas of forested terrain can incorporate considerable quantities of sediment and huge amounts of wood in this way.

Undercutting of steep slopes, fluvial terrace scarps, and active stream banks is probably the most important way in which lahars erode and incorporate sediment.

**FIGURE 2** Schematic model of a lahar moving down a river undergoing downstream dilution from debris-flow phase to hyperconcentrated-flow phase and deposit facies derived from it [adapted from Fig. 3.31 in Pierson and Scott (1999), "Surficial Hydrological Hazards at Volcanoes," U.S. Geological Survey Open-file Report]. The model shows the expected sequences of hyperconcentrated- and debris-flow deposits in cross section (A–D).

Undercutting is active during both debris-flow and hyperconcentrated-flow phases. Large lahars are capable of incorporating megablocks ( $>10$  m in dimension) of unconsolidated sediment, and sometimes even of bedrock, in this way. Clastic megaclasts may move tens of kilometers downstream before they deform and ultimately break up into individual fragments.

Progressive downstream bulking imposes downstream changes of character on lahars. Bulking transforms flood flows and hyperconcentrated flows to more sediment-rich phases (Fig. 1). If the process continues, both waxing and waning stages of flow ultimately become debris flows. With continued transportation, debris flows become richer in exotic sediment, such as alluvium, colluvium, and glacial drift. Typically, the waxing flow front and following peak stages of the flow are the most erosive and thus most readily incorporate exotic sediment. The sediment-rich falling flow that follows peak flow is less erosive and commonly actively deposits sediment rather than erodes it. The final waning-stage flow is typically more watery, and more erosive, but less voluminous in discharge than the preceding stage. Final waning stages of lahars commonly incise previously deposited laharic sediment.

## B. Particle-Size and -Density Segregation Processes

Particles in lahars can effectively segregate by density or size, but the most important segregation processes are mediated by solids fraction, proportion of coarse particles, and fluid density, the latter being determined by the proportion of fine-grained particles in suspension. More dilute flow favors particle settling or buoyant rise because there are fewer particles to hinder these processes. Greater solids fractions hinder these processes and may favor percolation, a process that counteracts preferential settling of large particles. Percolation is a process in which particles, under the influence of gravitational body forces, move downward into gaps that open beneath them. The process occurs chiefly when individual particles influenced by body forces such as gravity rub or collide in vibrating or shearing mixtures.

Particles such as pumice that are less dense than water rise buoyantly. In addition, particles slightly more dense than water rise to the surface of lahars whose fluid phases suspend sufficient fines (generally clay and silt but in some cases fine-grained sand) to increase the effective fluid density. Consequently, low-density particles com-

monly collect at the surface of lahars and may ultimately form rafts of material that appear to move en masse. Friction at the bed retards lahars and causes vertical profiles in which velocities are smallest at the base and gradually increase upward. Low-density particles will migrate upward toward the surface where velocities are greater than average and will then migrate forward toward flow margins.

Particles that are more dense than the fluid will settle if the solids fraction is not great. In a viscous liquid, large dense particles will have higher terminal velocities and will settle faster than small particles of the same density. Through this process, the largest particles collect in the lowest horizon of the moving flow and progressively smaller particles will collect in horizons above that; thus a normally graded flow develops. If particle concentrations are great enough, particles collide with and rub one another as they settle. Such particle interactions inhibit the settling process.

In shearing or vibrating flows with particles denser than the fluid and with particle concentrations greater than about 40%, percolation predominates rather than settling. In such flows voids periodically open beneath the particles. If the size of a particle is comparable to or smaller than the size of a void, the particle falls down into the void. In a flow with a mixture of grain sizes, the probability is greater that voids of sufficient size will open beneath small particles than will open beneath larger ones. Percolation operates only downward; so in order to preserve vertical mass balance, there must be a process by which particles migrate upward. Force imbalances or particle rotations can push particles from one layer into another. This process, termed squeeze expulsion, can operate either up or down and need not be size preferential. The combination of percolation and squeeze-expulsion processes in shearing or vibrating particle flows is known as kinetic sieving. The net result of kinetic sieving is that small particles migrate downward and displace large ones, and large ones gradually migrate upward. (Readers should note that in granular flows such as lahars, increased dispersive stress corresponds with increased granular temperature or energy dissipation owing to grain collisions and inhibits size segregation rather than promotes it as suggested by Bagnold.) The large particles then migrate forward toward the margins of the flow because velocities are greatest near the surface. The kinetic-sieve process thus not only can cause the inverse vertical grading that is common in moving debris flows but can also cause the accretion of large particles at flow perimeters (Fig. 3).

Waxing flow fronts are commonly the most erosive part of lahars, especially on steep slopes. The debris

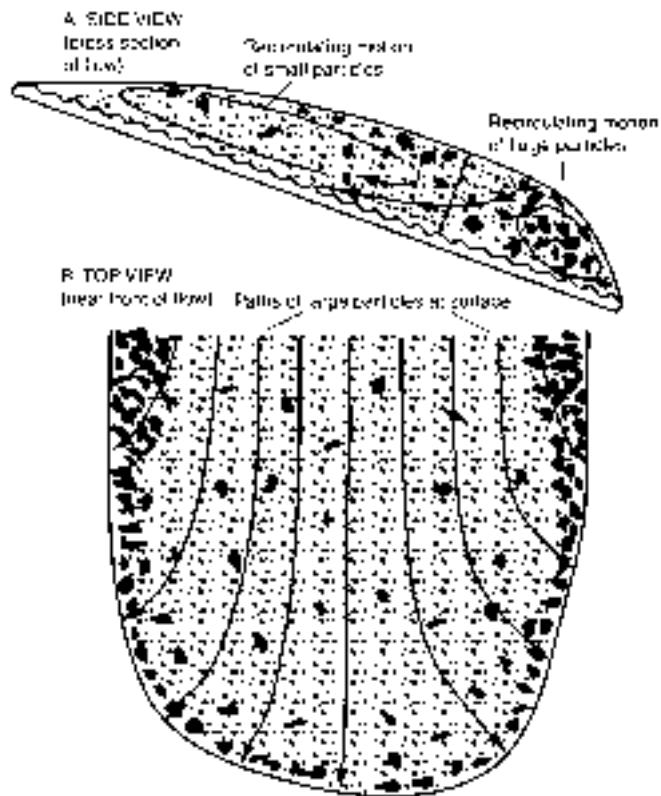

FIGURE 3 Schematic diagram illustrating how inverse particle-size segregation results in (A) longitudinally and (B) laterally graded flows.

available to be eroded and incorporated is commonly coarser grained and better sorted (like alluvium, colluvium, or bedrock) than debris in the main body of the lahar and will be preferentially incorporated at the flow front (Fig. 4). This process can enhance or independently form the coarse-grained, better sorted perimeters that are commonly observed in moving debris flows and their deposits.

### C. Downstream Dilution and Transformation

The gradual incorporation of water at the front of a lahar flowing down an active stream channel causes progressive loss of carrying capacity and an eventual change in the nature of the flow with distance downstream (Fig. 1). This process is important only in lahars that follow active rivers or other bodies of water. Though dilution of large lahars can occur, the process has little effect on the behavior of lahars so huge that their volumes are

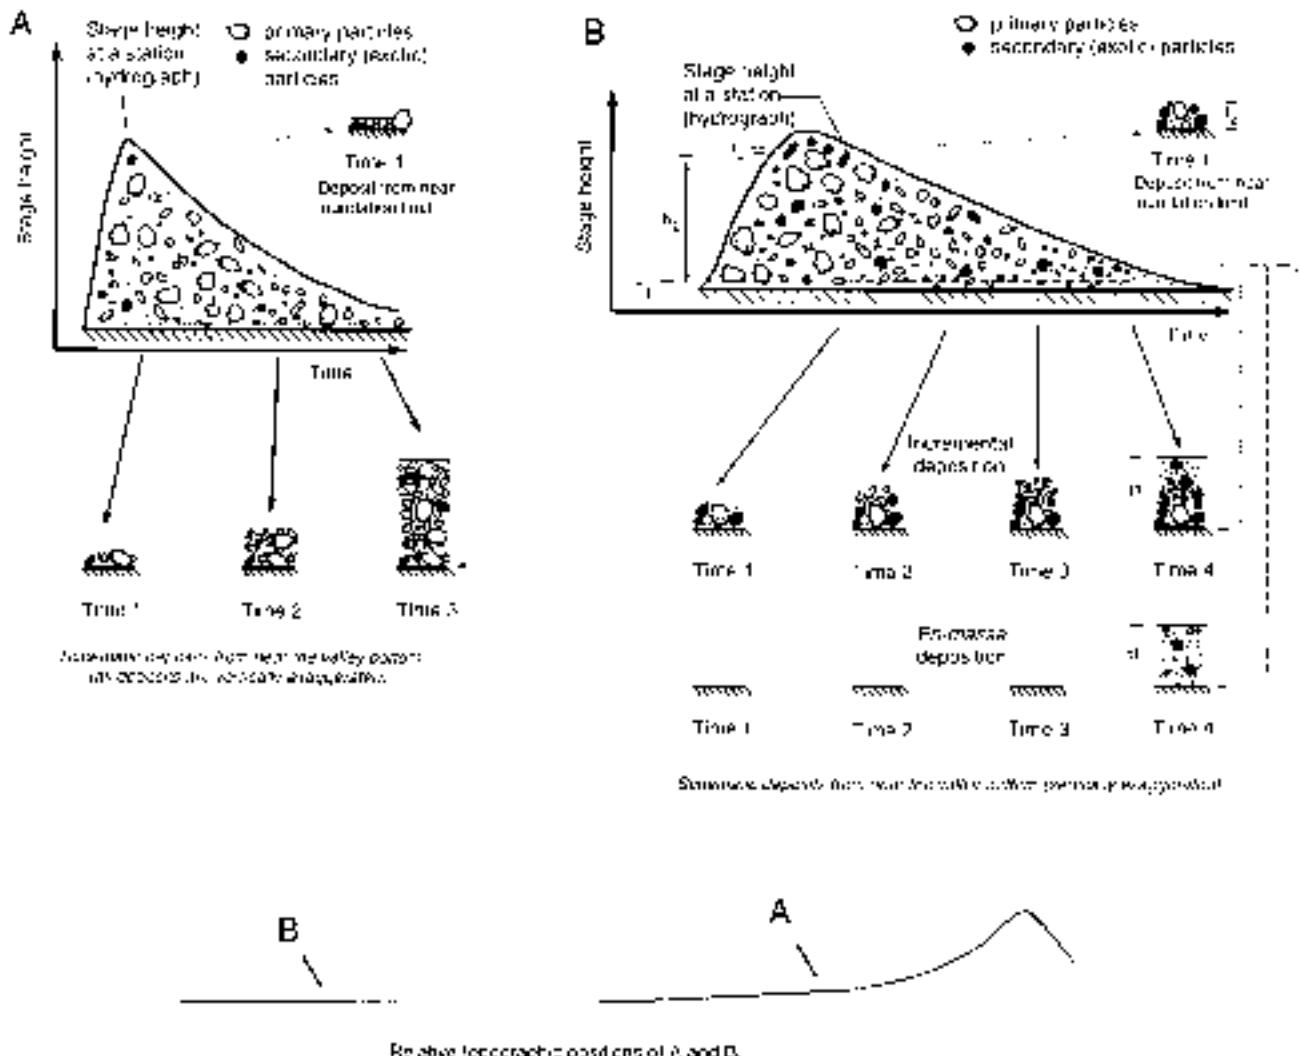

FIGURE 4. Schematic hydrographs showing the behavior and downstream changes of lahars that begin as avalanches of water-saturated debris. Note that with distance downstream (A to B), the lahar incorporates secondary exotic particles, especially near its flow front. The diagram (B) also illustrates how an inverse longitudinally graded flow can accrete incrementally to form a normally graded deposit [adapted from Vallance and Scott (1997)]. Exotic particles are most common at the base of normally graded deposits and at inundation limits (B).

significantly greater than that of the water in the river being overrun. The process of downstream dilution occurs more readily in clay-poor lahars than in clay-rich lahars because (i) clay-poor lahars mix more readily with water and (ii) clay-rich lahars are typically much larger.

Once off the flanks of the volcano and confined in river channels, lahars, which typically move faster than normal stream flow, push river water ahead of them and gradually, with distance downstream, begin to mix with that water. As the flow front becomes progressively more watery, it loses its capacity to carry larger gravel particles, and these progressively lag behind the flow front.

With time and distance downstream, a dilution front progresses from the front of the lahar to its middle, and eventually the entire lahar becomes more dilute. In lahars that occurred at Mount St. Helens in 1980 and 1982, downstream dilution occurred over the course of tens of kilometers and caused a complete transformation from debris flow to hyperconcentrated flow (Fig. 1D). In medial reaches, the hyperconcentrated-flow phase preceded the debris flow of the lahar because the dilution process began at the flow front and then gradually worked backward toward the tail as the flow migrated downstream (Fig. 1C).

#### D. Depositional Processes

Emplacement of lahar deposits can occur en masse, by steady incremental accretion, or, most likely, by some intermediate process in which accretion begins and then accelerates, wanes, or does both alternately. Debris-flow deposits are poorly sorted, generally massive, and unstratified. It is common to infer that such massive deposits are emplaced en masse and that they represent a frozen portion of the debris flow itself. In contrast, hyperconcentrated-flow deposits are better sorted, commonly show faint stratification, and hence are assumed to accrete during significant time intervals.

An increasing body of evidence suggests that deposits of both hyperconcentrated flows and debris flows accrete incrementally. Such evidence includes (1) strong alignment of elongate clasts parallel to flow directions or imbrication of such clasts in upstream directions, (2) strong changes in composition of particles with vertical position in outcrops, especially those that are graded, (3) inundation-limit deposits with clast compositions similar to those at the base of thick valley-bottom deposits, (4) marks of peak-flow levels in upland valleys that indicate flow depths 5–10 times greater than deposit thicknesses, (5) abundant evidence of cataclasis (breakage of clasts owing to collisions), and (6) stratification in deposits of transitional or hyperconcentrated flows.

Although rapid deposition of a vertically size-segregated flow can generate normally and inversely graded deposits, incremental accretion of longitudinally size-segregated flow can also be responsible. Because lateral and longitudinal variations in both sizes and compositions of particles commonly occur in moving lahars, accretion from such laterally graded systems during significant time intervals can cause vertically graded deposits. Figure 4B (Times 1 to 5) illustrates schematically how accretion from a debris-flow wave with a concentration of large particles at its front can generate a normally graded deposit. Note that accretion occurs for a short time only near inundation limits where grading does not occur (Time 1–2). The front of a lahar wave that flows down a river becomes progressively more dilute and less capable of carrying larger particles, which lag behind (Figs. 1C and 1D). Therefore, accretion from a dilute debris flow that coarsens from head to tail produces inversely graded deposits (Fig. 1C). Farther downstream, the entire lahar, and especially its flow front, becomes hyperconcentrated so that accretion produces finer grained beds that may be inversely graded or both inversely graded and normally graded (Fig. 1D). Note that deposits in positions higher in the valley may also be graded, but often less obviously so.

Debris flows that do not undergo downstream dilution commonly form cobble–boulder-rich perimeters owing to the size segregation process described above (Fig. 3). The surface of the flow with its concentration of large particles moves faster than the rest of the flow so that cobbles and boulders migrate to the flow front. Once the flow peak has passed at any particular cross section, boulders begin to accrete at flow margins to form coarse levees. Flow fronts, with concentrations of large angular particles, that move onto gentle slopes become progressively drier because water can more easily escape from more permeable coarse-grained flow perimeters than from fines-rich flow interiors. The net result is a dry, frictional, resistant flow perimeter that surrounds a liquefied interior. When flows of this type reach sufficiently gentle slopes, the frictional perimeter slows to a stop and leaves behind a steep-fronted fines-poor margin and a partly liquefied fines-rich interior. Because resistance to flow is greater at the margin than the interior of the flow, bifurcation of the flow into fingers can result as the more mobile fines-rich interior diverts around the more static perimeter.

Avulsion can occur in lowland areas with gentle slopes where sediment-rich portions of lahars accrete and fill the active channel so that its cross-sectional capacity is diminished. When channel capacity is sufficiently diminished, the flow overtops this channel and cuts a new one. In the strict sense, the term applies only to the breaking away and establishment of the new channel, although a precondition for avulsion is accretion during debris-flow phases of lahars.

#### E. Two Spectra of Downstream Behavior

Edifice-collapse-induced lahars are debris flows that transform directly from avalanching debris that contain enough water to become water saturated upon deformation. Such lahars commonly contain large megaclasts composed of relatively fresh volcanic rock from the edifice. As they migrate downstream, they incorporate exotic debris, especially at their flow fronts (Fig. 4). Because of their size, avalanche-induced lahars [generally] rarely undergo complete transformation to hyperconcentrated flow as they migrate downstream.

Lahars that begin with water floods can bulk up rapidly to form debris flows or hyperconcentrated flows (Figs. 1A and 1B). If they continue down active river channels, they will gradually incorporate water, become progressively dilute, and undergo transformations to hyperconcentrated flow and muddy streamflow (Figs.

1C and 1D). The flow transformation begins at the flow front and migrates back through the lahar wave as it travels downstream. If lahars of this type occur in arid regions without perennial streamflow, they will bulk up to become debris flows, not undergo significant downstream transformation, and remain debris flows to their termini. Such debris flows will typically develop relatively dry bouldery flow fronts that surround more liquefied interiors.

#### IV. LAHAR DEPOSITS

##### A. Characteristics of Deposits

Lahar size, origin, and depositional environment all influence the character of deposits and determine the facies that form. Clay-rich lahar deposits at Mount Rainier reflect deposition solely from debris-flow phases. Such deposits are massive, extremely poorly sorted, and commonly normally graded (Fig. 5). The Osceola Mudflow at Mount Rainier, for example, has proximal and medial hummocky facies that are megaclast rich (Fig. 6). Proximal and medial valley-side facies form thin (0.1–1 m) veneers on steep slopes, and proximal, medial, and distal axial facies form thick (2–20 m) fills with common normal grading in valley bottoms and lowlands. Clay-poor lahar deposits at Mount St. Helens have channel facies, floodplain facies, transition facies, and lahar-runout facies (Figs. 7–10). The last three of these facies reflect downstream dilution of the lahar. Changes in grain size, sorting, and grading are shown schematically in Fig. 7.

FIGURE 5 Photograph showing normally graded debris-flow deposit. Clay-rich normally graded deposits are common to collapse-induced lahars. A shovel, 60 cm long, is present for scale.

FIGURE 6 Photograph showing hummocks on the surface of an avalanche-induced lahar deposit and, in the upper right, Mount Rainier. Hummocks in foreground are up to 40 m in plan and 10–15 m high. Mount Rainier, 70 km upstream, is the source of the lahar deposit.

In medial reaches, some channel and floodplain facies exhibit unusual basal deposits called sole layers (Fig. 7). Sole-layer deposits are generally fines deficient and contain abundant gravel-size particles that are broken by cataclasis. Unlike other deposits, sole layers apparently accrete during the waxing-flow stages of lahars. Clay-poor lahar deposits not affected by downstream dilution exhibit blunt snouts and prominent lateral levees that contain concentrations of large boulder- and cobble-size clasts (Fig. 11). Deposit interiors are more uniform, massive, poorly sorted, and matrix rich. Deposits left on steep upland slopes typically form thin lags with concentrations of the coarsest, densest particles and a deficiency of matrix.

Generally, lahar deposits may be massive to crudely stratified and graded to ungraded, depending on the proportion of water that the flows contained and the degree of their downstream evolution. Inverse and normal grading, or both in the same outcrop, are common. Sorting is generally extremely poor to poor. Although lahar deposits formed by debris flows, and the hyperconcentrated flows that commonly evolve from them, have some similarities, they have many differences too, and it is necessary to characterize each type of deposit separately.

Debris-flow deposits are massive and very poorly sorted to extremely poorly sorted (greater than 2  $\Phi$  units and typically greater than 4  $\Phi$  units on the Wentworth scale). Grain-size distributions are commonly bimodal (Fig. 12). They may be normally or inversely graded throughout or, in some cases, can be inversely graded

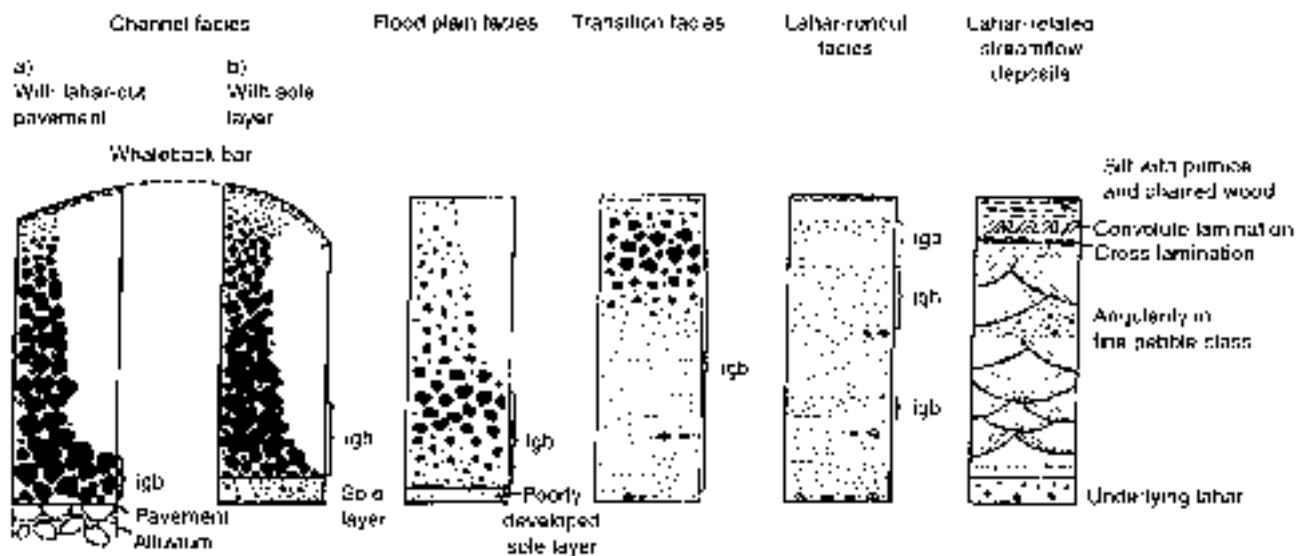

FIGURE 7 Schematic portrayal of facies types in lahars (clay-poor type) that undergo downstream dilution and transformation to hyperconcentrated flow [from Scott (1988)].

near their bases and normally graded near their tops. Fabrics generally are weakly developed. Deposits are extremely compact or, in some cases, indurated so that digging in them is difficult. Particles found within lahar deposits can be monolithologic but are more commonly

heterolithologic; they can be rounded to angular, but primary particles are usually subangular to angular. Deposits commonly exhibit vesicles in the matrix, which result from entrapment of air bubbles. Other common constituents include wood fragments, casts of wood fragments, and charcoal. Concentrations of coarse particles, especially low-density particles such as pumice, are common at deposit tops.

Thicknesses of debris-flow deposits can vary from tens of centimeters to tens of meters. Thick fill deposits occur in valley bottoms and on lowlands. Deposits on higher terraces and slopes within valleys are thinner

FIGURE 8 Photograph showing clay-poor debris-flow deposit that is inversely graded at its base and both massive and ungraded at its top (dashed line indicates base of deposit). A shovel, 60 cm long, is present for scale.

FIGURE 9 Photograph showing faintly stratified hyperconcentrated-flow deposit and overlying transitional debris-flow deposit. A lens cap is present for scale.

FIGURE 10 Photograph showing hyperconcentrated-flow deposit that is inversely graded in the lowest two-thirds of the outcrop and normally graded in the upper third of the outcrop. Note that the deposit comprises silt, sand, granules, and small pebbles with a single mode of coarse sand and granules. Deposit is about 1 m thick.

than those in valley bottoms, and those on steep slopes will drape underlying topography as thin veneers. Both levees and steep terminal flow fronts are common in the deposits of debris flows relatively unaffected by downstream dilution.

FIGURE 11 Photograph showing coarse-grained lateral levee and terminal snout of an experimental debris-flow deposit. Dimension of grid in foreground is 1 m.

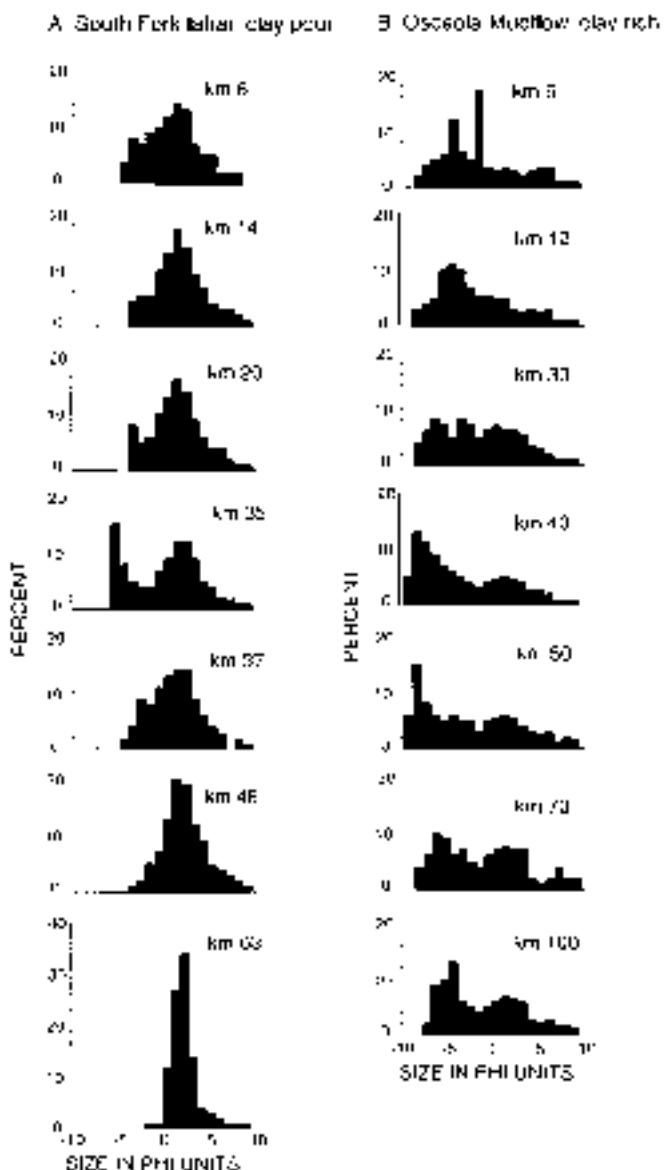

FIGURE 12 Grain-size histograms of (A) clay-poor and (B) clay-rich lahars showing downstream trends [A adapted from Scott (1988); B adapted from Vallance and Scott (1997)].

Hyperconcentrated-flow deposits have characteristics intermediate between debris-flow and alluvial deposits (Figs. 7 and 12). They thus have intermediate sorting coefficients (1–2 $\Phi$  units) and grain size. They can be massive (Fig. 10) but commonly have weak stratification defined by thin horizontal beds and very low angle cross bed sets composed of fine-grained laminae and thicker coarser grained beds (Fig. 9). Floodplain facies have grain size in the granule, sand, and silt range, with the

occasional floating pebble, cobble, or boulder (Fig. 13). If pumice was an important constituent of the flows, zones of nearly 100% pumice are commonly present at the tops of overbank deposits. These pumice concentrations result from pumice rafts stranded during falling-stage hyperconcentrated flow. Channel-facies deposits commonly exhibit strong bimodality and clast support, with huge concentrations of cobbles and boulders surrounding the granule–sand–silt matrix (Fig. 13). Fabrics are moderately strong. Vesicles are sometimes present but less obvious than in debris-flow deposits. Deposits are compact and, except for bouldery channel examples (Fig. 13), have a “chippy” quality when dug with a shovel. Though rare, dewatering features such as dish structures (Fig. 14) and pillar structures are sometimes present.

Hyperconcentrated flow deposits have very flat tops and may vary from a few centimeters to several meters in thickness. Thicker deposits occur in channels or other nearby low areas. Thinner deposits occur on higher ground such as floodplains and valley slopes. Flow tops exhibit scattered pebble and larger particles, especially pumice if present; they also commonly have thin layers of fine sand and silt that form during compaction and dewatering.

FIGURE 13 Photograph showing transitional debris-flow to hyperconcentrated-flow deposits. The basal unit (at the point of the ice axe) contains floating, rounded cobbles and boulders and probably reflects deposition from a hyperconcentrated flow in a channel.

FIGURE 14 Photograph showing dish structure in a hyperconcentrated-flow deposit. The structure evolves during or after deposition owing to dewatering during compaction. Note that the structures are more strongly inflected toward the top of the unit. Tape measure for scale.

Primary particles in lahar deposits derive from contemporaneous eruptions or, in the case of avalanche-induced lahar deposits, from the original avalanche mass; secondary particles derive from the erosion and incorporation of downstream volcaniclastic debris, alluvium, colluvium, glacial drift, bedrock, etc. It is difficult to recognize the provenance of small particles, though it can be done in some instances. Gravel-sized particles can be readily divided into three groups. Angular volcanic rocks derive from the volcano and are generally taken to be primary. Angular secondary clasts derive from exotic colluvium, drift, bedrock, and any other erodible materials along the lahar path. Secondary rounded clasts derive from exotic alluvium, fluvium, or glaciofluvial deposits. Using these criteria (or sometimes unique compositional or textural features of components of the clast population), one can calculate lahar-bulking factors. The lahar-bulking factor for a size fraction (or any other component) is defined as the proportion of secondary particles to secondary + primary particles in that size class. The total bulking factor, which is the bulking factor for all size classes, can be difficult to determine because of the difficulty of measuring lahar-bulking factors for small particles. If there is a size class or another distinctive component that is relatively uniform in proximal deposits and is not present in bulked material, then apparent bulking factors of small particles and total bulking factors can be estimated. The estimated apparent bulking factor is given by the equation

$$\text{ABF} = 1 - (R_t/R_i)(S_i/S_d),$$

where  $R$  is the proportion of the reference component (or size class) not affected by bulking,  $S$  is the proportion of any other component (or size class) of interest,  $i$  indicates proximal (initial) value, and  $f$  indicates downstream values. To calculate an ABF total, note that both  $S_i$  and  $S_f$  have values of 1 and

$$\text{ABF}_{\text{total}} = 1 - (R_f/R_i).$$

Debulking is the selective deposition of a component—generally large or dense particles. If the bulking factor is negative, debulking may be indicated and a debulking factor can be calculated. The debulking factor is defined as the ratio of a component lost through selective deposition to the initial amount of the component. Assessment of debulking factors of large particles is straightforward. For small fractions, a debulking factor can be calculated,

$$\text{ADF} = 1 - (R_i/R_f)(S_f/S_i),$$

where  $R$  is the proportion of the reference component not affected by debulking and  $S$  is the proportion of any other component ( $f$  and  $i$  are as before).

## B. Distinguishing Lahar Deposits from Other Common Diamictons

No one characteristic serves to distinguish lahar deposits from those of unwelded pyroclastic flows, glaciers, debris avalanches, and local landslides. Unlike lahar deposits, unwelded pyroclastic-flow deposits do not have matrix vesicles, are not indurated, and contain mainly juvenile particles. Carbonized wood and magnetically oriented clasts help to distinguish them from cold lahar deposits (the vast majority) but not necessarily from hot lahar deposits. Unwelded pyroclastic-flow deposits are usually looser and less compact than lahar deposits. Debris-avalanche deposits generally have more irregular surfaces than lahar deposits. Although lahar deposits, especially clay-rich ones, can have hummocks and lateral levees, these features are more prominent in debris-avalanche deposits. Distal and marginal parts of debris-avalanche deposits can be relatively flat and can contain matrix vesicles, but these features are more typical of lahar deposits. Till can be distinguished from lahar deposits if lateral or terminal moraines can be identified. Unlike lahar deposits, till does not contain matrix vesicles, casts of wood fragments, or the wood fragments themselves. Till is also more heterolithologic than most lahar deposits. Landslide deposits generally have more local distribution and more uniform lithology than lahar

deposits do. Mapping will distinguish between landslide and lahar deposits.

---

## V. PHYSICAL MODELING

Diverse models have been proposed to explain the behavior of lahars, but there is no convincing evidence that lahars behave according to the assumptions of traditional models. In the absence of evidence to the contrary, it might therefore suffice to model these flows in a unified manner as simple cohesionless grain flows moderated by the influences of diverse grain sizes, sorting processes, varying pore pressure, and varying granular temperature. Any viable model needs to account for significant recent advances in the understanding of granular fluid mixtures. Such advances include recognition that (1) flows of such mixtures are neither steady nor uniform owing to abrupt initiations, flow instabilities, and particle segregation processes; (2) pore pressures in such flows are laterally heterogeneous; (3) the mobility of such flows is often governed by highly fluid interiors with nearly lithostatic pore pressures and resistant coarse-grained perimeters with little or no pore pressure; and (4) there is a gradation from frictional to collisional particle interactions, dictated by the granular temperature.

The Bingham model was developed to describe the behavior of clay slurries and is commonly invoked if a rigid plug is observed or inferred. In its simplest form the model assumes that resistance to flow is the result of viscosity and strength of material:

$$\tau_B = S + \mu \frac{du}{dz},$$

where  $\tau$  is resisting shear stress,  $S$  is the yield strength,  $\mu$  is viscosity, and  $u$  is velocity in the downstream direction. The model assumes a viscous boundary layer and an overriding plug layer but neglects particle interactions such as collisions, frictional rubbing, or segregation. Because cataclasis, rounding, and particle segregation are important in those debris flows with significant gravel fractions (i.e., nearly all debris flows), the Bingham model is incomplete. A simple alternative hypothesis emphasizes particle interactions and explains rigid plugs as the result of particle locking owing to low granular temperature.

A collisional or Bagnold-type model is commonly invoked if inverse grading is observed and if grain colli-

sions are believed important, but Bagnold performed his analysis for a mixture of uniform, neutrally buoyant particles and fluid, and the application of his model to gravity-driven debris flows therefore requires the relaxation of his very restrictive assumptions. Further, high granular temperatures that characterize collisional flow regimes inhibit inverse grading rather than promote it. The resisting stress owing to particle collisions in a shearing granular flow can be simply approximated,

$$\tau_c \sim \nu \rho_s d^2 \left( \frac{du}{dz} \right)^2,$$

where  $\nu$  is the solids fraction,  $\rho_s$  is the solids density,  $d$  is the characteristic particle diameter, and  $d^2(du/dz)^2$  is proportional to the granular temperature,  $T$ . Some authors combine Bingham and collisional (Bagnold type) models to derive a “unified” model. However, the mechanics assumed in the two models are incompatible because collisional models (like that of Bagnold) derive ultimately from particle interactions that the Bingham model does not allow.

A few authors have suggested that lahars, or at least their more dilute phases, can be modeled as gravity or turbidity currents. Models of this type presume very low solids fractions and a consequent lack of particle interactions. Since observations of deposits and eyewitness accounts of lahars refute both of these conditions, gravity-current models are wrongly applied to lahars.

A simple model, in which energy dissipation in the flow includes some combination of Coulomb friction and collisional losses at higher granular temperatures, mediated by viscous pore fluid, appears adequate to explain the behavior of many natural grain flows, including lahars. The resisting stress owing to Coulomb friction can be given in simple form as

$$\tau_f \approx \nu(\rho_s g b - P)\tan(\phi),$$

where  $g$  is the gravitational constant,  $b$  is the depth from the surface,  $\tan(\phi)$  is the friction coefficient, and  $P$ , the fluid pressure, is hydrostatic such that  $P \sim \rho_f g b$ . In large-scale debris-flow experiments, however,  $\rho_f g b < P < \rho_s g b$  is common and the flow is thus partly liquefied. (Note that if  $P \sim \rho_s g b$ , pressure is lithostatic and the flow is completely liquefied such that it will move across even the gentlest gradient.) These experiments further show that  $P$  varies with position such that the flow perimeter is commonly not liquefied ( $P = \rho_f g b$ , or hydrostatic) and the flow interior is approximately 80% liquefied ( $P = 0.8 \rho_s g b$ , or close to lithostatic) (Iverson gives a more detailed discussion of this subject).

Variation in  $P$  results from the segregation and migration of large particles to flow margins. Concentrations of large particles at flow margins diminish permeability there and thus preclude even short-duration pressures greater than hydrostatic. However, interior parts of flows contain abundant fine-grained particles that greatly decrease permeabilities to such small values that pressures much greater than hydrostatic can be maintained for times greater than the duration of debris flows.

Because lahars are unsteady and nonuniform, owing to particle segregation processes, and, in particular, owing to probable variation in  $P$  and other parameters with position in each lahar, no simple mechanical model can be successfully applied to these flows. Numerical analysis can approximate lateral and longitudinal variations that are obviously common in most lahars. A two-dimensional, depth-averaged model can include lateral heterogeneities and gives reasonable predictions of flow shape and runout for a wide variety of conditions. Indeed, such a model can qualitatively explain all observed features of large-scale experimental flows described in Iverson. In the future, modelers may be able to extend models of this type to three dimensions without too many restrictive assumptions or too many troublesome analytical problems.

## GLOSSARY

**amphitheater** An arm-chair-shaped landscape formed at the source of a sector collapse. The depth, width, and height of an amphitheater are variable. Amphitheaters associated with a major debris avalanche at composite volcanoes may enclose the summit vent.

**debris avalanche** The product of a large-scale collapse of a sector of a volcanic edifice under water-undersaturated conditions. The deposit is characterized by two depositional facies, “block” and “matrix.” An amphitheater at the source and hummocky topography on the surface of the deposit are characteristic topographic features of a debris avalanche.

**debris-avalanche block** A fractured and deformed piece of the source volcano included within a debris avalanche deposit. The sizes of single blocks are variable, more

than several hundred meters across as a maximum and less than a meter across as a minimum.

**debris-avalanche matrix** A debris-avalanche matrix is a mixture of small volcanic clasts derived from various parts of the source volcano. This facies is massive, poorly sorted, and made of fragments of volcaniclastic formations and occasionally of fragments of paleosols and plants.

**hummocks** Characteristic topographic features for debris avalanche deposits. The shape of hummocks is variable and irregular. No overall trend in the alignment of hummocks is found.

**jigsaw cracks** Jigsaw cracks are characteristic joint patterns within a debris-avalanche block. Jigsaw cracks are typically more irregular than the cooling joints of massive igneous rocks. The joint planes usually remain closed, but many of them open wide due to deformation during the transport of the debris avalanche.

**sector collapse** A destructive volcanic process during the growth history of a volcano. Debris avalanche deposits are the products of sector collapses.

**A** SECTOR COLLAPSE of a volcanic edifice produces a debris avalanche. A debris avalanche is triggered typically by intrusion of new magma, a phreatic explosion, or an earthquake. A debris avalanche is generated at water-undersaturated conditions. The

deposit is characterized by two depositional facies, the debris-avalanche block and the debris-avalanche matrix facies. The debris-avalanche block facies is composed of large, coherent yet fractured and deformed pieces of the source volcano that formed the debris avalanche deposit. The debris-avalanche matrix facies is a more uniform and fine-grained mixture of volcanic fragments derived from various parts of the source volcano. An amphitheater at the source and hummocky topography on the surface of the deposit are characteristic topographic features produced by a debris avalanche.

texture, internal structure, or surface morphology. Scientists from the United States Geological Survey (USGS) analyzed the eruptive processes, flowage, emplacement mechanisms, and depositional structure for the 1980 Mount St. Helens debris avalanche. Other researchers then summarized the general characteristics of debris avalanche deposits. Since this critical eruption, research related to debris avalanches has increased significantly. It is now clear that the formation of debris avalanches is a common phenomenon within the growth history of many composite volcanoes.

## I. INTRODUCTION

Debris avalanches are recently recognized volcanic phenomena. One of the recent historical events was when the northern sector of Mount St. Helens collapsed to be emplaced as a debris avalanche deposit in the upper tributary of Toutle River on May 18, 1980. Similar processes were observed and recorded during the 1888 eruption of Bandai in Japan and the 1956 eruption of Bezymianny in Kamchatka. These events were first classified as ultravulcanian eruptions until their true nature was understood. Before the eruption of Mount St. Helens in 1980, most debris avalanche deposits were interpreted as lahar deposits. Some other debris avalanche deposits have been interpreted as pyroclastic flow deposits, lava flows, or moraines, due to the similarities in

## II. GEOMORPHIC CHARACTERISTICS

Hummocky topography, natural levees, a marginal cliff, a distal cliff, remnants of temporary river channels, and an amphitheater at the source are characteristic geomorphic features of a debris avalanche deposit (Fig. 1). Hummocky topography is perhaps the most significant geomorphic feature. The shape of individual hummocks is variable and irregular (Fig. 2A). Although parallel alignments of the long axes of hummocks have been described in some deposits, no consistent overall trend has been observed. The volume and height of hummocks are larger in the proximal to medial part of the deposit and decrease toward the distal end. Some glacial terminal moraines show a similar topographic expression. Due to irregularity in form and composition, it is often

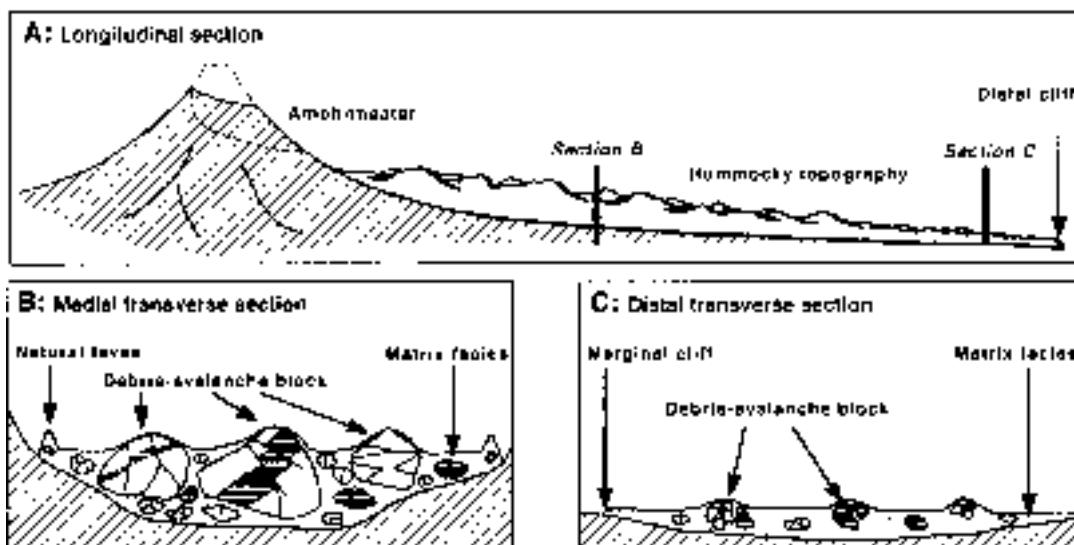

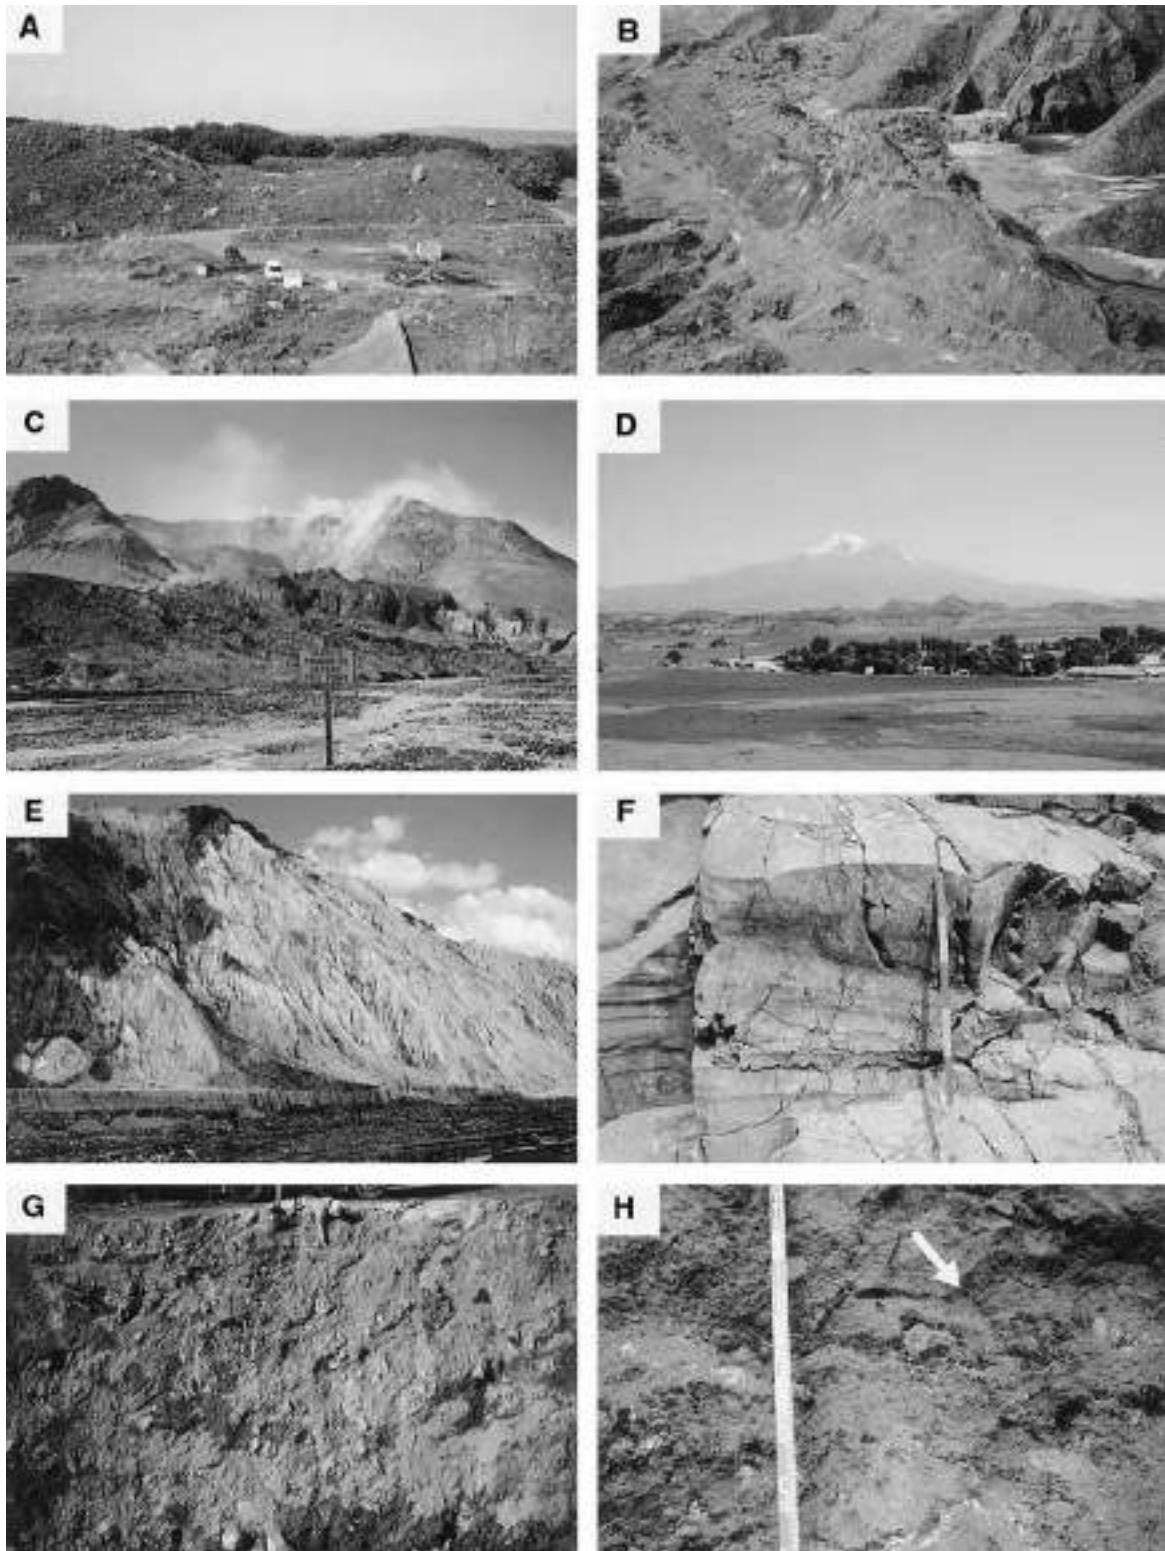

FIGURE 1 Schematic section for a debris avalanche deposit: (A) a longitudinal section stretching from the source amphitheater to the distal end; (B) a transverse section of the medial region; (C) a transverse section for the distal region. Size of hummocks gradually decreases toward the distal area. Debris-avalanche blocks are smaller and scarce at the distal area.

hard to discriminate debris avalanche deposits based on topography alone. Internal depositional features should be examined to confirm the origin of a deposit. Similar undulating topography is also known in the case of small-scale pyroclastic flow deposits. However, their gentle and regularly undulating pattern differs from the hummocky topography of debris avalanche deposits.

Natural levees (Fig. 2B), a marginal cliff, and a distal cliff are other characteristic topographic features in a well-preserved debris avalanche deposit. Natural levees have been described that rise 40 m above the debris avalanche deposit at Socompa Volcano, in northern Chile. A well-preserved example of a natural levee is the 1792 debris avalanche deposit of Mayuyama lava dome, Unzen volcano, Japan. Marginal cliffs (Fig. 1) occur at both the 1792 Mayuyama debris avalanche deposit and the Zenkoji debris avalanche deposit of Usu volcano, Japan. The height of marginal cliffs is up to 10 m. The cliffs develop at the lower part of a debris avalanche deposit if it is emplaced on a wide plain. Distal cliffs are a continuation of the marginal cliff at the distal end of the deposit. The height of the distal cliff at the nonvolcanic Blackhawk Landslide, California, is about 20 m.

Remnants of temporary river channels are left on the surface of the valley-filling debris avalanche deposits. Typical examples of this are seen at the Kisakata debris avalanche of Chokai volcano and the Nirasaki debris avalanche of Yatsugatake volcano in Japan. Such phenomena form soon after the emplacement of the debris avalanche. In the case of the 1980 Mount St. Helens eruption, stream capture began just after the emplacement of the debris avalanche and the river channel had stabilized within several years after emplacement of the deposit.

The shapes of the source amphitheaters can vary widely. The amphitheater formed during the 1980 Mount St. Helens debris avalanche is a fairly typical example, showing a U-shaped plan view (Fig. 2C). The floor slopes northward toward the opening (Fig. 1). The initially steep wall of the amphitheater has slumped now to form a lower gradient apron. The growth of a central lava dome partially has filled the amphitheater (Fig. 2C). Ultimately, lava flows and dome growth will fill the amphitheater as seen at Mount Taranaki in New Zealand and Mount Shasta (Fig. 2D) and Mount Rainier in the United States. Amphitheaters can also be formed by relatively small-scale debris avalanches on the outer slope of a volcanic edifice, as in the case of the 1792 Mayuyama debris avalanche at Unzen volcano. These amphitheaters show relatively wide angles and shallow depths.

### III. INTERNAL FRAMEWORK

The internal framework of debris avalanche deposits comprises debris-avalanche blocks and a debris-avalanche matrix. Debris-avalanche blocks are surrounded by a debris-avalanche matrix. Fracture patterns and fault displacement in debris-avalanche blocks, heterogeneity in the debris-avalanche matrix, and paleomagnetic evidence are clues to the mode of emplacement.

#### A. Debris-Avalanche Blocks

Most debris-avalanche blocks are fragments derived from the source volcano (Fig. 2E). These blocks are fractured and deformed but preserve many of the primary textures and geologic structures of the source volcano. Some debris-avalanche blocks are fragments eroded from the ground surface during transportation of the avalanche. The size of such debris-avalanche blocks is generally not so big as the blocks derived from the source volcano. The maximum measured diameter for a debris-avalanche block is 280 m in the Mount Shasta debris avalanche deposit. The diameter of smaller debris-avalanche blocks may be less than 1 m. Fracture patterns called jigsaw cracks are commonly observed within debris-avalanche blocks (Fig. 2F). Jigsaw cracks within a debris-avalanche block are typically not as regular as the cooling joints of massive igneous rocks. These joint planes usually remain closed, but some of them open widely, due to deformation during transport of the debris avalanche. Conjugated joint patterns can form in the massive part of debris-avalanche blocks, suggesting the existence of local compressive stresses. Jigsaw cracks are common within debris-avalanche blocks formed from massive lava flows and dikes and are scarce within debris-avalanche blocks made of volcaniclastic materials. The frequency of jigsaw cracks depends on both the rock type and travel distance.

Some debris-avalanche blocks show minor fault displacements (Fig. 1). The paleomagnetic orientations of samples collected from a single debris-avalanche block are often nearly uniform. However, the declination varies between debris-avalanche blocks and differs from that of the source volcano. This implies that initial avalanche material split into many pieces and the rotation of large (>ca. 10 m) debris-avalanche blocks is only about an axis perpendicular to the ground surface. There is little or no rotation parallel to the ground surface.

## B. Debris-Avalanche Matrix

The debris-avalanche matrix consists of a mixture of smaller volcanic fragments derived from various parts of the source volcano (Fig. 2G). No jigsaw cracks develop within the debris-avalanche matrix. The paleomagnetic orientation of clasts in the matrix is random. This suggests that the debris-avalanche matrix is formed by the collision and fragmentation of debris-avalanche blocks. Fluvial gravels, soil layers, and basement rocks are eroded and mixed with the primary debris-avalanche matrix material during flowage. The abundance of such exotic material logarithmically increases with distance away from the source. Hummocks are mainly made of huge debris-avalanche blocks and surrounded by the debris-avalanche matrix. Smaller (<ca. 2 m) debris-avalanche blocks float within the debris-avalanche matrix (Fig. 1). The lithology of the debris-avalanche matrix is variable even within a large exposure scale.

The lithology within a few meters of the basal contact of a debris avalanche deposit differs from that of the other parts of the deposit. Fine-grained material is more abundant and large debris-avalanche blocks are not present. Deformed soft sediments are common near the basal contacts (Fig. 2H). This reflects higher shear strains at the base of flows.

“Block facies” and “matrix facies” are terms used to define mappable areas of a debris avalanche deposit. In the block facies many debris-avalanche blocks are assembled to form hummocky terrain. Matrix facies deposits contain a predominance of debris-avalanche matrix and are topographically flat (Fig. 1).

## IV. FREQUENCY AND MAGNITUDE

The largest Quaternary debris avalanche deposit known in the world is the 300- to 360-kyr-old Mount Shasta deposit in the United States. The collapse height for the deposit is estimated as 3500 m and the runout distance is at least 45 km. A database for Japanese Quaternary volcanoes includes 71 deposits from 52 volcanoes (Fig. 3) (Table I). The maximum runout distance ( $L$ ) ranges from 1.6 to 32 km, and the maximum collapse height ( $H$ ) ranges from 0.2 to 2.4 km. The ratio  $H/L$  is equivalent to the apparent coefficient of friction during sliding, or the slope of an energy cone for an eruption.  $H/L$  is generally between 0.2 and 0.06. The ratio is generally lower than that of nonvolcanic landslides of similar size. It has been

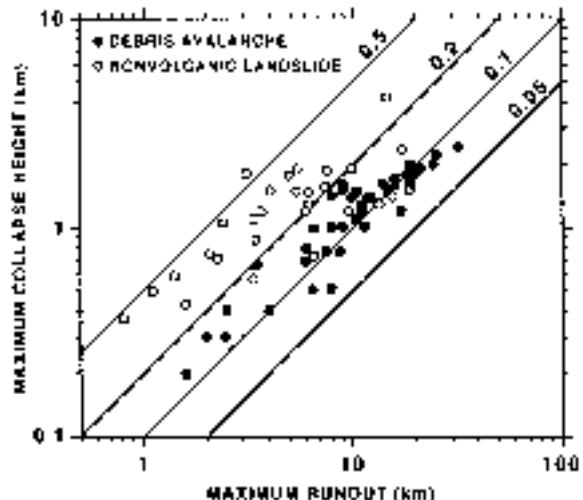

FIGURE 3 Relationship between the collapse height and runout distance for Japanese Quaternary debris avalanche deposits (solid circles) and nonvolcanic landslide deposits (open circles). The ratio of collapse height to runout distance for debris avalanche is generally between 1.2 and 0.06. It is possible to establish hazard zones for future debris avalanches using this ratio.

suggested that this greater mobility results either from the presence of fragmented volcaniclastic materials within a volcanic edifice or from phreatic explosions triggered by sudden decrease of the confining pressure at the time of sliding. Another possible cause of lower  $H/L$  is the more common occurrence of weak hydrothermally altered rocks within volcanoes.

Some debris avalanches transform during transport to clay-rich lahars and spread more widely than ordinary debris avalanches. The existence of long-runout debris avalanche deposits has been shown at Colima and Citlaltépetl volcanoes, Mexico. The source region for the latter is thought to be centered in hydrothermally altered materials in a water-saturated condition. The collapse started in an avalanche manner but transformed to a clay-rich cohesive lahar and moved an unusually long distance, over 120 km away from the source. Collapse height is assumed to be 3–4 km and its  $H/L$  ratio is 0.04. The Osceola Mudflow from Mount Rainier, United States, transformed from a debris avalanche only 2 km away from the source and traveled down to more than 120 km from its origin. The source material included a large volume of pore water and hydrothermally altered rock.

Debris avalanches are common phenomena during the entire growth history of composite volcanoes. The frequency of debris avalanches in the entire Japanese islands is, on average, about once per century. The fre-

TABLE I List of Selected Debris Avalanche Deposits

Volcano	Deposit	Height (km)	Length (km)	Volume (km <sup>3</sup> )	Type	Source
Unzen	1792	0.7	6	0.48	U	D

Abbreviations: Bz, Bezymianny type; Ba, Bandai type; U, Unzen type; L, long-runout debris avalanche; S, stratovolcano; D, lava dome.

quency of debris avalanches at each composite volcano is less than one per 10 kyr. Older debris avalanche deposits will generally be covered by younger deposits or eroded. Thus the exact frequency of debris avalanche events is often difficult to confirm.

## V. ERUPTION PROCESSES

The processes that form debris avalanches are variable. Three types of debris avalanches have been proposed: Bezymianny, Bandai, and Unzen types. Bezymianny-type debris avalanches are associated with magmatic eruptions, as in the case of Mount St. Helens in 1980. The Bandai type is associated with a phreatic eruption, as in the case of Bandai, Japan, in 1888. The duration of precursory phenomena associated with recorded ex-

amples is variable. No juvenile material is included within this type of deposit. The Unzen type is not directly related to volcanic activity, but triggered by an earthquake. Another origin for debris avalanches is slumping of a caldera wall during the process of caldera collapse. Major slope failure of oceanic islands also causes submarine debris avalanches.

The collapse process is not always simple as the case of Mount St. Helens in 1980. Two successive collapses creating two separate deposits also occurred during the 1640 debris avalanche of Hokkaido-Komagatake, Japan. In the case of the debris avalanche deposit of Banahao volcano, Philippines, two successive collapses occurred and flowed in different directions in the proximal area but merged into a single flow at the middle to distal area.

A lateral blast accompanied the 1980 Mount St. Helens debris avalanche and the 1956 debris avalanche of Bezymianny volcano. The lateral blasts spread over a much wider area than the debris avalanches and

destroyed a large area of forest. A lateral blast did not accompany the 1792 debris avalanche of Unzen volcano.

## VI. FLOW AND EMPLACEMENT PROCESSES

More than 20 dynamic emplacement models have been proposed to explain the high mobility of large volcanic and nonvolcanic debris avalanches and many controversies over their emplacement still continue. The air fluidization theory was proposed based on geologic relations of the Saidmarreh, Frank, and Madison debris avalanches as well as on eyewitness accounts of their emplacement. A "hovercraft" mechanism, involving air-layer lubrication, was proposed to explain the long runout and sedimentological and morphological features, for example, preserved intact primary stratigraphy, bulldozed distal ridges, three-dimensional jigsaw-puzzle breccia, distal rims, lateral levees, and transverse ridges and troughs, in the Blackhawk and Sharman debris avalanches, United States. However, the air-layer lubrication mechanism has difficulties in explaining debris avalanches on Mars and the Moon and subaqueous debris avalanches on Earth. A basal gaseous pore pressure model was proposed to explain the rapid velocities and low apparent angle of friction of large coherent debris avalanches using pore fluid vaporization along their bases due to frictional heating during sliding. A basal self-lubrication mechanism is an alternative explanation of the low angle of friction and other characteristic features of the Blackhawk debris avalanche. The Blackhawk debris avalanche bulldozed a distal heap of sandstone ahead of it as it progressed downslope at high speed. The sandstone "breccia" at the front of the flow was "smeared out" beneath the overriding marble breccia, providing a zone of high fluidity beneath the front of the debris lobe (self-lubrication).

A mechanical fluidization model based on the revived idea of grain contact linked with granular flow theory has also been suggested. This assumes the presence of an intergranular fluid and proposes that highly energetic interstitial dust could reduce the effective normal pressure on grains and consequently reduce frictional resistance. For wet debris avalanches, such as the 1970 Huascarán debris avalanche, it is thought that mud could have formed the fluid component between clasts. In the case of large dry debris avalanches, fine dust might act as the interstitial fluid. A combination of mechanical

fluidization and sliding on a lubricated substrate model can explain the depositional characteristics of the Sherman Glacier debris avalanche, Alaska. In this case it was thought that the debris avalanche was caused through mechanical fluidization, derived from the vibration and energy of the Great Alaska earthquake. This debris avalanche behaved as a Bingham plastic and its high viscosity prevented turbulence and kept deformation in the avalanche largely confined to shear at the base on glacier ice, so that for the most part, the avalanche slid as a thin flexible sheet.

The acoustic fluidization model has been proposed as a more geologically and energetically acceptable version of fluidization than the dispersive grain flow model. This model suggests that acoustic fluidization is produced indirectly by the released fall energy through the propagation of strong sound waves of just the right frequency through a flowing breccia stream. Acoustic fluidization requires much less energy than mechanical fluidization.

For debris avalanches composed of limestone, notably Films (Switzerland), another lubricated sliding model has been suggested. It is believed that high temperatures developed along a discrete slip surface would continuously dissociate the carbonate rock into a mixture of lime ( $\text{CaO}$ ) and  $\text{CO}_2$  gas during travel and the  $\text{CO}_2$  gas would provide a lubricant along a basal slip surface.

A mechanical fluidization model in spreading avalanches has been proposed. In this model, the debris avalanche deposits are formed by fluidlike spreading of the debris under the action of gravity, and this spreading occurs due to fluidization of the debris by high basal shear stress as it moves rapidly across the ground. The correlation between volume and the apparent angle of friction is a result of fluidlike spreading of debris avalanches during runout into thin sheets: the larger the volume, the larger the area covered by debris, and the larger the runout length for a given fall height.

A Bingham flow model has been proposed for the Mount St. Helens debris avalanche based on the geomorphology of the Mount St. Helens deposit. The existence of natural levees (Fig. 2B) and marginal and distal cliffs (Fig. 1) suggests non-Newtonian (Bingham) flow behavior. The Bingham flow model has also been used to explain the depositional features and eyewitness of the 1984 debris avalanche, Ontake volcano, Japan. A transport model using initial sliding and later plug (Bingham) flow was proposed after quantitative data were obtained from the Iwasegawa debris avalanche deposit at Tashiro-dake volcano, Japan, and the Kaida debris avalanche deposit at Ontake volcano, Japan.

The granular flow model has also been proposed for

the 1980 Mount St. Helens debris avalanche, based on detailed field evidence of the deposit. The granular flow model has also been used for the debris avalanche at Cantal volcano, France, using anisotropy of magnetic susceptibility (AMS) measurements of the matrix fabric. The data suggest transport of the avalanche by liquefied nonturbulent granular flows. Distally, imbricated deposits suggest more turbulent flow. Emplacement of the avalanche results from progressive aggradation of the particles related to a loss of the nonturbulent liquefied stage. The mass of the avalanche becomes a plug flow that exerts strong friction on the basement.

Another model uses basal low-density layers, based on computer simulation of interacting two-dimensional disks. The basal low-density layer is a region where the particles are very active in the sense that they have large random velocity components (high granular temperature). A basal low-density layer supports an overriding high-density, low-mobility debris "plug" during travel. Computer simulations of granular avalanches were performed using from 5000 up to 1,000,000 two-dimensional disks. The model results suggest that the basal friction coefficient varies with shear rate, where higher shear rates give rise to higher friction coefficients. For debris avalanches with a given fall height to particle diameter ratio, debris avalanches with larger volumes have lower internal shear rates, and thus, lower basal friction coefficients.

Another concept is the mass loss model, which suggests the low apparent angle of friction values achieved by debris avalanches occur because they selectively deposit low-velocity material during movement. The ultimate runout length of a debris avalanche traveling by such a mechanism would depend on the rate and timing of the mass loss. In this model, once a debris avalanche reaches a depositional area, material at the trailing end of the moving avalanche begins to deposit, transferring its energy forward to the moving part of the avalanche. The toe of the avalanche continues to move downslope propelled by the input of momentum from decelerating trailing clasts until the stopping wave catches up with the toe.

A seismic energy fluidization model was given for the 1944 Mount Vesuvius block-and-ash avalanches in Italy. In this model the relative importance of seismic tremor to maintaining avalanche mobility is stressed. A basal pressure wave model has also been suggested where a wave propagated along the basal layer at the phase velocity, which is initially greater than the debris avalanche velocity. With increasing avalanche velocity, the avalanche mass catches up with the guided wave. Over a threshold avalanche velocity, a "sonic boom" is gener-

ated around the basal layer, and the shock contributes to a loosening of the avalanche mass into a fluidized state.

A biviscous flow model has been used to simulate realistic peak velocities and travel times for the 1974 Mayunmarca debris avalanche, Peru, the 1980 Mount St. Helens debris avalanche, United States, and the 1984 Ontake debris avalanche, Japan. Numerical biviscous modeling indicates that the avalanche at Mayunmarca and avalanche I at Mount St. Helens in 1980 ( $H/L \sim 0.2$ ) were of relatively high strength, with apparent Newtonian viscosities of up to several hundred  $m^2/s$ . In contrast, the explosively triggered avalanche II/III flow at Mount St. Helens in 1980 and the Ontake debris avalanche in 1984 ( $H/L \sim 0.1$ ) were of relatively low strength, with apparent Newtonian viscosities 1–2 orders of magnitude lower.

Some combination of these models probably applies in most cases, and each debris avalanche, depending on its composition, cause, volume, and environment, could be simulated by only some of the models listed here.

## VII. EXAMPLES

### A. 1980 Mount St. Helens (Bezymianny Type)

A swarm of volcanic earthquakes was first detected on March 20, 1980. An initial phreatic explosion occurred on March 27, after 123 years of dormancy. Several phreatic explosions followed and normal faults gradually developed at the summit crater. The north side of the volcanic edifice gradually bulged outward, beginning in early April. Phreatic explosions were repeated and deformation accelerated. A maximum horizontal displacement of 120 m was recorded in the middle of May. Finally, the northern sector of the volcanic edifice collapsed at 8:32 a.m. on May 18. The resulting debris avalanche filled the upper tributary of the Toutle River and traveled up to 28 km away from the source. Its volume was  $2.5 \text{ km}^3$ . The velocity of the avalanche was about 50–70 m/s, judging from a series of photographs. The collapsing mass was affected by a secondary explosion producing a lateral blast and destroying over  $500 \text{ km}^2$  of forest area. The maximum velocity of the blast was assumed to be more than 80 m/s. A plinian eruption followed just after the emplacement of the debris avalanche and a pyroclastic flow of  $0.1 \text{ km}^3$  was also emplaced. The climactic eruption was over in the evening of May 18. The total number of fatalities was 57.

Plinian eruptions with pyroclastic flows were produced on several occasions through October 1980 and then a new lava dome began to grow on the floor of the amphitheater. Small-scale explosive eruptions and intrusion of new lobes were repeated until October 1986.

### B. 1888 Bandai (Bandai Type)

The first seismic activity began on July 8, 1888. Continuous seismicity occurred almost every day until the morning of July 15. Then a strong earthquake was felt about 7:30 a.m. on July 15. A series of strong earthquakes followed and finally a phreatic explosion occurred at the summit. After a further 15–20 explosions occurred, the northern sector of the volcano collapsed to produce a debris avalanche. The debris avalanche covered an area of 3.5 km<sup>2</sup> and its volume was 1.5 km<sup>3</sup>. Small-scale explosions followed 30–40 min after the climactic event. The eruption was over by the evening of the same day. The total number of fatalities was 461.

### C. 1792 Unzen (Unzen Type)

A swarm of earthquakes began in November 1791. A magmatic eruption began on February 29, 1792. The volcano produced a dacite lava flow from a vent at the northern slope of Unzen volcano by April 23. Its volume was about 0.03 km<sup>3</sup>. A swarm of tectonic earthquakes occurred simultaneously with the discharge of the lava flow. A small-scale collapse of part of a 4000-year-old lava dome, Mayuyama, located 4 km away from the vent of the new lava, occurred on April 9. A second and climactic collapse was triggered by a relatively large tectonic earthquake ( $M = 6.4$ ) on May 21. The avalanche flowed into Ariake Bay and generated a major tsunami. The total volume of the avalanche was 0.48 km<sup>3</sup>. The total number of fatalities was 15,190, including 11,000 taken by the tsunami.

amphitheater at the source is also a characteristic geomorphic feature. The internal framework that characterizes debris avalanche deposits is composed of debris-avalanche blocks and a debris-avalanche matrix. The former comprises large fractured and deformed fragments mostly derived from the source volcano, preserving original internal structures and textures. The latter consists of a mixture of smaller volcanic fragments derived from various parts of the source volcano and mixed with a minor amount of exotic materials.

Three types of link to eruption processes are defined: debris avalanches associated with intrusion of new magma, those associated with phreatic explosions, and those triggered by earthquakes. The ratio of collapse height to runout distance is generally between 0.2 and 0.06. In some cases, clay-rich debris avalanches may transform into lahars and spread over a much wider area.

The eruption and emplacement of debris avalanches are now recognized as common phenomena during the entire growth history of composite volcanoes. However, the transportation process for debris avalanches is not yet fully understood. The frequency of this type of volcanic activity is lower than the other styles of eruption, but the magnitude of single events is generally large and hazardous. Thus, further work, both theoretical modeling and case studies of deposits, is necessary for the mitigation of volcanic risk.

in a turbulent fashion downslope under the influence of gravity.

**volcaniclastics** Particles formed by the fragmentation of volcanic rocks, irrespective of the method of fragmentation or the nature of the transporting agent.

**volcaniclastic apron** Wedge-shaped accumulation of volcaniclastic material in the backarc area of an island arc.

---

## GLOSSARY

- debris flow** Dense mixture of particles and water that moves in a laminar fashion downslope under the influence of gravity.
- epiclastics** Particles formed by the erosion or weathering of preexisting volcanic rocks.
- hydroclastics** Particles formed by the fragmentation of magma by interaction with external water.
- marginal basin** Basin located in the backarc area of an island arc that forms by either extension or capture of a piece of oceanic crust.
- pyroclastics** Particles formed by the explosive fragmentation of magma.
- turbidites** Deposits produced by sedimentation of particles from a turbidity current.
- turbidity current** Mixture of particles and water that moves

**I**SLAND ARCS ARE arcuate belts of volcanoes linked to subduction of ocean crust into the Earth's mantle. They occur throughout the world's oceans but are especially abundant around the rim of the Pacific Ocean, where they form a nearly continuous belt known as the "Ring of Fire." Volcanic activity at subduction zones produces abundant fragmental material, referred to as volcaniclastics, owing to the explosive nature of the eruptions and the potential for interaction of magma with water. In this article the term volcaniclastic is applied to all clastic material produced by the fragmentation of volcanic rocks, irrespective of the method of fragmentation or the nature of the transporting agent. Pyroclastic is a term applied to particles formed directly from an explosive eruption. Hydroclasts are also particles formed by fragmentation of magma during eruptions but involve the interaction of magma with external

water. Finally, epiclasts are particles formed by the erosion or weathering of preexisting volcanic rocks.

The percentage of volcanoclastic material in island arcs is typically in excess of 90% by volume, compared to less than 40% for intraplate oceanic islands, such as Hawaii, and less than 10% for midocean ridges. A majority of the fragmental material produced in island arcs is deposited in the marine environment surrounding the arc as thick sequences of volcanoclastic sediments. The composition, distribution, and facies variations of these deposits are controlled by a complex interplay between the tectonic evolution of island arcs, the rate and type of volcanic activity, and the nature of the transporting processes.

Island arc volcanoclastic sequences are valuable for the reconstruction of the history of volcanic activity associated with plate subduction. Such sequences are often incorporated into continental margins by accretion and constitute an important component of ancient continental crust. In addition, the coarse-grained nature of the deposits and their location in areas of high heat flow make them a potential reservoir for hydrocarbon production if the organic content of the sediments is high enough. Finally, in some arc environments the circulation of high-temperature fluids through these types of deposits provides favorable conditions for the formation of economically important metal ore deposits of copper, lead, zinc, silver, and gold.

Information about the nature of island arc volcanoclastic deposits has come from a wide variety of sources, including drilling in modern arc environments, coring of recent sediments, submersible observations, and the study of ancient uplifted sequences. Deep drilling by the Deep Sea Drilling Project (DSDP) and its successor,

the Ocean Drilling Program (ODP), has been especially useful for defining the characteristics, distribution, and facies evolution of arc volcanoclastics in modern and ancient arc environments. This drilling has focused primarily on island arcs of the western Pacific, such as the Marianas, Izu-Bonin, Tonga, and Japan, and provides a wealth of new information concerning these important types of deposits.

## 1. DEPOSITIONAL ENVIRONMENTS SURROUNDING ISLAND ARCS

### A. Structural Elements of Island Arcs

Considerable variability exists among island arcs throughout the world but a generalized model can be adopted for the purposes of defining areas where volcanoclastic sediments accumulate. Subduction of oceanic crust beneath other ocean crust creates a number of distinct depositional environments that trap volcanoclastic sediment derived from various sources in island arcs (Fig. 1). A conspicuous feature of island arcs is a deep sea trench that defines the intersection between the subducting and overriding plates. These trenches can be very deep (up to 11 km), rather narrow, and laterally continuous for hundreds of kilometers. In some cases, trenches are filled with sediment and their bathymetric expression is subdued or obliterated. In others, where sediment supply is low, they contain only minor amounts of sediments and extend to great depths.

Moving toward the volcanic arc, there is a broad fore-

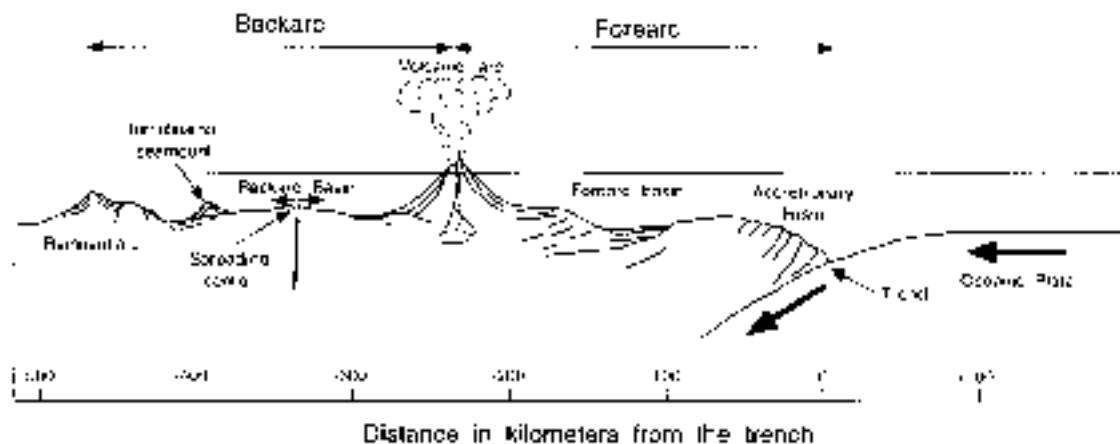

FIGURE 1 Cross section through a typical oceanic island arc showing the major structural components. The arc is subdivided into the backarc and forearc by the active volcanic arc.

arc region that is formed by a combination of the seaward flanks of volcanoes from the volcanic arc and material accreted onto the forearc through the process of subduction (Fig. 1). The accretion of material occurs when the downgoing slab is capped by a sedimentary sequence that can be scraped off as it enters the trench. A decollement typically develops between an upper sequence of sediments that eventually becomes incorporated into the forearc and a lower sequence that continues on beneath the overriding plate. Progressive scraping-off of sediment leads to the development of an accretionary prism, consisting of packages of sediment that are separated from one another by thrust faults (Fig. 1). Each package experiences arcward rotation and uplift. In some cases the uplift is sufficient to raise the sequence above sealevel as a series of nonvolcanic islands in front of the volcanic arc. There are a variety of potential configurations of the forearc area, depending on the supply of sediment to the trench, the extent of scraping off of sediment, and the extent to which the downgoing slab is coupled to the overriding plate. The potential exists to form forearc basins that can trap large quantities of volcaniclastic debris.

The volcanic arc forms the main elevated structural feature of an island arc and consists of an elongate belt of submarine and subaerial volcanic centers where the majority of volcanism takes place (Fig. 1). These centers consist of a core of intrusive/extrusive igneous rocks that record their growth on oceanic crust from deep-to shallow-water conditions and/or emergence as a subaerial edifice. In some arcs small intra-arc basins are developed between volcanic centers and act as traps for coarse-grained volcaniclastic sediment.

A major environment for the deposition of volcaniclastic material in island arcs occurs in the backarc area, where small basins are formed by either (1) backarc spreading (extensional) or (2) trapping of existing segments of ocean crust (nonextensional, Fig. 1). Basins formed by extension show similar characteristics to major ocean basins produced by spreading from midocean ridge systems such as crustal thickness, occurrence of magnetic lineations, basaltic composition, and a layered structure. However, the depths of the backarc basins tend to be deeper compared to typical oceanic basins of similar age.

## B. Evolution of Depositional Environments

Island arcs are dynamic systems that evolve tectonically and geomorphically as subduction progresses. Deposi-

tional environments change location and size in response to this evolution both in the backarc and in the forearc. In the forearc, the growth of an accretionary prism by accretion of sediments will lead to trenchward extension of the forearc and uplift of forearc basins. Alternatively, tectonic erosion of the overriding plate by the subducting plate may lead to forearc regression and subsidence.

More profound changes occur in the backarc environment of island arcs. Analysis of the history of several western Pacific arcs, such as the Marianas, has revealed that they exhibit a cyclic behavior in the formation of backarc basins (Fig. 2). Initiation of basin formation occurs with rifting of the volcanic arc. Part of the arc becomes inactive and migrates away from the active arc by extension. The inactive segment forms a remnant arc that remains as an elevated, but submerged, ridge. Rifting eventually develops into a spreading center where new crust is generated to feed the growth of the backarc basin. With time, the basin becomes wider and new crust on either side of the spreading center subsides as it cools (Fig. 2). At some point the spreading center migrates far enough away from the active arc that volcanism at the center begins to wane. Rifting then jumps back to the volcanic arc and a new cycle of basin formation begins. The exact cause of the decline is not well understood. Not all arcs exhibit this type of behavior and new rifting can occur either behind or in front of the active volcanic arc. However, the cyclic behavior of backarc basin generation appears to be a common feature of many systems, especially in the western Pacific.

---

## II. SOURCES AND TRANSPORT MECHANISMS OF VOLCANICLASTIC SEDIMENT

### A. Subaerial Arc

The principal source of volcaniclastic material to marine basins adjacent to island arcs is the subaerial volcanic arc where the majority of volcanism is focused (Figs. 1 and 3). Explosive fragmentation of magma is a characteristic feature of subduction zone volcanism, with a wide range of compositions being erupted (basalt to rhyolite). Eruption styles vary from small events, such as strombolian, to very energetic eruptions of plinian scale. Large quantities, up to hundreds of thousands of cubic meters, of pyroclastic and/or hydroclastic material can be generated during single eruptions and dispersed over large areas by a variety of transport mechanisms. The main

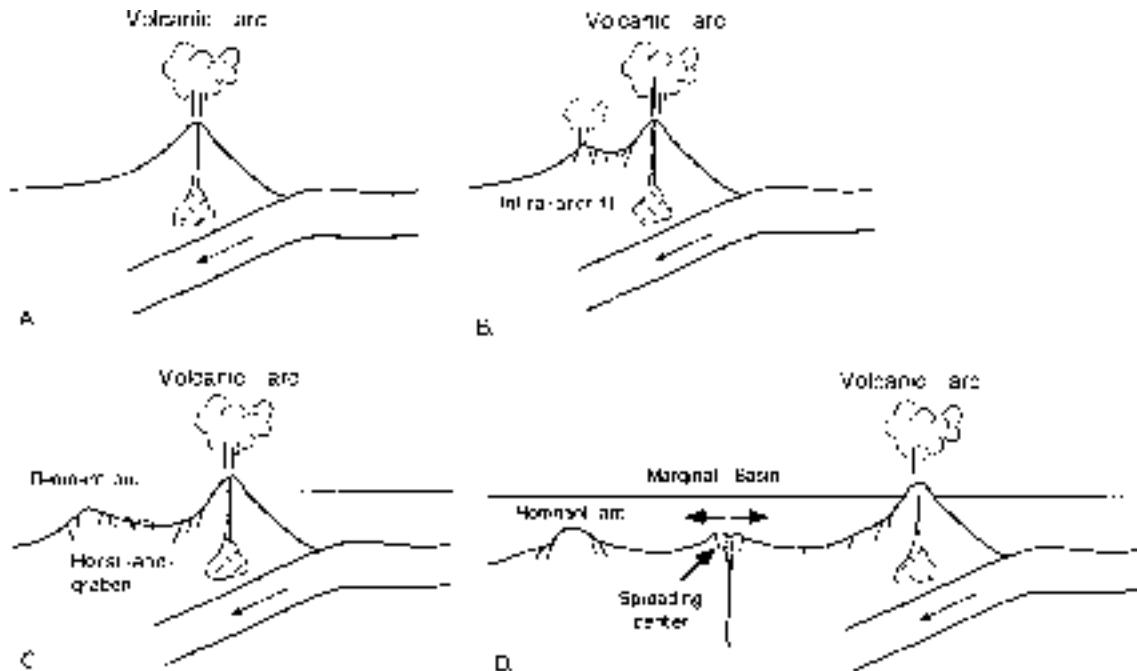

FIGURE 2 Generalized tectonic evolution of an oceanic island arc. A backarc marginal basin is created by rifting of the volcanic arc and the development of a backarc spreading center. The sequence may repeat several times during the history of a single island arc system.

components of this material are (1) pumice and/or scoria (coarse fragments formed by exsolution of dissolved gases from magma), (2) glass shards (fine-grained particles formed by the explosive disruption of magma), (3) crystals (silicate minerals that were growing in the magma prior to eruption), and (4) foreign lithics (pieces of the old volcanic edifice that are ejected during eruption). In general, the compositional variation of material derived from an individual eruption will be restricted and correlation of deposits over a wide area can be accomplished based on geochemical characteristics.

An effective mechanism for dispersal of pyroclastic material into the ocean is by direct fallout from volcanic plumes generated by explosive eruptions. These plumes transport particles and gas high into the atmosphere by thermal convection and are then dispersed over wide areas by the prevailing winds. Fallout of particles from such plumes may extend over thousands of square kilometers and produce a blanket deposit that extends over the entire extent of island arc basins.

Large amounts of pyroclastic material can also be directly discharged into the ocean by different types of pyroclastic density currents generated during explosive eruptions on the volcanic arc (Fig. 3). Pyroclastic flows are hot mixtures of gas and particles that move down

the slopes of island volcanoes at high velocity and may discharge directly into the sea. The nature of the interaction between these high-temperature flows (up to 600°C) and seawater is controversial but there is evidence that parts of the flows may continue on underwater and retain high temperatures to form primary submarine pyroclastic flow deposits. In other cases, the flows mix with seawater and are transformed into debris flows or high-concentration turbidity currents. A more dilute form of hot flow, known as pyroclastic surge, can also transport freshly erupted material to the sea. However, the mass transported by surges is usually less than that from pyroclastic flows.

Another important type of flow that can transport large amounts of fresh pyroclastic material to the sea is lahars. These are mixtures of water and pyroclastic material that move as hyperconcentrated flood flow or debris flows. They can be generated during explosive eruptions by rainfall onto freshly deposited pyroclastic deposits on steep volcanic slopes or the ejection of a crater lake by explosive activity. Discharge of lahars along island coasts where river valleys reach the sea produces deltas and turbidity currents that move sediment into deeper water.

It is common for explosive eruptions in island arcs to

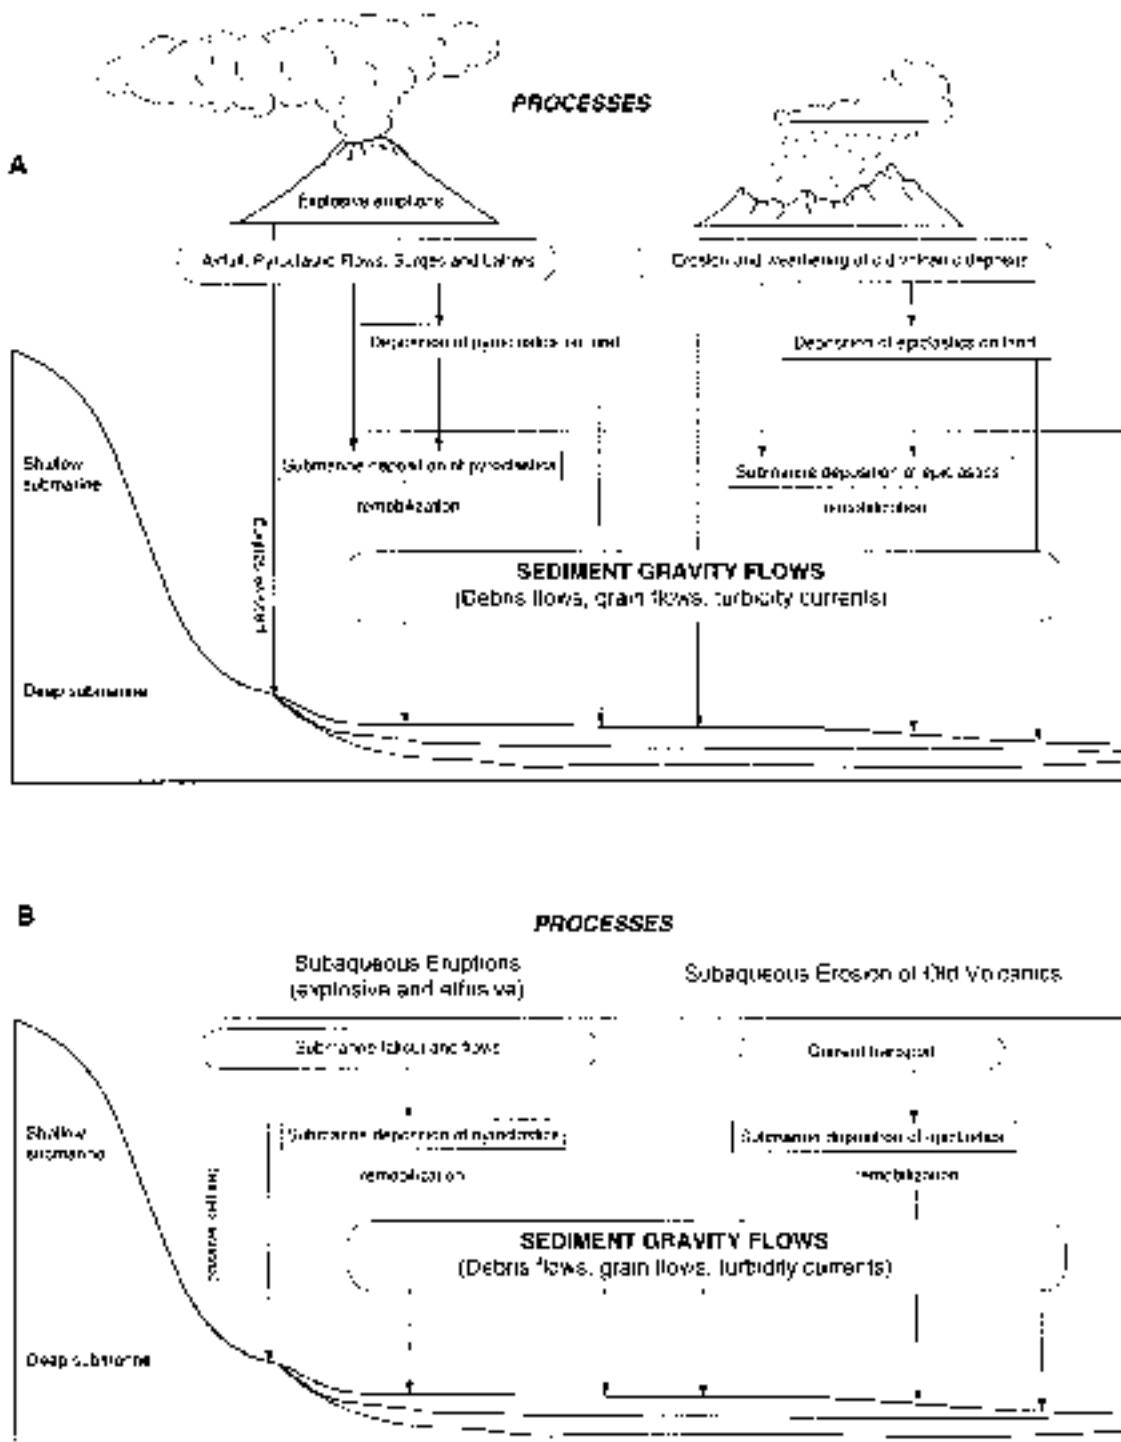

FIGURE 3 Summary of the sources and transport processes of volcaniclastic sediment in island arcs derived from (A) the subaerial volcanic arc and (B) the submarine volcanic arc.

generate large quantities of low-density pumice. If the density of the clasts is less than the density of seawater, then delivery by fallout or flow can produce thick, extensive rafts of pumice. Eventually all pumice will sink, but some may remain buoyant for several months, allowing for widespread dispersal by ocean currents. The rafts continually lose pumice as they move along, as saturation of smaller pieces takes place and large clasts are broken up by abrasion.

Delivery of freshly erupted pyroclastic material to the ocean occurs episodically during explosive eruptions. Enormous volumes of sediments (100s of km<sup>3</sup>) can form during single eruptions in major sedimentation events in adjacent marine basins. The duration of such events can vary widely from a few days to prolonged periods of activity that may span several years. Volcaniclastic material is also supplied to the sea from the subaerial arc on a more continuous basis through the slower erosion of preexisting pyroclastic deposits, lava flows, and other volcanic deposits to form epiclastic particles (Fig. 3). These are delivered by runoff from streams and rivers, aeolian transport by local winds, and slope failure into the sea. The composition of epiclastic material is likely to be more diverse than that of primary pyroclastic material owing to the larger variability of older volcanic deposits that are susceptible to erosion and weathering. Furthermore, deeply dissected volcanic centers may expose plutonic rocks with more diverse compositions, larger crystal sizes, and different mineral assemblages.

## B. Submarine Arc

Significant production of volcaniclastic particles also takes place in the submarine environment of a volcanic arc (Fig. 3). Explosive volcanism is limited by the effect of water pressure and studies suggest that it occurs to depths of 200–500 m, and possibly as deep as >1000 m for some gas-rich magmas. Fragmentation by degassing can generate subaqueous eruption columns and submarine pyroclastic density currents consisting of abundant pumiceous material. In addition, the mixing of hot magma with seawater provides an additional mechanism for generating particles by explosive fragmentation. Such phreatomagmatic activity is also limited to water depths of less than a few hundred meters. However, fragmentation of freshly erupted magma can occur even at great water depths as a result of thermal granulation and spallation that takes place during the rapid quenching of magma exposed to cold seawater.

Recent studies of submarine arc volcanoes in the Ker-

madec arc have led to new insights about volcaniclastic processes operating in these environments. Submarine stratovolcanoes are characterized by fine-scale spatial variability in the distribution of volcaniclastic material, lava flows, and background sediments. Mass movement of material occurs by frequent small-volume debris flows that redistribute material to the lower portions of the edifice. Eruption of submarine lavas is often accompanied by the production of localized pillow breccia. Bottom currents continually rework primary and epiclastic deposits on the submarine slopes of the volcanoes, leaving winnowed and rippled deposits and removing fine-grain material for deposition in deeper water.

## C. Backarc Sources

Sources of volcaniclastic sediment in the backarc environment include the remnant arc, the backarc spreading center, and intrabasinal seamounts (Fig. 1). The remnant arc typically represents an inactive portion of an original arc and consequently is not an important source of primary pyroclastic material. However, submarine erosion and weathering of the structure provide a source of epiclastic sediment for adjacent basins. Movement of sediment from the remnant arc occurs primarily by mass wasting, small-scale turbidity currents, and reworking by bottom currents. Downslope movement is likely to be initiated by frequent earthquakes because arcs are seismically very active.

Backarc spreading centers provide a minor source of volcaniclastic sediment by the formation of hyaloclastites associated with the quenching of dominantly basaltic magma. Such deposits of sand-to-silt-sized basaltic glass are usually restricted to the axial spreading zone but can be dispersed to deeper water if strong bottom currents are active. A more important source of volcaniclastic sediment in the backarc is intrabasinal seamounts that form during the early stages of backarc rifting. For example, in the Sumisu rift in the Izu-Bonin arc of the western Pacific, intrabasinal seamounts have been shown to be a source of basic to silicic volcaniclastic sediment for nearby basins. The compositional diversity of magmas from these sources can be large and thus the potential for more explosive types of volcanism is greater.

---

## III. DEPOSITIONAL SEQUENCES

The types of volcaniclastic sequences in island arcs vary greatly depending on their position relative to the arc

and the distribution of sediment sources. Deep sea drilling has provided important information about the lithology, thickness, and origin of volcaniclastic deposits within specific arc environments. Furthermore, the drill sites provide a valuable record of the temporal facies changes that occur in different depositional environments. These types of records are critical for building models of sedimentation because the relationships between the depositional sites and their sources are well constrained and facies evolution can be documented. In this section, a series of examples of volcaniclastic sedimentary sequences from each of the major arc environments will be given to illustrate the diversity of these sections and the major processes responsible for their creation.

### A. Forearc

Although there are many different potential configurations for a forearc environment, the area east of the Izu-Bonin arc in the western Pacific serves as a good example of the types of deposits that are typical of such areas. ODP Site 792 was drilled in a forearc sedimentary basin about 60 km east of the active volcanic arc in a water depth of 1798 m (Fig. 4). The sedimentary section at this site contains a wide variety of volcaniclastic deposits (Fig. 5). In the upper section (Unit 1) vitric sand and silt layers, usually less than 20 cm thick, are abundant. They consist of fresh glass (mafic and/or silicic) and crystals of orthopyroxene, clinopyroxene, and plagioclase. Some layers show planar laminations and normal

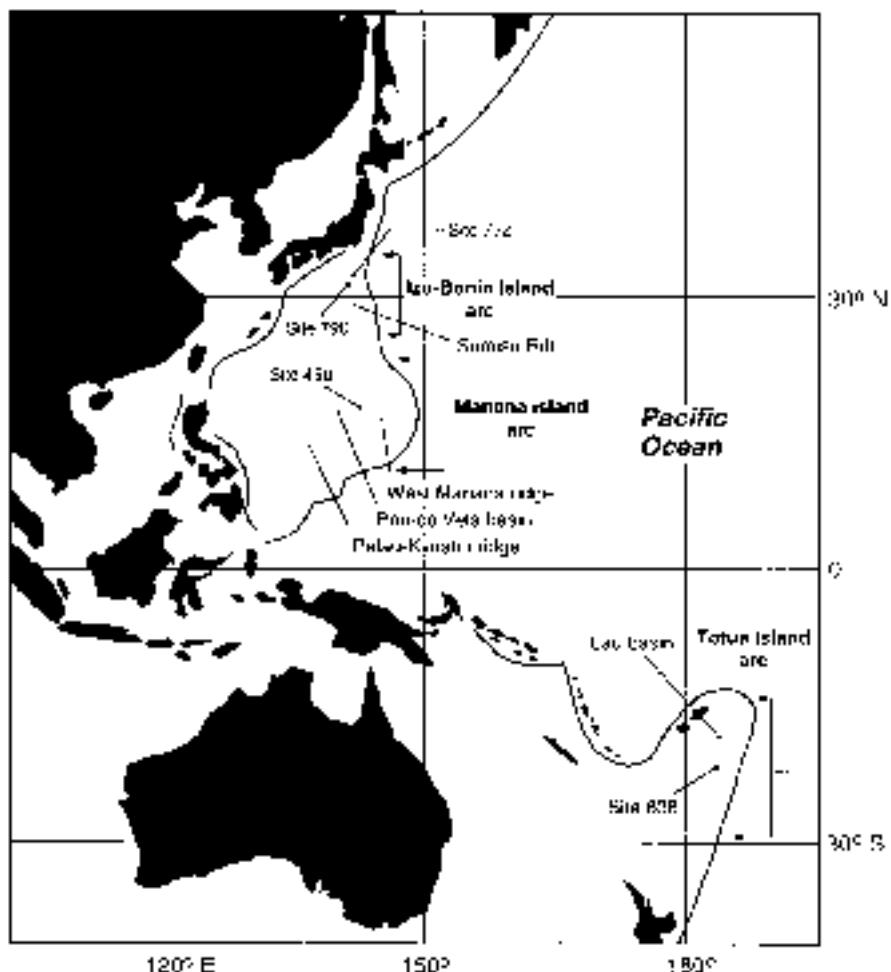

FIGURE 4 Island arc systems of the western Pacific margin. Solid line indicates the trace of the trenches where ocean crust is being subducted. Shaded patterns outline the shape of backarc basins. Drill sites are shown as small solid circles.

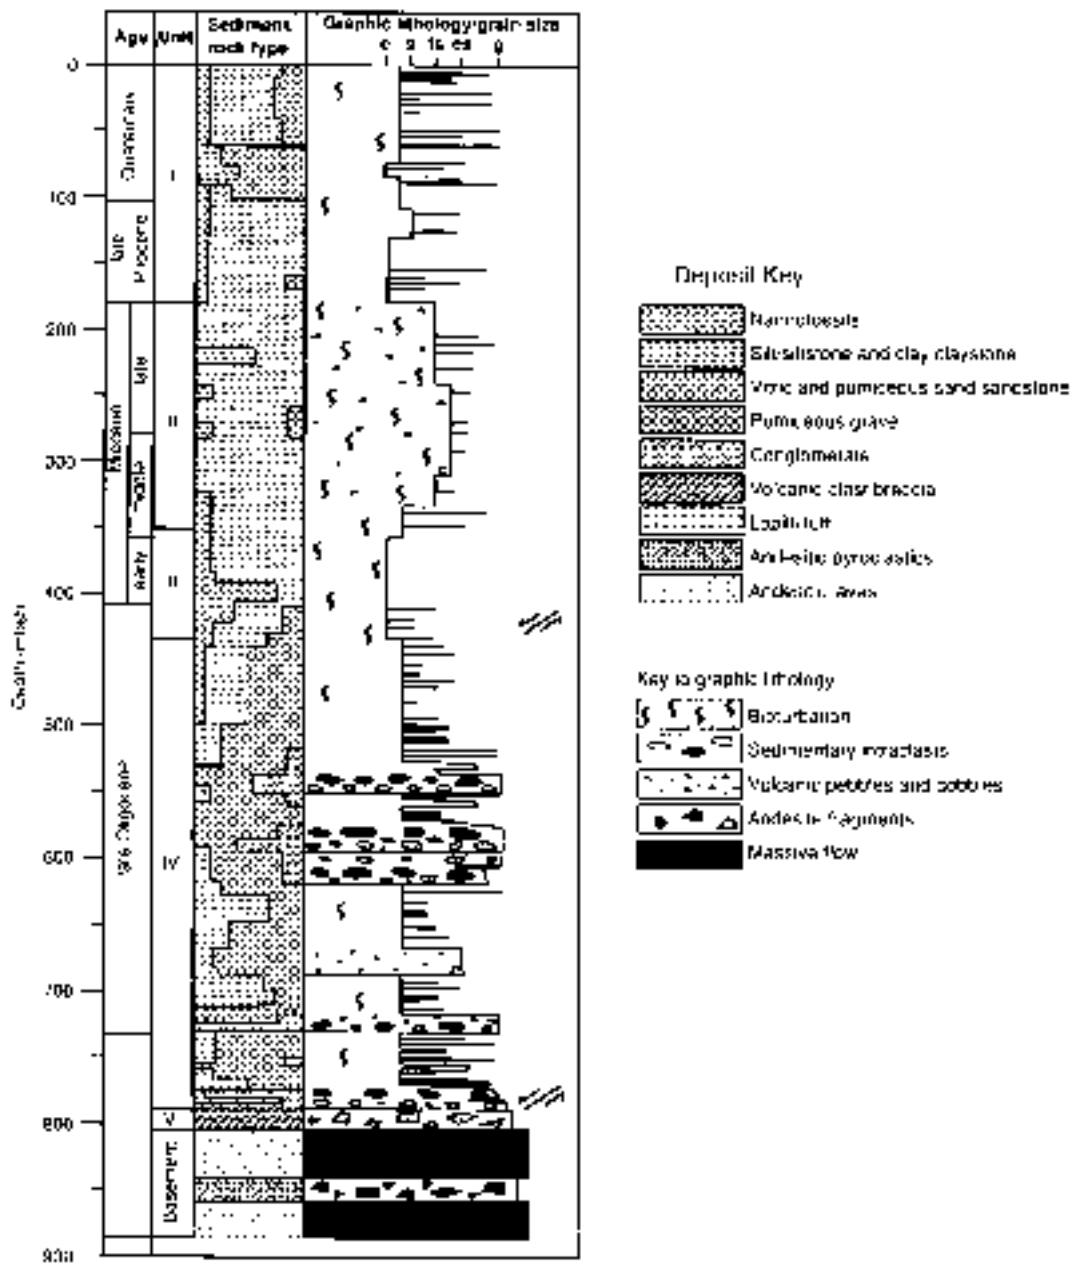

FIGURE 5 Stratigraphic section of ODP Site 792 drilled in the forearc area of the Izu-Bonin island arc (see Fig. 4 for location). In the graphic lithology/grain size, c = clay, s = silt, fs = fine sand, cs = coarse sand, and g = gravel. Mbsf refers to meters drilled below the seafloor.

grading is also a common feature. These deposits are interpreted as fall deposits formed from explosive eruptions that took place on the volcanic arc to the west. Some are also likely to be the result of small turbidites that have reworked relatively fresh pyroclastic material.

Lower in the section the volume of volcanioclastic material increases and thick vitric sandstones and conglom-

erates are abundant (Unit IV, Fig. 5). Individual vitric sandstones are up to 3 m thick but range down to a few centimeters. The thickest units are typically massive, with some normal grading and rarely with laminated tops. Thinner beds include planar and cross laminations, flute casts, and flame structures. Their composition is dominated by either mafic or felsic components (glass

and crystals), but there are rare examples of mixed lithologies. These units are predominantly turbidites and are similar to deposits that are found on the middle and outer parts of submarine fans. There is, however, no strong evidence for the formation of highly structured submarine fan systems in the forearc, and the multiple and episodic source nature of the volcaniclastic material in this area is expected to produce a complex oversupplied depositional system.

Conglomerates form thick, coarse-grained deposits that exhibit both massive and normally graded types. Intraclasts of sedimentary material up to several centimeters in diameter are common and found "floating" within the units. Massive conglomerates likely formed from debris flows whereas the normally graded types are the products of highly concentrated turbidity currents. Some of the conglomerates have a diverse composition, with mixed clasts of andesite, dacite, and other porphyritic rocks. This suggests that they are associated with the erosion of existing deposits and not directly related to eruptive activity.

Figure 6 summarizes the major depositional processes taking place in the forearc environment of the Izu-Bonin island arc. The principal mechanisms of volcaniclastic sediment input include fallout from explosive eruptions, syneruptive turbidity current initiation, redeposition of

material by turbidity currents during noneruptive periods, and debris flow generation on the forearc slopes.

### B. Early Intra-arc Rift

The evolution of an island arc often involves the repeated formation of backarc basins by rifting and extension (Fig. 2). In the early stages of this cycle, the arc develops isolated basins that serve as important depositional sites for volcaniclastic sediment. The Sumisu rift in the Izu-Bonin arc of the western Pacific is considered to represent the early stages of arc rifting (Fig. 4). It is subdivided into a series of smaller basins by submarine volcanic centers that trend from southwest to northeast. ODP Site 790 was drilled within a small basin (Minami Sumisu) of the Sumisu rift in a water depth of 2222 m (Fig. 4). The upper part of the sedimentary sequence of Site 790 consists of a spectacular sequence of thick pumiceous gravels and sands interbedded with vitric silts and sands (Fig. 7). Pumiceous gravels often grade upward into sands and silts, forming a series of distinct fining-upward sequences that are 15–30 m thick. They typically contain pumice, crystals, and glass of silicic composition. A secondary component of the deposits is

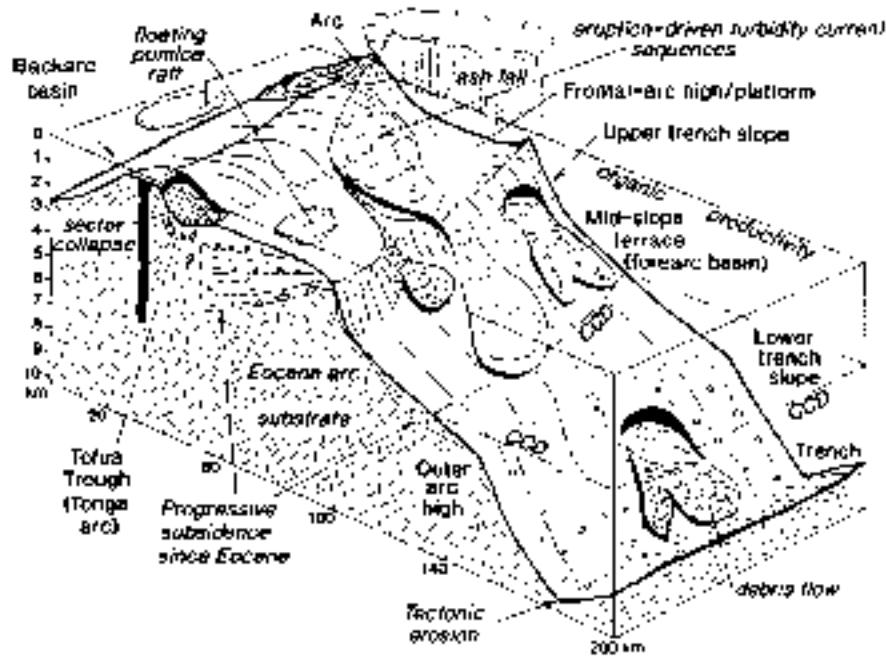

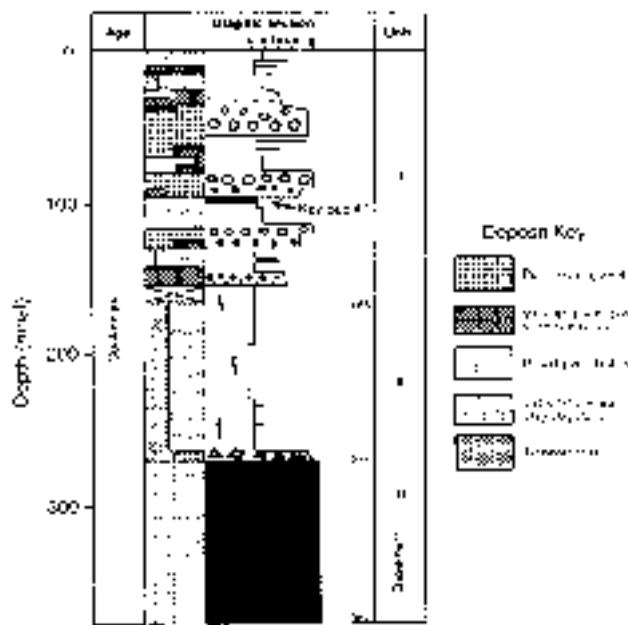

FIGURE 6 Summary of volcaniclastic sedimentation processes in the forearc area of an intraoceanic island arc [from Underwood et al., 1995].

**FIGURE 7** Stratigraphic section of ODP Site 790 drilled in the intra-arc rift of the Izu-Bonin island arc (see Fig. 4 for location). In the graphic lithology/grain size, c = clay, s = silt, fs = fine sand, cs = coarse sand, and g = gravel. Mbsf refers to meters drilled below the seafloor.

biogenic grains of molluscs, bryozoans, and foraminifers. Mafic material is restricted to thinner, finer grained intervals separating the coarse units. The gravels are poorly sorted, contain angular to subrounded clasts, and are generally structureless. In contrast, the vitric sands and silts are often normally graded and show parallel lamination. In the lower part of the sequence the thickness and grain size of the volcaniclastic material decrease significantly and only thin ash beds and scattered clasts of pumice and scoria are present (Fig. 7).

The thick silicic pumiceous deposits in the upper part of Site 790 were derived from great submarine explosive eruptions of either the Minami Sumisu or Tori Shima calderas to the east of the Minami Sumisu basin. Emplacement of the units occurred predominantly by sediment gravity flows during the eruptions. These include primary submarine pyroclastic density currents and/or remobilization of submarine fallout as debris flows and highly concentrated turbidity currents. Coarse pumice is also likely to be transported to the basin by floating pumice rafts generated by submarine eruptions that breach the surface. Drifting pumice eventually becomes waterlogged and sinks to the seafloor.

The sequence from Site 790 indicates that young interarc basins are subject to rapid influxes of coarse pumi-

ceous volcaniclastic material that form very thick sequences of gravity flow deposits interbedded with minor amounts of background marine sediment derived from biological and epiclastic inputs. In the Sumisu rift the facies evolution was an overall coarsening upward, suggesting an initially low flux of material at the start of rifting followed by a period of more vigorous explosive eruptions. Because of the proximity of source volcanoes, the sedimentation rates in these environments can be as much as 1000 m/myr.

### C. Young Marginal Basin

As backarc extension evolves, the intra-arc rift gives way to a wider basin where spreading centers begin to develop. However, the configuration of such basins can be complex depending on the location of initial rifting. The Lau basin of the Tonga-Kermadec island system is an example of a backarc basin that evolved by the splitting of an island arc in the forearc region (Fig. 4). Consequently, the growth of the basin was accompanied by an eastward migration of arc volcanism until a new arc, the Tofua island arc, was created to the east. The migration of arc volcanism and the development of active spreading centers in the basin created a complicated tectonic structure upon which volcaniclastic sedimentation was superimposed. A principal effect of the migration was to compartmentalize the area into a sequence of small isolated subbasins with horst-and-graben structure. Drilling within these small subbasins revealed sedimentary sequences that were very similar in overall structure yet quite independent of one another. ODP Site 838 was drilled in one of the small subbasins to the west of the Valu Fa ridge in water depth of 2400 m (Fig. 8).

The basal part of Site 838 consists of a thick sequence of polymict vitric gravels, sandstones, and siltstones with minor interbeds of hemipelagic ooze (Fig. 8). The gravels contain fragments of mafic igneous rocks, pumice, and tuffaceous sediment. Their composition consists of a mixture of rhyolite, dacite, and basaltic andesite. Overlying the basal sequence is a thick interval of vitric sands and silts, interbedded with pumiceous gravels. The vitric sands and silts are a few centimeters to 5 m thick. They contain abundant colorless glass shards, pumice fragments, and crystals, together with lesser amounts of brown, more mafic glass shards. Basal contacts are typically erosive and individual units exhibit normal grading and occasional lamination. Pumiceous gravels form thick units (8–15 m), with abundant pumice lapilli.

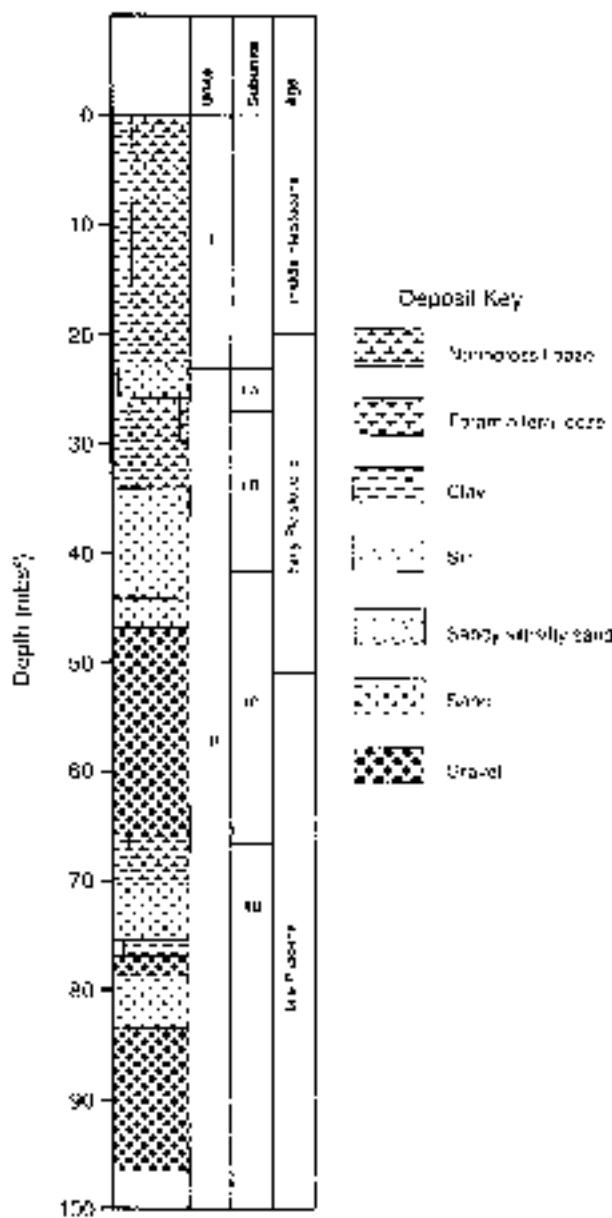

FIGURE 8 Stratigraphic section of ODP Site 838 drilled in the backarc area of the Tofua island arc (see Fig. 4 for location). Mbsf refers to meters drilled below the seafloor.

Pumice diameters are up to 7 cm and the units are poorly sorted. Pumice compositions are dominantly rhyodacitic but hyaloclastites of basaltic andesite composition are also present.

The coarse-grained and mixed-lithology basal conglomerates were produced by mass flows of epiclastic material derived from local sources. Similarly, the overlying coarse-grained pumiceous gravels were deposited

from debris flows generated by mobilization of volcaniclastic material near the basin margins. The likely source of this volcaniclastic material is intrabasinal seamounts linked to the migration of arc volcanism to the west. Each small basin was subject to proximal deposition from these centers but then subsequently isolated as the locus of volcanism shifted. The development of horst-and-graben structures eventually led to the isolation of the basins from extensive deposition by mass flow processes. This is seen in the general upward fining of the sequence at Site 838 and other sites located in similar basins. The vitric sands and silts were emplaced by turbidity currents but their source remained proximal to the basin because of the tectonic isolation imposed by the local structure. In the uppermost sediments, corresponding to the most recent times, volcaniclastic input is restricted to the fallout of volcanic ash from subaerial eruption plumes from the active arc to the west and the local redeposition of that material by small turbidity currents.

#### D. Mature Marginal Basin

Prolonged backarc extension leads to the development of a wide mature basin. Spreading is focused at an axial rift where basaltic volcanism creates new basin crust. The average life span of backarc spreading is usually less than 25 million years. In the Mariana arc system, repeated formation of backarc basins has occurred for at least 30 million years (Fig. 4). The Parece Vela basin represents an inactive mature marginal basin that is flanked on the west by a remnant arc (Palau–Kyushu ridge), contains an old spreading rift (Parece Vela rift), and is bordered on the east by a young remnant arc (West Mariana ridge). DSDP drilling in the Parece Vela basin provides a good example of the types of volcaniclastic sequences developed in mature marginal basins.

Site 450 is located west of the Mariana ridge in 4707 m of water (Fig. 4). At the base of the sequence is a thin sequence of pillow basalts intruded into wet sediments during the earlier stages of basin spreading (Fig. 9). Overlying the pillow basalts is a thick sequence of middle Miocene vitric tuffs and tuffaceous volcaniclastic conglomerates that accumulated at a rate as high as 100 m/myr. The vitric tuffs were produced by fallout from explosive eruptions on the West Mariana ridge and redeposition of pyroclastic and epiclastic material by turbidity currents. Thick tuffaceous conglomerates were the products of concentrated turbidity currents or debris flows. The dominantly epiclastic nature of the conglomerates is reflected in the large size of the clasts and the lack of significant sorting.

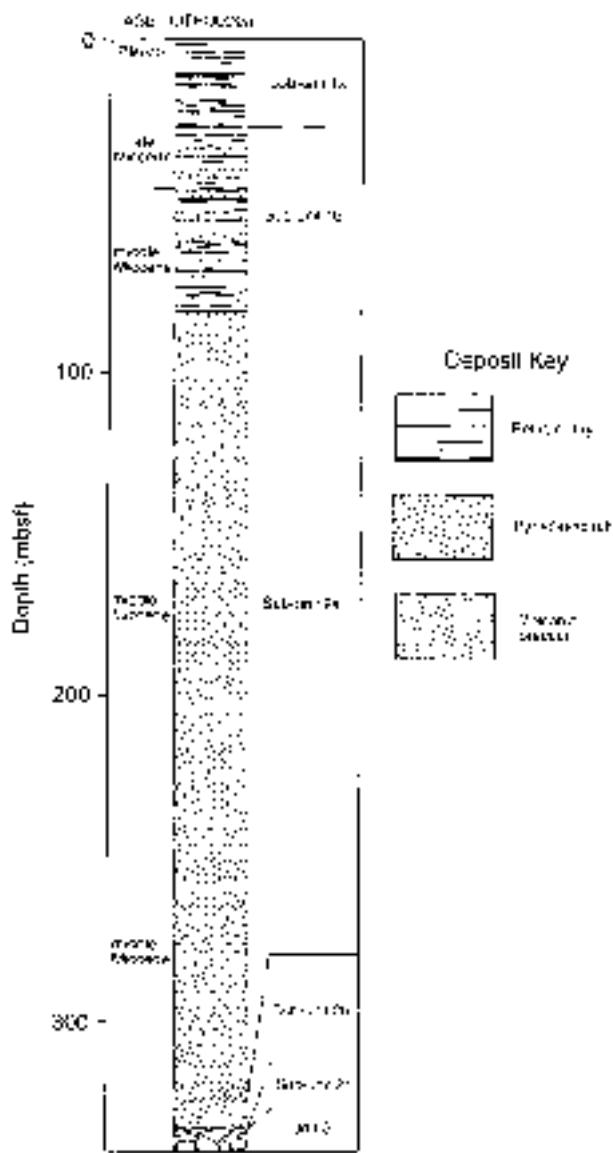

FIGURE 9 Stratigraphic section of DSDP Site 450 drilled in the backarc area of the Mariana island arc (see Fig. 4 for location). In the graphic lithology/grain size, c = clay, s = silt, fs = fine sand, cs = coarse sand, and g = gravel. Mbsf refers to meters drilled below the seafloor.

erates indicates redeposition of material from the erosion and weathering of older volcanic centers. In addition, the lower sequence of tuffs and conglomerates contains a significant amount of hyaloclastites derived from the submarine volcanism. The source of this material was most likely the spreading center of the Parece Vela basin and/or submarine volcanism on the west Mariana ridge. Hyaloclastites disappear upsection, reflecting waning of submarine volcanism in the backarc.

In the upper part of the sequence there are significant decreases in the amount of volcanoclastic sediment and the accumulation rate (Fig. 9). The dominant deposits are thin dark gray and brown vitric layers interbedded with pelagic clay. These were produced mainly by fallout of volcanic ash from explosive eruptions on the west Mariana ridge. However, these layers eventually die out in the most recent sediments, where volcanic ash is mostly found dispersed within pelagic clay. The sequence at Site 450 thus records an initial period of high volcanoclastic influx from the active west Mariana arc and the backarc spreading center to the east. As the basin widened, the supply of material from the backarc spreading center diminished, either because of the increased distance to the site or the waning of volcanism. In addition, the source of volcanoclastic material from the west Mariana ridge decreased as well, eventually becoming inactive in the late Miocene.

#### IV. VOLCANICLASTIC FACIES EVOLUTION IN ISLAND ARCS

The results of deep sea drilling and sediment core studies can be combined with the tectonic evolution of island arcs to produce a model for temporal and spatial facies changes in volcanoclastic sediments. The following discussion assumes a simple model for the tectonic evolution of an arc (Fig. 2) with the understanding that it will not apply to all oceanic arcs but nevertheless encompasses many of the stages shown by a typical arc. The model considers volcanoclastic and nonvolcanic marine sediments that form an integral part of the sedimentary sequence. In deep water the nonvolcanic sediments include (1) carbonate oozes consisting of microfossils of foraminifers, nannofossils, and pteropods, (2) pelagic clay consisting of windblown dust and dispersed volcanic ash, and (3) hemipelagic clay formed from a combination of microfossils and terrigenous input.

##### A. Initial Arc Rifting

Initial stages of arc rifting produce a narrow trough that is flanked by volcanoes of the active arc and elevated portions of the arc platform (Fig. 10A). Smaller volcanic centers within the rift subdivide it into a series of subbasins. These small basins receive large amounts of volcanoclastic material from nearby arc volcanoes and, to a

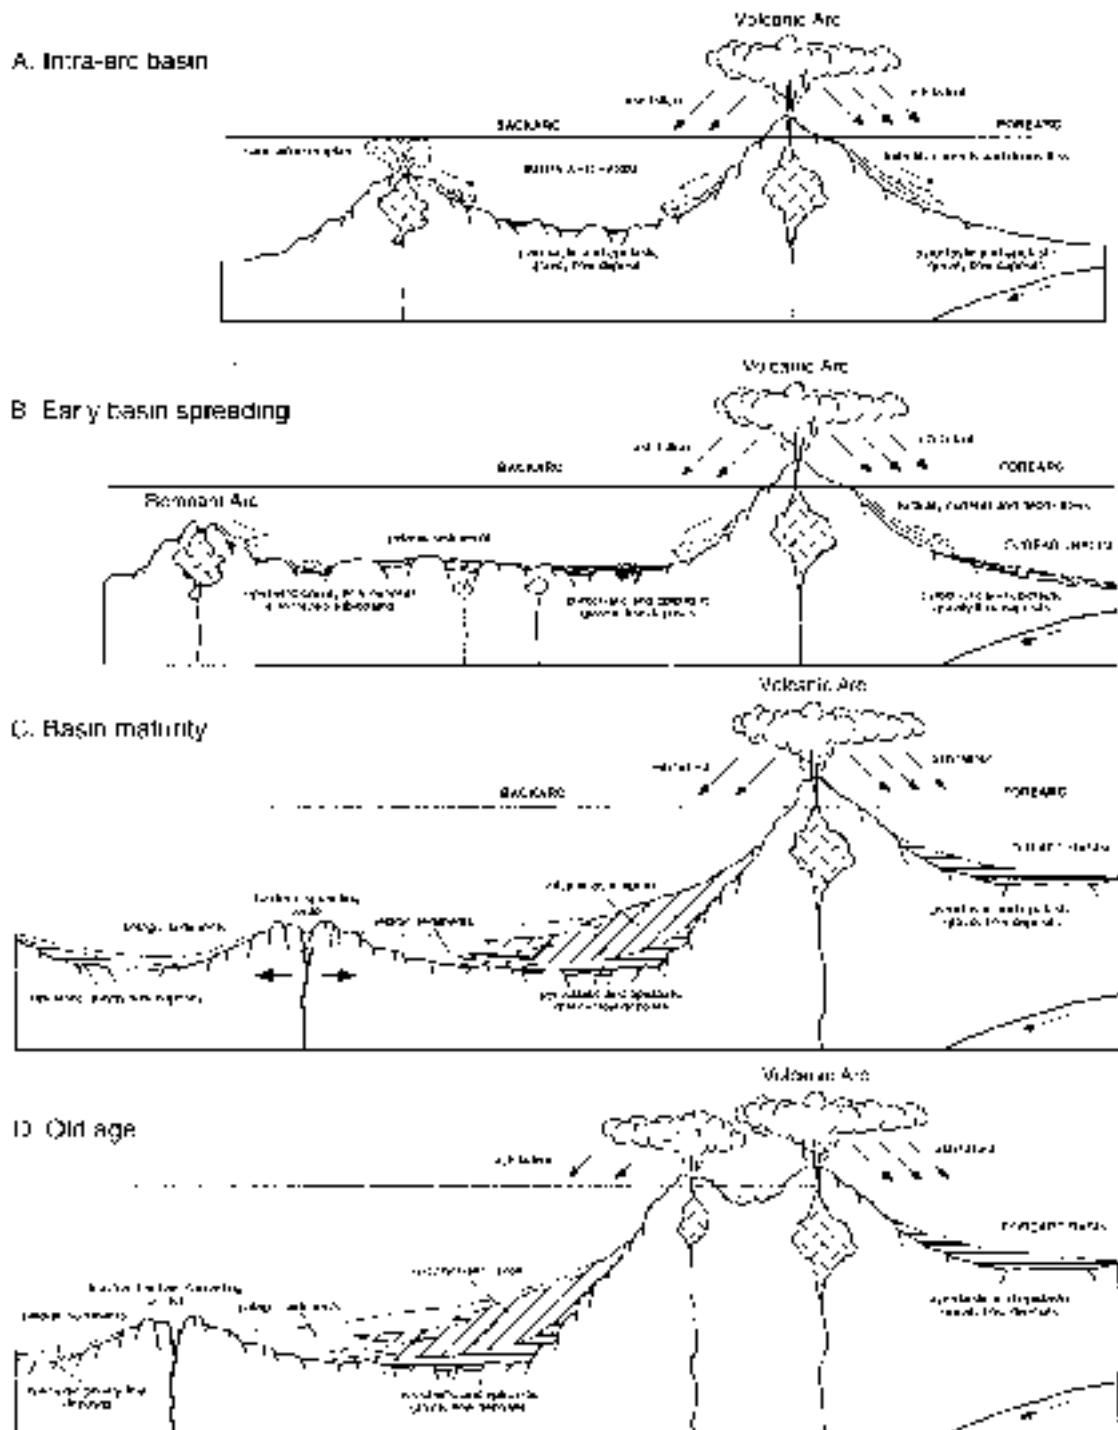

FIGURE 10 Sources and transport processes of volcaniclastic sediments during the tectonic evolution of an oceanic island arc.

lesser extent, the intra-arc submarine volcanic centers. Pyroclastic material is transported by subaerial eruption plumes and by sediment gravity flows triggered by syn-eruptive activity or posteruptive remobilization of freshly erupted material. Thick, coarse-grained pumiceous deposits are produced by high particle concentration turbidity currents and debris flows. Rifting of the arc also generates epiclastic material, by erosion of faulted terrains, that is similarly transported to the basins by sediment gravity flows. The ratio of pyroclastic to epiclastic material will depend upon the level of volcanic activity in the arc and the extent of tectonic displacement. Accumulation rates of volcanoclastic material in these intra-arc rifts are among the highest of any submarine arc environment, up to 1000 m/myr. Nonvolcanic sediment represents a small percentage of the total sediment because of the large volcanoclastic input.

The early stages of rifting are generally accompanied by active arc volcanism and therefore transport of material will also take place into the forearc area. Deposition of volcanoclastic material will occur by fallout from eruption plumes and the generation of syneruptive sediment gravity flows. In the forearc the material will be distributed over a broader area and consequently the accumulation rates will be less than those of the intra-arc basins. Fallout will produce thin, widespread deposits of vitric ash depending on the strength and direction of the local winds. Influx of pyroclastic and epiclastic material to the forearc by sediment gravity flows builds up significant sequences of turbidites in forearc basins. However, because the number of sediment sources can be large and the influxes highly episodic, the sequences do not resemble submarine fan assemblages that are typically found offshore of areas with significant coarse-grained sediment influx. The volcanoclastic material is interbedded with hemipelagic clay and/or carbonate oozes close to the arc. With increasing depth and distance from the arc, the nonvolcanic sediment will be replaced with pelagic clay due to the dissolution of calcium carbonates in water depths greater than 4500 m. Rates of sediment accumulation in the forearc area can be as high as 300 m/myr.

## B. Early Basin Spreading

Enlargement of the backarc basin by rifting produces a complex bathymetry of small subbasins isolated from one another by faults and intrabasin volcanic centers (Fig. 10B). These are depositional centers for volca-

noclastic sediment from adjacent bathymetric highs. Coarse pyroclastic material is deposited from submarine eruptions of nearby volcanoes as turbidity currents and debris flows. Volcanic activity may migrate across the area prior to the establishment of a focused spreading center and thus the influx of primary volcanoclastic material to a particular basin may be terminated abruptly. The complex bathymetry of these rifted environments results in the isolation of the small basins from sediment gravity flows generated from more distal sources. Fallout of volcanic ash from eruption plumes remains one of the only ways to supply these basins with additional material. The forearc environment may not experience major structural changes during this time and consequently the sedimentation patterns remain similar to those of the first stage.

## C. Basin Maturity

Establishment of active backarc spreading centers leads to the widening of the backarc area by crustal formation (Fig. 10C). Volcanism becomes more focused along the spreading rift and the basin deepens due to crustal aging and subsidence. During this period volcanoclastic sedimentation in the backarc is concentrated in several different areas. The most important is along the margin of the basin flanked by the active volcanic arc. In this area a thick sequence of deposits referred to as the volcanoclastic apron is established. The apron accumulates by primary volcanoclastic influx from subaerial and/or subaqueous arc eruptions, a semicontinuous supply of epiclastic material from erosion of the subaerial and/or subaqueous arc complex, and deposition of nonvolcanic sediment. Influx from multiple sources along the arc produces an apron that is elongate parallel to the trend of the arc and wedge-shaped in profile. The growth of the arc and its lateral extent into the backarc are directly related to the intensity of arc volcanism. During vigorous arc volcanism the apron will prograde into the basin toward areas previously dominated by nonvolcanic sedimentation. Peak accumulation rates of the volcanoclastic apron will be in the range of several hundred meters per million years. As arc volcanism wanes, the extent of the apron will recede and nonvolcanic sedimentation will become more important. Temporal variations in the extent of the apron into the backarc thus provide a record of the history of arc volcanism during basin spreading.

The volcanoclastic apron consists mostly of turbidites

and debris flows but like the forearc sequences, does not resemble a typical deep-sea fan. Deep-sea fans are most often found at the base of a single submarine canyon that funnels sediment from a continental shelf or subaerial river source. They show systematic changes in the types of deposits as a function of position on the fan that result from sediment influxes of various strengths through a main distribution channel. In contrast, the volcaniclastic apron receives massive, periodic influxes of coarse-grained volcaniclastic sediment that is delivered from multiple sources and not constrained by a single distribution path. Consequently the apron builds up by the overlapping of many different flow deposits, with significant amounts of transport parallel to the arc. Under these conditions, it is not surprising that systematic facies variations within the apron are rare.

Another area of active volcaniclastic deposition within the backarc area is along the border of the basin with the remnant arc. Erosion of the submerged structure leads to the deposition of epiclastic material in the basin by sediment gravity flows. The composition of the deposits is likely to be heterogeneous as a result of the dissection of the older arc structure. Accumulation of material in this area will be less than in the volcaniclastic apron adjacent to the active arc and is of the order of several tens of meters per million years. With time the influx of epiclastic material from the remnant arc is expected to diminish as it subsides and is continuously modified by erosion. At the base of the remnant arc the sedimentary sequence will become more fine grained upward and nonmarine sediments will constitute an increasingly larger fraction of the deposits.

In the forearc the accumulation rate of volcaniclastic material also responds to the level of volcanic activity in the active arc. Shallower submarine slopes and the partitioning of the area into multiple forearc basins result in a less continuous accumulation of volcaniclastics compared to the wedge-shaped apron formed in the backarc. The evolution of the forearc is difficult to generalize because of the many factors that affect its development. In some cases, the forearc experiences subsidence associated with extension or tectonic erosion by the descending slab. Subsidence will increase the supply of epiclastic material and lead to changes in the type of nonvolcanic sediment. Alternatively, some forearcs experience uplift related to progressive buildup of an accretionary prism by scraping off of sediment. These forearc basins may become isolated from the influx of pyroclastic and epiclastic material by sediment gravity flows or limited to only proximal sources. However,

fallout of volcanic ash from eruption columns will continue to supply some volcaniclastic material if explosive eruptions are occurring along the volcanic arc. Nonvolcanic sediment would change its character to reflect the prevailing water depths.

#### D. Old Age

At the end of a tectonic cycle, a wide marginal basin has developed and the backarc spreading center becomes inactive (Fig. 10D). A new episode of rifting begins in the volcanic arc with extension somewhere in the vicinity of the active arc. In the backarc the extent of the volcaniclastic apron is diminished by the deposition of nonvolcanic sediment. Primary pyroclastic sediment is still dispersed by fallout from eruption plumes but widespread transport by gravity flows has waned. The new arc rifting may supply a fresh influx of epiclastic material to the backarc but its extent may be limited by structural complexity. If arc volcanism remains vigorous during the new rifting stage, volcaniclastics will continue to be supplied to the forearc by fallout and gravity flow processes.

---

#### V. FUTURE RESEARCH

Significant progress has been made toward the understanding of volcaniclastic sedimentation around island arcs. Largely through the Ocean Drilling Program, there has now been deep sampling of the stratigraphic sequences in different environments around active arcs. This has provided key information about the general distribution and lithology of volcaniclastic sediments and the evolution of sedimentary sequences in response to changes in volcanism and structural complexity. These results have led to the development of regional-scale models such as shown in Fig. 10. However, much remains to be learned about the finer scale details of sedimentary processes and the architecture of the deposits. At present, the density of sample sites does not allow for the development of detailed sedimentological models similar to those already existing for other types of marine depositional systems. Smaller scale observational experiments that integrate high-density sampling and subbottom imagery are required to improve the spatial resolution of volcaniclastic sediments in island arcs. The potential for economically important mineral deposits,

volcanic hazards from transport and depositional processes, and value for hydrocarbon source reservoirs provides important impetus to invest in such studies.

## GLOSSARY

- ash, volcanic** Fine pyroclastic material, down to dust size, that is formed by explosive volcanic eruptions.
- ash-flow tuff** Rock formed by the deposits of pyroclastic flows. Synonymous with ignimbrite; common usage in North American literature.
- crater** A bowl- or funnel-shaped depression, generally in the top of a volcanic cone, often the major vent for eruptions.
- ignimbrite** Pyroclastic-flow deposit. Synonymous with ash-flow tuff.
- intrusion** A subsurface igneous rock body formed when molten igneous rock forces its way into surrounding host rocks and then cools.
- magma** Molten rock material with dissolved gases that forms igneous rocks on cooling; magma that reaches the surface erupts as lava or pyroclasts.
- magma chamber** An underground reservoir in the Earth's crust filled with magma, from which volcanic materials are erupted.

**pyroclastic flow** Laterally transported, fluidized mass of hot dry rock fragments mixed with hot gases. Moves away from a volcano at high speeds.

**welded tuff** A hard pyroclastic rock compacted by internal heat and the pressure of overlying deposits. Forms the interiors of thick ash-flow (ignimbrite) sheets.

**C** ALDERAS ARE LARGE volcanic depressions, more or less circular in form, the diameter of which is many times greater than that of included vents. Formation of calderas, by some form of roof collapse over an underlying shallow magma reservoir, is now widely recognized as accompanying most eruptions that involve magmatic volumes greater than a few cubic kilometers. Small calderas (<5 km in diameter) associated with lava eruptions are common at crests of basaltic and andesitic volcanoes; calderas as much as 75 km in largest dimension have formed during large ignimbrite (ash flow) eruptions. In general, caldera diameter increases in proportion to volume of the associated eruption. Diverse subsidence geometries and collapse processes for ash-flow calderas are inferred to reflect varying sizes, roof geometries, and depths of the source magma chambers, in combination with preexisting volcanic and regional tectonic influences.

## I. INTRODUCTION: CALDERAS AND ERUPTIVE PROCESSES

Calderas have been much studied during the past half century, stimulated by recognition of their association with large ash-flow sheets and by several landmark reviews (see Further Reading), yet the processes of caldera formation remain incompletely understood and controversial. Origin dominantly by subsidence has been overwhelmingly recognized, with only minor proportions of the caldera volume being generated by explosive ejection and removal of older rocks. In their origin by subsidence, even small calderas are thus distinct from large volcanic craters that form by constructional accumulation of cinders and spatter or by explosive ejection of wall rocks adjacent to a volcanic vent. Varied processes have been inferred as important or dominant: piecemeal or chaotic subsidence, plate (piston) subsidence of a relatively coherent floor bounded by ring faults, funnel-shaped subsidence into an areally restricted central vent, and hinged down-sag of a central area with little or no boundary faulting. Many calderas are geometrically complex, containing elements of more than a single structural type and subsidence process. Most caldera subsidences have been attributed to collapse accompanying or following large-volume eruptions, but inception of subsidence at some calderas has been attributed to subsurface movement of magma, which in turn may have triggered an eruption. The term caldera, as used here, includes features previously described as "cauldrons," which are considered to represent deeper erosional levels of the same fundamental structures and igneous processes. In many volcanic areas, successive large eruptions and associated overlapping subsidence events have produced caldera clusters that have complex resulting geometries and structures.

In addition to real diversity among caldera structures, the divergent interpretations of dominant subsidence processes reflect ambiguities resulting from the large dimensions of many calderas, gross slumping of caldera walls, incomplete cross-sectional exposures, overprinting by postsubsidence structures, and resulting uncertainties about subsidence geometries. Little-eroded young calderas with well-preserved eruptive morphology generally provide minimal direct information on underlying structures, depth of subsidence, or relation to the source magma reservoir. In contrast, where erosion has proceeded sufficiently to expose subvolcanic structures and granitic rocks of the solidified magma reservoir, the relations of such structures and intrusions

to individual eruptions and to surface volcanic morphology commonly have been largely obscured. Complete sections from surface volcanic rocks to deep features of ash-flow calderas are preserved and exposed only rarely—in regions of exceptional topographic relief or sites of rapid tectonic rotation of the upper crust. Geophysical studies and drill-hole information can provide important additional information on caldera geometry and structure, although geophysical models are commonly ambiguous due to uncertain physical properties at depth. Few drill holes penetrate deeply through the fill of large calderas.

On Earth, calderas have been recognized throughout the documented geologic record, back into Archean time, and likely were part of faintly preserved earlier processes of crust formation, as suggested by evidence from other planetary bodies. Calderas of varying sizes are associated with virtually every type of volcanic activity, including summit calderas on basaltic shields of oceanic islands and andesitic stratovolcanoes of volcanic arcs. Larger calderas are commonly associated with regions of crustal extension, both within volcanic arcs and in continental rift zones; the largest calderas have formed in regions of thick continental crust. Even larger calderas have been imaged on other planetary bodies, such as Olympus Mons on Mars. Some representative terrestrial calderas, cited in this review, are listed in Table I. Especially informative are many recent studies of the numerous Tertiary calderas in the western United States and in Japan, although only a few of the latter are readily accessible in the international literature.

### A. Historical Development of Geologic Concepts

Early 19th century interpretations that large volcanic depressions represent the collapsed crests of structural uplifts ("craters of elevation") or explosive excavation were gradually abandoned later in the century, largely in response to careful observations at La Palma in the Canary Islands (probably the type locality for the term caldera) by Lyell, at Kilauea in Hawaii by Dutton, and at Santorini in the Aegean by Fouqué, and especially by the evidence developed by Verbeek for the great 1883 Krakatau eruption in Indonesia.

Early in the 20th century, arcuate intrusions and ring faults bounding subsided blocks were described as cauldron structures in Scotland by Clough, Bailey, and others; similar structures were recognized in the San Juan Mountains in the United States by Cross and Burbank.

TABLE I Some Well-Documented Caldera Eruptions

Date	Caldera name	Location	Edifice; structure	Topographic caldera diameter (km)	Eruption volume [km <sup>3</sup> (DRE)]	Reported collapse geometry
1991	Pinatubo	Philippines	Stratocone	2.5	4–5	Funnel?
1968	Fernandina	Galapagos	Basaltic shield	5 × 6	0.1	Trapdoor; composite
1912	Katmai	United States	Stratocone	2.5 × 4	12	Funnel?
1883	Krakatau	Indonesia	Clustered stratocones	8	10	Funnel?
1750–1790?	Kilauea	Hawaii	Basaltic shield	3 × 5	??	Plate
1.4 ka	Rabaul	Papau, New Guinea	Volcano cluster	10 × 15	11	Plate
1.8 ka	Taupo	New Zealand	Rift/caldera cluster	35	35	Downsag? <sup>a</sup> ; composite
3.6 ka	Santorini	Mediterranean	Volcano cluster	7 × 10	25	Composite
7.7 ka	Crater Lake	United States	Volcano cluster	8 × 10	55	Plate
22 ka	Aira	Japan	Caldera cluster	18 × 22	300	Funnel? <sup>a</sup>
35 ka	Campi Flegrei	Italy	Volcano cluster	13	80	Plate
75 ka	Toba	Indonesia	Dacitic arc; fault zone	30 × 80	1500	Plate (R) <sup>b</sup>
95 ka	La Primavera	Mexico	Volcano cluster	11	20	Plate
600 ka	Yellowstone	United States	Caldera cluster	60	1000–2000	Plate (R)

2.2 Ma	Cerro Galán	Argentina	Volcano cluster	25 × 35	2000	Plate (R)
2.8 Ma	Chegem	Russia	Collision zone	15 × 20	>300	Plate?
5.6–3.8 Ma	Dorobu	Japan	Caldera cluster	6 × 13	??	Piecemeal, composite
25.9 Ma	Lake City	United States	Caldera cluster	15 × 20	200–500	Plate (R)
26.6 Ma	Creede	United States	Caldera cluster	24	>500	Plate (R)
27.6 Ma	Silverton	United States	Caldera cluster	15 × 20	50–100	Trapdoor
27.8 Ma	La Garita	United States	Volcano cluster	35 × 75	5000	Multiple plates? (R)
73 Ma	Tucson	United States	Andean arc	25	>500?	Trapdoor
Ordovician	Scafell	England	Volcanic arc	>15	??	Piecemeal (composite?)

<sup>a</sup> Alternatively interpretable as plate subsidence.<sup>b</sup> (R), resurgent postcollapse uplift of caldera floor.

By the mid-20th century, the subsidence origin of many volcanic calderas was emphasized by Williams in his study of Crater Lake in Oregon (Fig. 1) and his comprehensive 1941 review “Calderas and Their Origin,” by Matumoto’s concurrent identification of large clustered calderas in southern Japan, and by later recognition of the Valles resurgent caldera type by Smith and Bailey. More recent studies have built on these concepts to decipher stratigraphy and structure of caldera-related volcanic deposits, constrain timing of eruption and collapse, determine compositional and temporal relations between volcanism and solidification of subcaldera magma chambers, and document unrest and precursors to large caldera-forming events for hazards evaluation. Volcanic studies of calderas have also been applied to societal needs to utilize volcano-generated ore deposits,

generate electrical power from geothermal heat, and evaluate potential effects of large caldera eruptions on global climate.

## B. Notable Historical Eruptions

Much has been learned about caldera-forming processes from historical eruptions, although none have been on the scale of the largest older caldera-forming eruptions evident in the geologic record. Well-documented historical and near-historical caldera-related eruptions include Pinatubo (1991), Fernandina (1968), Katmai (1912), Krakatau (1883), Kilauea (1750–1790?), Taupo (1.8 ka), and Santorini (3.6 ka). Such young volcanoes

**FIGURE 1** Crater Lake caldera, United States, as viewed from its south rim. The caldera formed 7700 years ago by collapse of the volcano known as Mount Mazama. The prominent cliff on the north caldera rim, Llao Rock, is a rhyodacite lava flow erupted within a few hundred years before the caldera-forming eruption. The cinder cones and lava flows of Wizard Island are the top of a 1- to 2- $\text{km}^3$  andesitic cone, erupted soon after caldera collapse. [Photograph by C. R. Bacon, U.S. Geological Survey.]

provide only limited information on the internal structure of magmatic systems, however, in comparison with exposed features of deeply eroded older volcanic edifices. Complementary study of both young and ancient volcanic systems (Table I) are needed to understand caldera-forming processes.

The 1991 eruption of Mount Pinatubo in the Philippines, during which a small caldera (2-km diameter) formed during eruption of 4–5  $\text{km}^3$  (DRE, dense-rock equivalent) of ignimbrite and tephra-fall deposits, has been the best monitored caldera-forming event thus far. This eruption demonstrated that caldera collapse can accompany even relatively small-volume pyroclastic eruptions. The timing of the recurrent subsidence events can be inferred from several peaks in seismic energy release during the eruption.

In 1968, subsidence of 300 m within the summit caldera of the Fernandina basaltic shield in the Galapagos was preceded by a subaerial eruption that was an order of magnitude smaller than the volume of caldera collapse. This event confirmed previous inferences that basaltic calderas can subside recurrently in response to subsurface magma withdrawal, in response to intrusion or perhaps to flank eruptions low on the edifice (underwater at Fernandina?).

The 1912 eruption from the funnel-shaped Novarupta crater in Alaska, the largest eruption of the 20th

century (about 12  $\text{km}^3$ , DRE), triggered 1200 m of subsidence at the summit of Mount Katmai (at least 5- $\text{km}^3$  subsidence volume), 10 km from the eruptive vent. Katmai thus documents an unusual spatial divergence between eruptive and subsidence processes where the magmatic plumbing system is complex. Stratigraphic relations between dust layers generated by subsidence at Katmai and tephra erupted from Novarupta demonstrate that the caldera subsided incrementally during this eruption.

The 1883 eruption of about 10  $\text{km}^3$  (DRE) of pyroclastic materials from Krakatau in Indonesia played a pivotal role in focusing attention on the relations between highly explosive pyroclastic eruption and formation of large calderas. Some key observations from this eruption include demonstration that erupted lithic debris was inadequate to account for the volume of the caldera (thus disproving prior hypotheses of explosive evacuation of caldera basins), recognition that caldera eruptions could generate destructive tsunamis capable of causing coastal damage far beyond the region directly impacted by eruptive deposits, and the effect of globally distributed volcanic ash dispersed in the atmosphere for several years after the eruption.

The summit caldera of Kilauea volcano in Hawaii, much visited while occupied by a lava lake during much of the later 19th century, was recognized early as having

resulted from collapse, probably in connection with eruptions along the long flanking rift zones. The most recent deep subsidence of Kilauea caldera occurred in conjunction with, or just preceding, major explosive activity in 1790; during the 19th century, the caldera was filled to overflow by lavas. Recent work has documented that such large basaltic shields undergo repeated cycles of caldera subsidence and filling throughout their shield-building stage. In addition, short-term inflation-deflation cycles preceding and accompanying eruptions have been documented in great detail by geodetic measurements.

The 1.8-ka Taupo eruption of  $35 \text{ km}^3$  (DRE) of magma on the North Island of New Zealand, probably the world's most violent and largest in the past 2000 years, would have been even more renowned than the roughly contemporaneous A.D. 79 eruption of Vesuvius if it had occurred in a populated region where historical records were preserved. The Taupo caldera has been interpreted by Walker to constitute a representative example of subsidence by down-sagging, although determination of caldera processes and even caldera size is impeded by poor exposures as a result of location within the extensional trough of the Taupo Volcanic Zone. Recent geophysical studies suggest the subsurface presence of a fault-bounded caldera complex nested within graben structures.

No true historical records exist for the 3.6-ka Bronze Age eruption of Santorini in the Aegean arc (about  $25 \text{ km}^3$  DRE), but this eruption is prominent in European archeological and volcanologic studies for its well-preserved caldera and proximal eruptive deposits and also for the Minoan cultural sites preserved beneath proximal deposits. In addition, recent studies by Druitt and associates have documented that the Bronze Age caldera is the youngest of at least four successive caldera cycles involving nearly confocal composite subsidence since 100 ka or earlier.

---

## II. CALDERA-FORMING ERUPTION CYCLES

Many large calderas form at sites of preceding volcanism that record shallow accumulation of caldera-related magma (Fig. 2). Large eruptions ( $>50\text{--}100 \text{ km}^3$  of erupted magma) typically cause caldera collapse concurrently with eruption, as indicated by thick intracaldera ash-flow fill, interleaved collapse slide breccias, and structural features. Postcollapse volcanism may occur

from vents within or on the margins of ash-flow calderas; eruptions from the bounding-fault zone are most common in resurgent calderas, reflecting renewed magmatic pressure. In addition to resurgence within single calderas, broader magmatic uplift occurs widely within silicic volcanic fields, reflecting isostatic adjustment to emplacement of associated subvolcanic batholiths. Large intrusions related to resurgence are exposed centrally or along the margins of some deeply eroded calderas.

### A. Precollapse Volcanism

Volcanism prior to a major caldera-forming event may provide the only record of the rise to shallow crustal levels and early chemical evolution of the growing magmatic system that culminates in large-volume eruptions and caldera formation. Buoyant rise of the magma body may cause broad uplift and generation of incipient ring and radial fractures. Volcanic "leaks" from the evolving magma body commonly produce clusters of vents over the magma chamber, at times in linear or arcuate patterns controlled by nascent radial and ring faults, at others controlled by regional tectonic structures. Virtually all well-documented young calderas have formed at sites of immediately preceding volcanism, although the volume and composition of such premonitory activity may vary substantially. Many small calderas have formed at the summits of basaltic shield volcanoes (Hawaii, Galapagos) or within single stratovolcanoes, but large ash-flow calderas typically have subsided within clusters of preexisting cones and domes. At many caldera sites, the caldera-forming event has covered or caved away much of the near-source record of precollapse volcanism.

### B. Morphologic and Structural Geometry

Major structural and morphologic elements of calderas (Fig. 3) include topographic rim, inner topographic wall, bounding faults (if present), structural caldera floor, intracaldera fill (mainly ponded ignimbrite and landslide debris from caldera walls), and the underlying magma chamber or solidified pluton. Although highly generalized and not intended to accurately depict relations at any actual caldera, such a model provides a basis for discussing caldera structural elements and subsidence processes, computing approximate volumetric proportions between subsidence geometry and caldera-filling deposits, and inferring relations between eruption and subsidence processes.

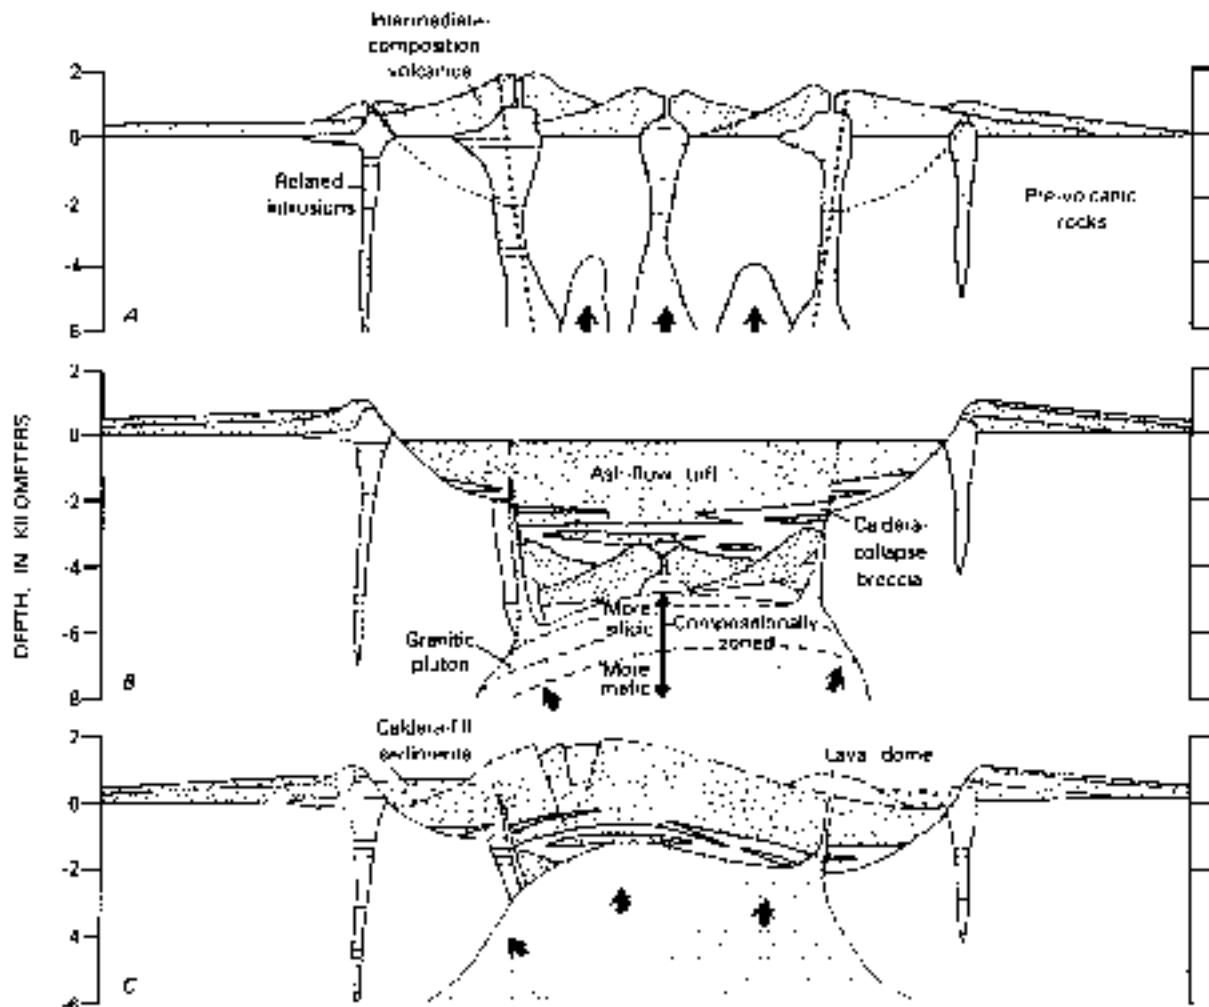

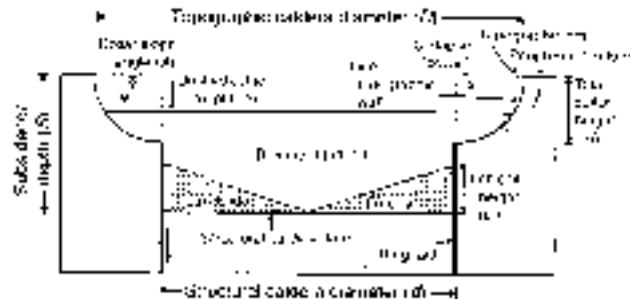

FIGURE 2 Generalized evolution of ignimbrite calderas (based largely on studies of Cenozoic calderas in the western United States). (A) Precollapse volcanism. Clustered intermediate-composition stratovolcanoes grow over isolated small high-level plutons that mark the beginning of accumulation of batholith-size silicic magma body that will feed ignimbrite eruptions. Broad uplift related to emplacement of plutons may lead to development of arcuate ring fractures. The site of subsequent caldera collapse is indicated by dotted lines; heavy arrows indicate upward movement of magma. (B) Caldera geometry just after ash-flow eruptions and concurrent caldera collapse. Central area of clustered earlier volcanoes caves into collapsed area. Intracaldera tuff ponds during subsidence and is an order of magnitude thicker than cogenetic outflow ignimbrite sheet. Initial collapse along bounding faults is followed by slumping of oversteepened caldera walls and accumulation of voluminous collapse breccias that interfinger with ignimbrite in the caldera fill. Caldera floor subsides asymmetrically and is tilted to the left side of diagram. Main magma body underlies entire caldera area and is compositionally zoned or layered (or was, prior to eruptions), becoming more mafic downward. (C) Resurgence and postcaldera deposition. Resurgence is asymmetrical, with greatest uplift in area of greatest prior collapse. Extensional graben faults from over crest of dome. Some resurgent uplift is accommodated by movement along ring faults in sense opposite that during caldera subsidence. Magma body has risen into volcanic pile and intruded cogenetic intracaldera ignimbrite. Original caldera floor has been almost entirely obliterated by rise of magma chamber to near level of prevolcanic land surface. Caldera moat is partly filled by lava domes and volcaniclastic sediments. Hydrothermal activity and mineralization are prevalent late in cycle. [From Lipman, 1984].

**FIGURE 3** Generalized structural model of plate (piston) caldera subsidence, showing simplified geometric relations. Ring faults, which typically dip steeply, are arbitrarily shown as vertical. The landslide breccia is shown schematically at the base of caldera fill, in order to permit geometrically simplified calculation of overall volume relations, rather than the more actualistic complex interfingering that occurs in many calderas. Presence of subcaldera magma chamber, any resurgent structures, and postcollapse volcanic constructs are omitted. [From Lipman, 1997].

### 1. Topographic Rim

The topographic rim is simply the top of the escarpment that bounds the caldera, beyond which lie largely undisturbed outer volcanic slopes. The rim encloses both the subsided area and also the area of scarp retreat due to rock falls and mass wasting. For young calderas, the topographic rim defines the overall areal extent of subsidence, although outlying circumferential fractures at some calderas (e.g., Kilauea in Hawaii and Chegem in Russia) accompany modest additional sagging toward the main subsided area. For old calderas, erosional mass wasting first tends to enlarge the original topographic rim, but later erosion of outer slopes of the upper caldera edifice can also reduce the apparent topographic diameter.

### 2. Inner Topographic Wall

The topographic wall is typically steepest in its upper parts, commonly as precipitous cliffs at young calderas, but tends to have a concave profile that flattens down-slope. Upper slopes of the inner topographic wall virtually never represent an unmodified subsidence fault scarp; rather, they develop in response to landslide enlargement and rock falls from oversteepened slopes during and after caldera collapse. At the base of the topographically enlarged caldera wall, intracaldera fill may deposit directly against caldera-boundary faults that have been unmodified by gravitational slumping (Glen Coe, Scotland; Lake City, United States; calderas of the Oslo graben in Norway). Such contacts are rarely preserved, because continued caldera subsidence causes further faulting.

In plan view, the topographic walls of most large ash-flow calderas are scalloped by scarps of landslides and rock falls. Suggestions that topographic enlargement and scalloped embayments along some caldera walls result from irregular peripheral subsidence of overhangs along satellite bounding faults may be valid for irregular walls of basaltic pit craters and other small collapse structures (e.g., pit craters of Kilauea's east rift zone) but are inconsistent with the structurally coherent bedrock stratigraphy that has been mapped and documented by drilling along the footwall embayments in many large calderas (Creede, La Garita, Timber Mountain, and Valles in the United States; Aso in Japan; Campi Flegrei in Italy; Chegem in Russia), some projecting 5 km or more back from the main caldera wall. Such shallowly rooted embayments can only have formed by surficial collapse and insliding along oversteepened caldera walls, an inference that is confirmed by the provenance and large volume of slide material in adjacent caldera fill. Large scallops in walls of some multicyclic ash-flow calderas may be related to successive eccentrically overlapping subsidences associated with recurrent eruptions (Toba, Santorini). At other multicyclic calderas, late large eruptions have caused subsidence of the entire prior caldera area, and earlier subsidence structures lie within the late caldera (e.g., Valles and Platoro in the United States and Taupo in New Zealand).

### 3. Collapse Collar

Material removed by mass wasting and scarp retreat defines a collapse collar (Fig. 3): the volume of rock lying between the topographic caldera wall and the structural caldera boundary. Average overall slopes of inner topographic walls (collar slope angle) are moderate:  $25^\circ$  is typical, and  $45^\circ$  a probable upper limit. Lower slopes along the collapse collar, dipping as gently as  $10\text{--}15^\circ$ , are the only parts preserved in many eroded calderas, where the inner wall is expressed as an irregular unconformity between precaldera and caldera-filling rocks. Gentle dips on lower slopes of the collapse collar permit exposure, by erosion or drilling, of precaldera rocks at shallow depths well inboard from the topographic rim. Such geometric relations had been inferred to demonstrate funnel geometry for large calderas such as Aso, Japan, where geophysical and drilling data now document the presence of concealed bounding faults.

### 4. Bounding Faults

Arcuate bounding faults (ring faults) are exposed at some deeply eroded volcanic areas (mainly 5 km and greater in diameter), unambiguously defining plate (piston) sub-

sidence at calderas, as well as at many volcanic "cauldrons" and plutonic ring complexes in older terranes. The presence of bounding ring faults in some less eroded calderas can be inferred from the distribution of caldera-forming or postcollapse vents and symmetrical resurgent uplift of caldera-filling volcanic rocks. Ring faults can accommodate uplift, as well as subsidence; e.g., domical magmatic resurgence at Lake City caldera, United States, occurred along the same faults as earlier had accommodated caldera collapse, and magma was injected as partial ring dikes. Similarly, trapdoor uplift within the 45-ka Cinque Denti caldera in Pantelleria was accommodated by reversed movement along old ring fractures.

Most observed ring faults are near-vertical or dip steeply inward. Ring faults that dip steeply inward at shallow crustal levels may steepen with depth and dip outward at levels just above the magma chamber into which the caldera subsided. Such a geometry may reflect sequential change, from an early stress field related to magma withdrawal (Fig. 4A) to later stresses related to slumping along caldera walls, as the thickness of precaldera rocks in the subsiding region is reduced by stoping during continued upward rise of magma (Fig. 4C). Because of such complexities and uncertainties, all ring faults are shown arbitrarily as vertical in Figs. 3 and 6. Some sizable young calderas lack clear evidence for the presence of arcuate bounding faults, but limited erosion depths typically preclude unambiguous interpretation. At many calderas, regional tectonic trends have influenced the geometry of collapse to varying degrees, but deeply eroded calderas bounded by strongly polygonal faults appear to be much less common than those with arcuate fault boundaries.

Circumferential extensional fractures peripheral to the topographic rims of young calderas are commonly associated with recurrent gravitational slumping of the free face of the inner caldera wall. Such peripheral fractures at Kilauea caldera have opened and closed repeatedly during major historical earthquakes, independently of caldera eruptive or subsidence events.

### 5. Intracaldera Fill

Intracaldera fill provides key evidence of caldera processes because most or all large calderas collapsed during the associated eruptions, and ignimbrites and interleaved caldera-wall slide breccias accumulated to multi-kilometer thickness within the subsided area. Distributions and volumes of slide breccia vs intracaldera tuff provide critical evidence on timing and geometry of subsidence.

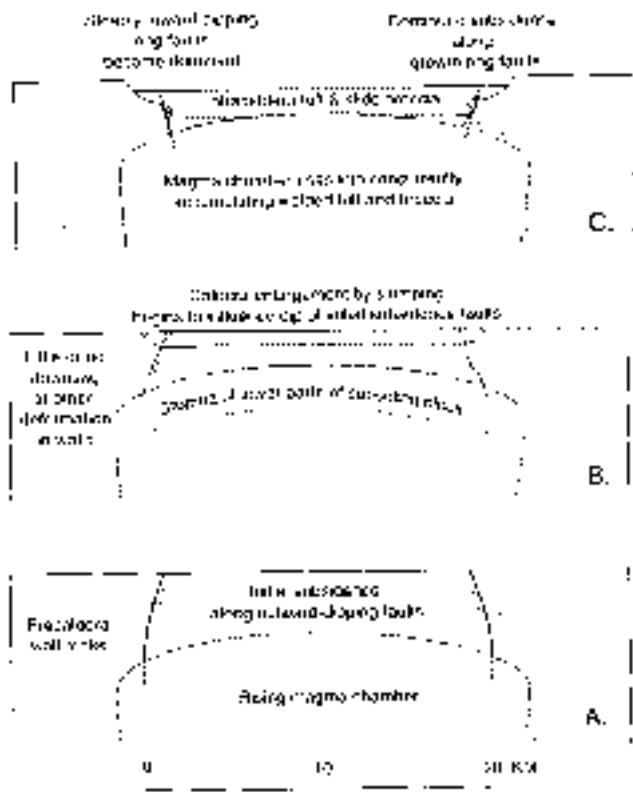

FIGURE 4 Possible evolution of ring-fault geometry, in which initial outward-dipping ring faults are replaced by inward dips, as progressive subsidence destabilizes the caldera walls and continued upward rise of magma reduces the thickness of the subsiding plate or piston.

In addition to ignimbrites and slide breccia that accumulated synchronously with caldera subsidence, most pre-Holocene calderas are partly to completely filled by younger lavas and tuffs erupted from postcollapse caldera-related vents, sedimentary debris eroded from adjacent volcanic highlands, and volcanic deposits derived from other volcanic centers. Such postcaldera deposits tend to conceal the primary volcanic structures, especially at nonresurgent calderas, impeding interpretation of subsidence processes or even the presence of some large calderas.

### 6. Caldera Floor

The geometries of caldera floors have been well documented at only a few large ash-flow calderas (e.g., Scafell in England; Tucson, Organ Mountain, Stillwater Range in the United States; Kumano in Japan), and the typical degree of disruption during subsidence remains uncertain. The structural floor is the subsided precaldera land surface, in contrast to the topographic caldera floor ex-

posed at the surface within a young caldera. Few calderas that provide a clear record of volcanic evolution are eroded to depths sufficient to expose their structural floors, and in many, cogenetic magma has risen to such shallow depth that much of the floor has been destroyed. Structures at many deeply eroded calderas are further complicated or obscured by multiple subsidence events associated with successive ignimbrite eruptions or by later regional tectonism.

For some calderas (Chegem, Cerro Galan, Lake City), exposures of structurally coherent fill that accumulated within the caldera concurrently with subsidence provide strong evidence of, at most, limited disruption of the caldera interior. Even where the fill consists of massive ignimbrite, partial cooling breaks, flow-unit partings, compositional boundaries, and interlayered landslide breccia sheets commonly provide stratigraphic markers to evaluate fault disruption within calderas. Most faulting of intracaldera fill that has been documented so far by such stratigraphic features occurred not during subsidence but during later resurgent doming or other uplift of the caldera floor, as indicated by displacement of all caldera-fill units (e.g., Valles, Bachelor, and Campi Flegrei). Intracaldera deposits are less well exposed in most nonresurgent calderas than those on resurgent domes, but erosionally inverted topography at some nonresurgent calderas, such as Chegem in Russia and Superstition in the United States, provides exceptional exposures of widely continuous flow units and cooling breaks within thick exposed intracaldera tuff without significant fault disruption. Complex disruption of caldera floors may accompany overlapping subsidence during successive caldera-forming eruptions, but available evidence suggests that most large calderas subside fairly coherently during individual eruptions.

Growth faults, with upward decreasing displacement, should be present within syncollapse fill if the caldera floor were significantly disrupted during subsidence, but documented examples are rare. Because synsubsidence faulting would disrupt high-temperature ignimbrites as they welded, growth faults should be marked by conspicuous local rheomorphic zones, even where offset of lithologic markers was obscure. Widespread growth faulting has been well documented at the Ordovician Scafell caldera, but these faults variably displace multiple separate eruptive units, and relations to individual collapse events are less clear.

Small calderas (less than a few kilometers in diameter) merge in geometry with diatremes and likely lack a coherent floor. Rather, the inner walls converge downward into the eruptive conduit in a funnel-shaped geometry, as discussed later.

## 7. *Subcaldera Magma Chamber*

Magma chambers, preserved as solidified plutons or batholiths, are exposed in many deeply eroded ash-flow calderas, as indicated by petrologic and age correlations with erupted volcanics (Chegem in Russia; Lake City, Questa, and Turkey Creek in the United States; Kumano in Japan). Such plutons have commonly been emplaced within a few kilometers of the regional volcanic surface, some roof zones protruding into the syneruptive fill of the associated caldera. Accumulation of low-density silicic magma in a large shallow chamber, which can generate uplift and tensile stresses at the surface, could be important in initiating ring faulting and permitting caldera collapse. Tumescence associated with growth of a subvolcanic magma chamber has been recorded instrumentally during many monitored eruptions and episodes of volcanic unrest, but the magnitude of uplift has typically been too small to generate geologic structures that would be detectable in the prehistoric record.

Shallow depths to incompletely solidified caldera-related magma chambers are documented for a few active calderas by seismic-attenuation studies, magnetic curie-temperature depths, and other geophysical data. Such studies indicate the presence of magma at depths as shallow as 4–7 km at the 0.76-Ma Long Valley caldera in the United States. At the historically active Rabaul caldera in Papua, New Guinea, seismic hypocentral locations define an elliptical area  $5 \times 10$  km, interpreted as bounded by ring faults, that overlies a central region of low seismicity at depths below 2–4 km that is inferred to represent the present-day magma chamber. For some older systems, the petrology of eruptive products also requires shallow depths of magmatic crystallization (e.g., presence of clinopyroxene rather than hornblende phenocrysts in H<sub>2</sub>O-rich magma).

Although only small intrusions are exposed at present erosional levels in eroded Tertiary calderas, geophysical data commonly document the subsurface presence of large magma bodies or solidified granitic rocks. For example, the clustered Tertiary calderas of the San Juan volcanic field, United States, lie within a large negative Bouguer gravity anomaly ( $-50$  mgal), characterized by steep marginal gradients, that has been interpreted to delimit a shallow batholith about  $75 \times 150$  km across with its roof at an average depth of about 5 km. Upper crustal accumulation and fractionation of magma in the subvolcanic batholith is interpreted to have been recorded by the regional volcanic succession in the San Juan field, involving eruption of intermediate-composition lavas from scattered volcanoes, followed by large

ash-flow eruptions associated with caldera collapse (Fig. 2). Individual calderas of the central cluster, as well as the overall caldera cluster, have only minor gravity expression, indicating that the density of caldera-filling rocks is only a minor component of the overall anomaly.

Detailed inferences about shapes of exposed intrusions and collapse geometry commonly remain ambiguous at eroded calderas, because subvolcanic magma bodies likely continue to evolve in composition, shape, and depth after cessation of the caldera-forming volcanism. Despite such uncertainties, some consistent relations have emerged between collapse geometry and pluton shape. For example, some trapdoor calderas expose high-level plutons along the most subsided side of an asymmetrical caldera (Silverton, Tucson), suggesting that maximum subsidence was influenced by the shallowest portion of the magma chamber. At several calderas, high-resolution dating has documented cooling of subcaldera plutons within brief time intervals after caldera subsidence. For example, at Chegem in Russia the intracaldera tuff and central granitic intrusion yield  $^{40}\text{Ar}/^{39}\text{Ar}$  ages that are indistinguishable at  $2.82 \pm 0.02$  Ma.

Several recent studies have inferred important roles for sills or shallow domical laccoliths of fine-grained hypabyssal rocks during caldera collapse and resurgence (Turkey Creek and several “laccocalderas” in the United States). Floors of such intrusions are generally not exposed, however, and their overall geometry remains uncertain. Other deeply eroded calderas expose large steep-sided subcaldera plutons containing granitic textures transitional to typical mesozonal batholithic bodies (e.g., Questa, United States). Perhaps resurgent intrusions initially spread as sill-like bodies near the base of the caldera fill, developing into stocklike plutons as continued emplacement of intrusive material gravitationally loads caldera floor rocks and encourages block stoping.

Any large caldera (>20-km diameter) must necessarily have been underlain by a large-scale magma chamber of broadly tabular aspect ratio in order for the intrusion to reside in the middle and upper crust, but to describe such large granitic bodies as laccoliths seems misleading. The concept of a laccolith, as used by most geologists, implies making space by doming the roof rocks; no such evidence exists for most large plutons, including sizable upper crustal bodies with associated volcanism. Few if any large subvolcanic batholiths can be demonstrated to have strongly domed their roofs, and many are composite aggregates of multiple plutons with smaller map dimensions and steep intrusive contacts. Many subcal-

era plutons have steep margins, cut across gently dipping wall rocks, and intrude associated volcanic sequences (Glen Coe, Peruvian Andes, Oslo Graben). The most feasible mechanism for generating the space needed for a batholith to rise into the upper crust in places like the San Juan Mountains, where regional tectonic faulting is nonexistent, is by large-scale stoping, and caldera formation can be considered a near-surface component of such stoping. Crustal rocks have negligible strength to support regional loads, as long recognized from isostatic adjustments to loading by glaciers or even manmade reservoirs. Much additional space for growing upper crustal batholiths likely results from subsidence of crustal rocks of the magma-chamber floor.

### C. Postcollapse Magmatism and Resurgence

Volcanic activity within and around margins of calderas after collapse can include eruptions from vents randomly scattered within the caldera, eruptions localized along regional structural trends, and eruptions along the caldera margins. Such events may begin shortly after initial collapse and continue intermittently for millions of years. Such postcollapse volcanism can closely constrain the timing and nature of differentiation in the subcaldera magma chamber. Thermal modeling of heat flow around young calderas suggests that heat loss by hydrothermal convection is so great that shallow caldera-related magmatic systems cannot survive more than a few hundred thousand years without replenishment by additional magma. Long histories of postcollapse volcanism at many calderas suggest that such replenishment is common.

Renewed rise of magma after collapse has resurgingly uplifted many calderas (Fig. 5). Such uplift varies from doming or block uplift of the cores of individual calderas to broad regional uplift of one or more calderas and adjacent portions of the volcanic field. Best known, although relatively uncommon, is symmetrical resurgent doming of the caldera floor, as in the Valles, Creede, Timber Mountain, and Turkey Creek calderas in the United States. Resurgent calderas appear to be more numerous within continental crust, as along the Cordilleran margin of the Americas than in young volcanic arcs within ocean basins. The first identified resurgent caldera was Toba in Sumatra, however, and although only a few of the numerous Tertiary calderas in Japan have been described in the international literature, several are reported to contain resurgingly uplifted blocks

**FIGURE 5** The resurgent Creede caldera, Colorado, as viewed from near its northwest topographic rim. Broad rounded hill in middle distance is the postcollapse resurgent dome. Arcuate valley marks topographic moat, now followed by the Rio Grande (see Fig. 7), which is underlain by Oligocene caldera lake sediments. Despite formation at 26.5 Ma, primary volcanic morphology is well preserved due to infilling of the caldera moat by sediments that have only been erosionally excavated in geologically recent time. [Photograph by J. C. Ratté, U.S. Geological Survey.]

or high standing intrusions (e.g., Onikobe, Hiwada, and Okueyama).

In addition to resurgent structures that are specific to individual calderas, some silicic volcanic fields containing clusters of calderas show weak regional uplift centrally within the volcanic field that is interpreted as indicating broad late resurgence over an underlying batholithic magma body larger than any individual caldera. Such broad uplift can be reflected in young volcanic fields by regionally high topography, mild tilting of volcanic strata away from central parts of the field, and extensional structures trending between individual calderas.

#### D. Hydrothermal Activity and Mineralization

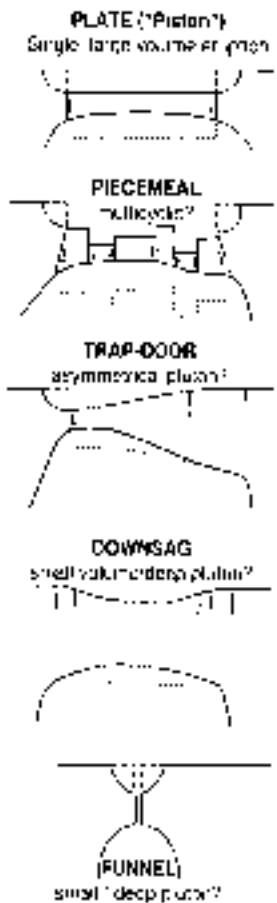

Hydrothermal activity and mineralization can accompany all stages of ash-flow magmatism, becoming dominant late during caldera evolution. Caldera-forming ignimbrite eruptions are probably unlikely to directly produce major ore deposits, because such explosive activity would tend to disperse any concentrations of metals that accumulated in upper parts of precaldera magma chambers, but the resulting caldera structures can be important loci for subsequent magmatic and hydrothermal ore-forming events. Much rich mineralization is millions of years younger than caldera collapse, where the caldera served primarily as a structural control for late intrusions and associated hydrothermal systems. Some calderas show little or no evidence of associated hydrothermal activity.

---

#### III. CALDERA-SUBSIDENCE PROCESSES

Prior approaches to subdividing and classifying calderas have tended to distinguish caldera types based on eruption style and magma composition at representative volcanoes: for example, Krakatoan type, Valles type, Katmai type, etc. Size of the eruption and geometry of the cogenetic magma chamber also bear on subsidence processes. For example, stated distinctions between “Krakatoan” and “Valles” caldera types (foundering of the top of a composite volcano versus subsidence independent of preexisting volcanoes) are mainly functions of reservoir area and eruption volume, which influence resulting caldera size without any necessary difference in subsidence processes.

Alternatively, the broad diversity of well-documented ash-flow calderas can be considered in terms of a continuum of features and processes. Many calderas have such varied transitional geometries and structures that subdivision into discrete types seems less useful than relating subsidence geometry and resulting structures to a few geometrically simplified end members (Fig. 6). Many larger calderas dominantly involve *plate (piston) collapse* of a coherent floor, bounded by steeply dipping faults. *Trapdoor subsidence*, bounded by an incomplete arcuate fault and by a hinged segment, reflects early down-sagging and incipient plate collapse. Simple *down-sag subsidence* seems rare, although many plate-subsidence calderas contain inward-tilted blocks along their margins. A component of *piecemeal-fault disruption* of caldera floors is fairly common, although such structures do not seem to accommodate the bulk of subsidence in

**FIGURE 6** Schematic models of alternative subsidence geometries in relation to depth and roof geometry of underlying magma chamber. Dashed lines indicate postsubsidence depths of down-dropped caldera floor blocks, which are inferred to have been partly removed by stoping into magma chamber during and immediately after caldera collapse. [From Lipman, 1997].

most large calderas. Pervasively brecciated *chaotic disruption* of subsiding caldera floors is rare, at least at calderas more than a few kilometers across. Small calderas (<3–5 km in diameter) commonly have a *funnel geometry* because of dominant enlargement by slumping into an areally restricted vent.

#### A. Plate Subsidence

Many large calderas have long been recognized to involve plate (piston) subsidence of a relatively coherent floor, bounded by steeply dipping bounding faults with kilometer-scale displacements (“Valles type”). Ring and arcuate intrusions have long been recognized as deeply eroded analogs of large plate-subsidence calderas.

Displacements along the bounding faults of a plate-subsidence structure, by definition, must be much greater than on any faults within the caldera floor, but some calderas contain structures transitional toward a piecemeal-subsidence geometry. At a few calderas that are well exposed and adequately studied (Glen Coe in Scotland; Grizzly Peak, Bachelor, Stillwater Range in the United States), the subsided lid over the source magma chamber was variably faulted (offsets of tens to hundreds of meters) due to differential movement during ash-flow eruptions and postcollapse magmatism, but the scale of internal disruption is typically an order of magnitude less than displacements on bounding faults. At the type Valles caldera, drilling and geophysical data show that the caldera floor was locally disrupted by faulting that occurred largely or entirely during postcollapse domical resurgent uplift. In some places, such as Glen Coe, current interpretations diverge as to whether subsidence was dominantly along the bounding ring faults or by internal disruption. Subsidence by highly chaotic disruption of the floor has not been clearly documented for any large caldera.

Many plate-subsidence calderas, 10 km or more in diameter and bounded by ring faults, have been recognized recently in Japan, as Tertiary volcanic areas have been mapped geologically and explored by drilling (e.g., work by Yamamoto and associates in the Inawashiro and Aizu districts of northern Honshu). Some calderas as small as 4–5 km in topographic diameter appear to have fault-bounded floors, based on evidence for ring faults and structurally coherent caldera fill. Examples in the United States include the 8 × 10 km Crater Lake and 4.5 × 8 km Kulshan calderas in the Cascade Range.

#### B. Downsag Subsidence

Large-scale downsag subsidence has been inferred by some researchers to be common, based on inward-sloping topography, inward-tilted wall rocks, and apparent absence of large-displacement bounding faults at some major calderas. Many large plate-subsidence calderas involve subordinate downsag, but no deeply subsided calderas appear to have been well documented where downdropping is accommodated dominantly by inward tilting without major bounding faults.

Components of downsag, in conjunction with dominant subsidence along bounding faults, appear to be common and include (1) mild flexuring and fracturing during initial subsidence prior to establishment of a well-defined fault boundary, processes that accompany inception of all faulting of brittle upper crustal rocks; (2)

incomplete ring-fault subsidence, transitional between downsag and plate subsidence, that produces a hinged or trapdoor caldera; (3) subordinate sagging of the structural caldera floor within bounding ring faults; and (4) gravitationally induced inward late tilting and fracturing of oversteepened unstable caldera walls, in conjunction with slumping and landsliding. Monoclinal flexures and extensional fractures probably accompany inception of all bounding faulting, as in regional tectonic faulting of brittle upper crustal rocks. The appearance of downsag on the flanks of multicyclic caldera depressions can also be generated by volcanic units draped over a preexisting caldera or structural basin.

Because most calderas resulting from large ignimbrite eruptions subside several kilometers or more and are topographically enlarged by late slumping, clear evidence for initial flexuring and fracturing is rarely preserved. Subordinate downsagging is common within caldera floors bounded by well-developed ring faults that accommodate the bulk of total subsidence (e.g., Glen Coe in Scotland, Sabaloka in Sudan, Grizzly Peak in the United States). Saucer-like geometry of an otherwise coherent caldera floor may result from inward dips along the bounding faults, inheritance from broader downsagging during initial subsidence prior to full development of the bounding faults, or generally from localized subsidence of the thermally weakened thin lid over a large shallow magma chamber as a result of focused magma drawdown during rapid eruption. Some large coherently rotated inward-dipping blocks along caldera walls are incipient slide blocks, related to second-order enlargement of the topographic caldera wall by landsliding, rather than primary collapse structures bounded by steeply dipping faults or fractures.

Inward-dipping foliations of intracaldera welded tuff that decrease in dip upsection have been cited as evidence of downsag during eruption and subsidence at several calderas (Chegem, Lake City). Alternatively, such geometries can also readily be interpreted as due to differential primary depositional compaction of intracaldera tuff against caldera walls and caldera-margin slide breccias without need for any downsagging. Compaction dips typically are highly varied near caldera walls (locally approaching vertical), and tuff foliations commonly correlate closely with adjacent buried slopes. Older volcanic strata in walls of many calderas dip horizontally or gently outward, and most prevolcanic strata are in continuity with regional structural attitudes—geometries incompatible with downsag as a dominant subsidence process.

Many basaltic lava-flow calderas (Hawaii, Galapagos, Olympus Mons, etc.) that have subsided repeatedly in small increments have an overall inward downstepping

geometry that has also been described as downsagged or downwarped. Such a geometry of nested sequential collapses within a single caldera during recurrent lava eruptions or intrusions along rift zones, although differing in scale from catastrophic caldera collapse during individual large explosive eruptions, may involve similar processes and be transitional to the multicyclic collapse histories that characterize many ash-flow calderas. In addition to small-scale incremental caldera collapse at basaltic volcanoes, at least some of these (e.g., Kilauea and Mauna Loa) also preserve evidence of longer term cycles of caldera filling and recurrent collapse. Nested recurrent collapse events, although cumulatively generating an inward-sloping composite subsidence profile, need not involve major downsag during individual eruptions and caldera-subsidence events.

### C. Trapdoor Subsidence

Trapdoor subsidence, bounded by a partial ring fault and by a hinged segment, constitutes incomplete or incipient plate collapse, intermediate between plate and downsag subsidence processes. Such partial subsidence may be related to smaller eruptions, an asymmetrical magma chamber, or regional structural influences. Geometrically well-defined examples of trapdoor subsidence in the western United States include Silverton, Organ Mountains, Eagle Mountain, Big John, Whitehorse, and Tucson Mountains calderas. Well-described hinged or trapdoor calderas elsewhere include Snowdon caldera in Wales, Bolsena in central Italy, and Sakugi in southwest Japan.

### D. Piecemeal Disruption

Small-displacement piecemeal faulting of subsiding caldera floors is probably common. Fracturing during subsidence has been demonstrated for a few calderas by growth-fault deformation of an intracaldera ignimbrite concurrently with welding. Complex piecemeal subsidence of caldera floors on a coarse scale, involving arrays of arcuate or rectilinear growth faults without large-scale bounding structures, has been interpreted as the dominant subsidence process for a few calderas. Such features could result from interaction with the prevolcanic structural grain or from intricate fracturing of the caldera floor during a single eruption, but without clear evidence of large-scale growth faulting during a single eruption, piecemeal fracturing of a caldera floor can be open to alternative interpretations.

Geometrically complex fracturing should be expected at sites of multiple nested or overlapping collapses that cause incremental subsidence during successive ash-flow eruptions, as is likely present in floors of overlapping caldera complexes that subsided recurrently at intervals of tens to hundreds of thousand years (documented by drilling data for Dorobu caldera in Japan, Bolsena and Latera calderas in Italy, and clustered calderas in the southwest Nevada volcanic field). Other multicyclic calderas, probably comparably geometrically complex but lacking caldera-floor structural data, include Santorini in the Aegean, the Kagoshima Bay area of southern Japan, and the central San Juan caldera complex in the United States. Such complexities in caldera-floor geometry may also be indicated by scattered or transverse distributions of postcaldera postcollapse vents within recurrently subsided calderas, as at Campi Flegrei, Aso, or Santorini. Analogous complexities in subsidence geometry appear likely for the historically active Rabaul caldera in Papua, New Guinea, where geologic relations document successive overlapping caldera subsidences during the past few hundred thousand years, even though present-day seismicity defines a geometrically simple ring structure for the active caldera.

The well-exposed Ordovician Scafell caldera in the English Lake District has been interpreted by Branney as a piecemeal subsidence structure, involving dispersed subsidence along growth faults during a single eruption, but the multiple intracaldera depositional units that have been mapped there appear to record diverse eruption and emplacement processes during accumulation of intracaldera fill. The stratigraphically complex fill at Scafell thus differs from the thick ignimbrite accumulations during single eruptive cycles at many younger calderas and suggests, alternatively, that subsidence could have been incremental during successive eruptions over a sustained time interval.

At the widely known Glen Coe caldera in Scotland, recurrent block faulting, with displacements of tens to a few hundred meters, accompanied successive early eruptions of relatively small-volume pyroclastic deposits. Much deeper subsidence along bounding ring faults at Glen Coe appears to have been associated with more voluminous later ignimbrites. The cauldron block subsided at least 1 km, as recorded by the thickness of preserved volcanic sequence, but this amount is a minimum because correlative volcanic rocks are not preserved outside the subsided block. Despite emphasis of recent work on the role of piecemeal faulting at Glen Coe, its overall structure seems reasonably interpreted as dominated by subsidence along the bounding ring faults, with smaller scale breakup of the floor largely preceding development of the ring-fault subsidence.

## E. Chaotic Subsidence

Chaotic subsidence, marked by intense wholesale disruption and brecciation of caldera-floor rocks, has been inferred to be an important caldera-forming process in some reviews, but such processes have not been documented for any well-exposed large ash-flow calderas. Chaotic subsidence has been proposed as a process (1) to generate low-density material within calderas that can account for the observed negative gravity anomalies and (2) to generate lithic breccias by collapse of the roof over a depressurizing magma chamber. However, observed gravity anomalies in calderas can be modeled successfully with alternative assumptions, and voluminous lithic breccias within many calderas are demonstrably formed by gravitational failure and landsliding of oversteepened walls adjacent to bounding faults. Thick megabreccias exposed in deeply eroded calderas typically are interleaved conformably with ash-flow tuff, indicating that such breccias are depositional units of the caldera fill, rather than drastically disrupted floor. Large landslides from the inner caldera walls (collapse collar volume of Fig. 3) are also a potential source of voluminous extracaldera lithic material, in addition to direct vent erosion, that could be entrained in the eruption column and emplaced as lithic lag breccia; chaotic disruption of floor or vent material need not be the sole or even dominant source. The volumes of lithic lag breccia in proximal outflow deposits are typically small in comparison to the slide breccias that accumulate within the subsided area.

## F. Funnel Calderas

The term “funnel shaped” is potentially ambiguous for caldera structures. Virtually all calderas are funnel shaped in overall geometry in the sense that their topographic walls flare outward from the structural boundaries due to gravitational slumping (Fig. 3). A funnel-shaped structural boundary could also result from severe downsag or piecemeal subsidence or, probably more commonly, from recurrent subsidence during successive eruptions.

Small calderas (<2–4 km in diameter at topographic rim) commonly have a simple funnel geometry, because enlargement by slumping of the inner wall into an areally restricted vent is the dominant process in establishing the overall size of the subsided area (Fig. 6). Such calderas are associated with explosive eruptions from a central vent, lack a bounding ring fault or a coherent subsided block, and probably overlie relatively small (or deep?) magma

chambers. Well-documented funnel calderas, associated with relatively small ash-flow eruptions, include Nigori-kawa and Sunagohara calderas in Japan, which are well constrained in three dimensions by geothermal drilling, and Red Hills in the United States. Such funnel calderas appear to merge in geometry and structural type with dia-tremes associated with explosive eruption of more mafic magma to form tuff rings and maars.

Based mainly on modeling of gravity anomalies, some large young calderas, especially in Japan (Aira, Aso, Kuttyaro), have been inferred to have a funnel structure attributed to broad upward flaring of the primary eruption conduit. Such funnel structures have been inferred to develop in relatively weak crusts of young island arcs, in contrast to ring fault and plate subsidence of calderas in cratonic environments. However, no large funnel structures have been clearly documented for eroded calderas in Japan, even though many ring-fault calderas and plate-subsidence structures have recently been recognized in eroded Tertiary volcanic fields.

A further complexity for large calderas inferred to have funnel geometry is the ambiguity of interpretations based on gravity data. A plate-subsidence structure with lithic debris concentrated near structural margins, as is commonly observed in eroded calderas, could generate a gravity profile indistinguishable from a funnel structure. Geometrically simplistic gravity modeling of some Japanese calderas as funnel shaped (e.g., Aso) is complicated by recurrent eruption of multiple large ash-flow sheets and multistage incremental subsidence. Recent detailed processing of gravity data and results from deep drilling at Aso suggest multiple flat-bottomed gravity lows and an overall “piston–cylinder type structure rather than a funnel-shaped structure.” Elsewhere, deep erosional exposure and/or exploration drilling has documented that an overall stepped funnel-like geometry can result at large ash-flow calderas from multistage subsidence along nested ring fractures (e.g., Campi Flegrei, Grizzly Peak, and several San Juan caldera complexes).

### G. Ignimbrite “Shields”

While caldera sources have been identified worldwide for most well-preserved large ash-flow sheets, among the late Tertiary volcanoes spectacularly exposed on the altiplano of the central Andes are silicic centers where a large-volume tuff sheet dips gently outward from a central lava dome complex. Initially interpreted mainly from satellite images for this difficult-of-access high-altitude region, these have been described as “ignimbrite shields” that erupted without significant caldera collapse

or resurgence. Ignimbrite shields have been proposed as an important but little recognized class of explosive silicic centers that reflect eruption from relatively deep magma chambers.

Because Andean volcanologists have also described many plate-subsidence and resurgent calderas similar to ash-flow centers elsewhere, the apparent absence of comparable ignimbrite shields in North America and elsewhere suggests possible interpretive problems with the Andean ignimbrite “shields” resulting from their lack of dissection, inaccessibility, and resulting limited field study. At least some ignimbrite “shields” seem alternatively interpretable as conventional (structurally bounded) nonresurgent calderas, surrounded by their ignimbrite aprons, that were then filled to overflowing by younger intracaldera lavas and tuffs.

Potentially analogous nonresurgent large calderas that were once completely buried by later lava flows and other volcanic deposits have been variably exposed by erosion in many volcanic areas (Black Mountain and Kane Springs Wash calderas in southwest Nevada and several calderas of the San Juan field in the United States; Cappadocia field in Turkey). Some intracaldera and caldera-margin constructs in the San Juan region were stratovolcanoes originally rising well above the regional terrain; others were clusters of smaller lava domes that interleave with pyroclastic-flow and volcanioclastic sedimentary deposits. The primary pre-erosion morphology of these filled calderas would have looked strikingly like the described “ignimbrite shields” of the Andes. In comparison with the altiplano region, and its superb exposures of near-pristine unvegetated volcanic features, the southern Rocky Mountains provide the advantage of exposing a third dimension in glacial canyons a kilometer or more deep (along with disadvantages such as heavy vegetation).

### H. Volcano-Tectonic Depressions

Inferred sources for some large ash-flow eruptions, which have been interpreted during reconnaissance studies as having vented directly from regional graben without developing localized calderas, have been described as volcano-tectonic depressions. While ash-flow eruptions and associated calderas have long been recognized as associated with extensional tectonics, no large pyroclastic eruptions have been shown unambiguously to be accompanied mainly by subsidence along regional fault troughs. Many typical calderas are known within and adjacent to major graben and rift zones. While the margins of subsequent calderas can be influenced by regional

structures, some developing polygonal fault boundaries, drastic elongation of individual ash-flow subsidence structures along regional structural trends seems rare. To the contrary, some calderas along regional fault troughs are elongate perpendicular to their graben setting (Long Valley, Questa in the United States).

Association of ash-flow eruptions and caldera formation with regional extension leads to subsidence and burial of calderas along axes of graben, obscuring relations between volcanism and tectonic setting. Increasingly, detailed geologic, geophysical, and deep-drilling data have demonstrated that several regions commonly cited as volcano-tectonic depressions contain clusters of subsequent calderas along the graben axis. Examples include the Taupo Volcanic Zone in New Zealand, where at least eight major ignimbrite calderas that have formed since 1.6 Ma are variably concealed beneath volcanic and sedimentary fill; the Toba depression in Indonesia, where four discrete ignimbrite eruptions were accompanied by caldera collapses from varying locations between 1.2 Ma and 75 ka; and Kagoshima Bay in Japan, where at least five calderas have erupted in the past million years. Even where bounding caldera faults consist of linear segments, the surface expression of caldera subsidence typically assumes a more nearly circular geometry as unsupported oversteepened walls slump into the central depression. On a smaller scale, even the strongest linear extensional structures can host circular volcanic subsidences, as exemplified by the development of equant pit craters along rift zones of Hawaiian volcanoes.

## I. Discussion

Many well-studied calderas involve subsidence processes intermediate between idealized end members: ring-fault calderas can have complex boundaries involving more than a single arcuate bounding fault, both hinged down-sag boundaries and ring faults are involved in trapdoor caldera subsidence, and floors within some ring-fault calderas have sagged or faulted at loci where magma erupted rapidly. Many calderas have such transitional attributes that subclassification can be inherently ambiguous and subjective. For example, the exceptionally exposed Grizzly Peak caldera in the United States, originally described as a nested ring-fault plate-subsidence structure, has impressed others as involving significant down-sag and piecemeal subsidence. Interpreting caldera structures in terms of a continuum of subsidence styles, rather than as end-member types, can clarify relations between eruptive and structural processes in comparison

to size of the eruption and the location and geometry of the cogenetic magma chamber.

The flaring of inner caldera walls as a result of landsliding during subsidence is a major process in generating caldera morphology and caldera fill. Lithic material, derived from vent enlargement and slumping of caldera walls, is more voluminous in caldera fills than commonly recognized from study of young, little-eroded calderas. In funnel calderas and small ring-fault subsidences, such lithic material is the dominant component of the caldera fill; model calculations suggest that some funnel calderas generate as great a volume of lithic debris as can be contained within the caldera (to the level of the unfilled collar height; Fig. 3). In larger calderas, wall-rock lithics are roughly equal in volume to the juvenile syncollapse volcanic ejecta that accumulate within the caldera. For the largest calderas, the proportion of intracaldera slide debris is lower, and only minor slide material would reach central parts of the caldera fill.

Caldera enlargement by landsliding and changes during postvolcanic erosion complicate comparisons of caldera geometries and structures. Postcollapse erosion of the inner caldera wall first enlarges the area of the topographic caldera basin, but continued erosional dissection down to structural boundaries of calderas will reduce the apparent caldera size. For example, the resurgent Creede caldera in the Oligocene San Juan volcanic field is presently best defined by the unconformity between caldera-filling and caldera-wall rocks (Fig. 7). This boundary is intermediate between the inferred initial topographic rim, parts of which are discontinuously preserved in the modern landscape, and the concealed structural boundary that is approximately defined by arcuate alignment of resurgent structures, postcaldera vents, and hot-spring upwelling loci. The structurally bounded subsided block has only about one-third the area of the original topographic caldera, demonstrating how heavily apparent caldera size is influenced by erosional depth. Despite such uncertainties, calderas associated with explosive eruptive activity worldwide have fairly similar ranges of dimensions, as approximated by plots of maximum diameter (Fig. 8). The largest calderas occur within continental crust, and many of these are composite, are multicyclic, or provide evidence of sequential subsidence into geometrically complex magma chambers.

---

## IV. SOCIETAL IMPLICATIONS

Caldera-forming eruptions, like most volcanic activity, can have both positive and adverse impacts on the envi-

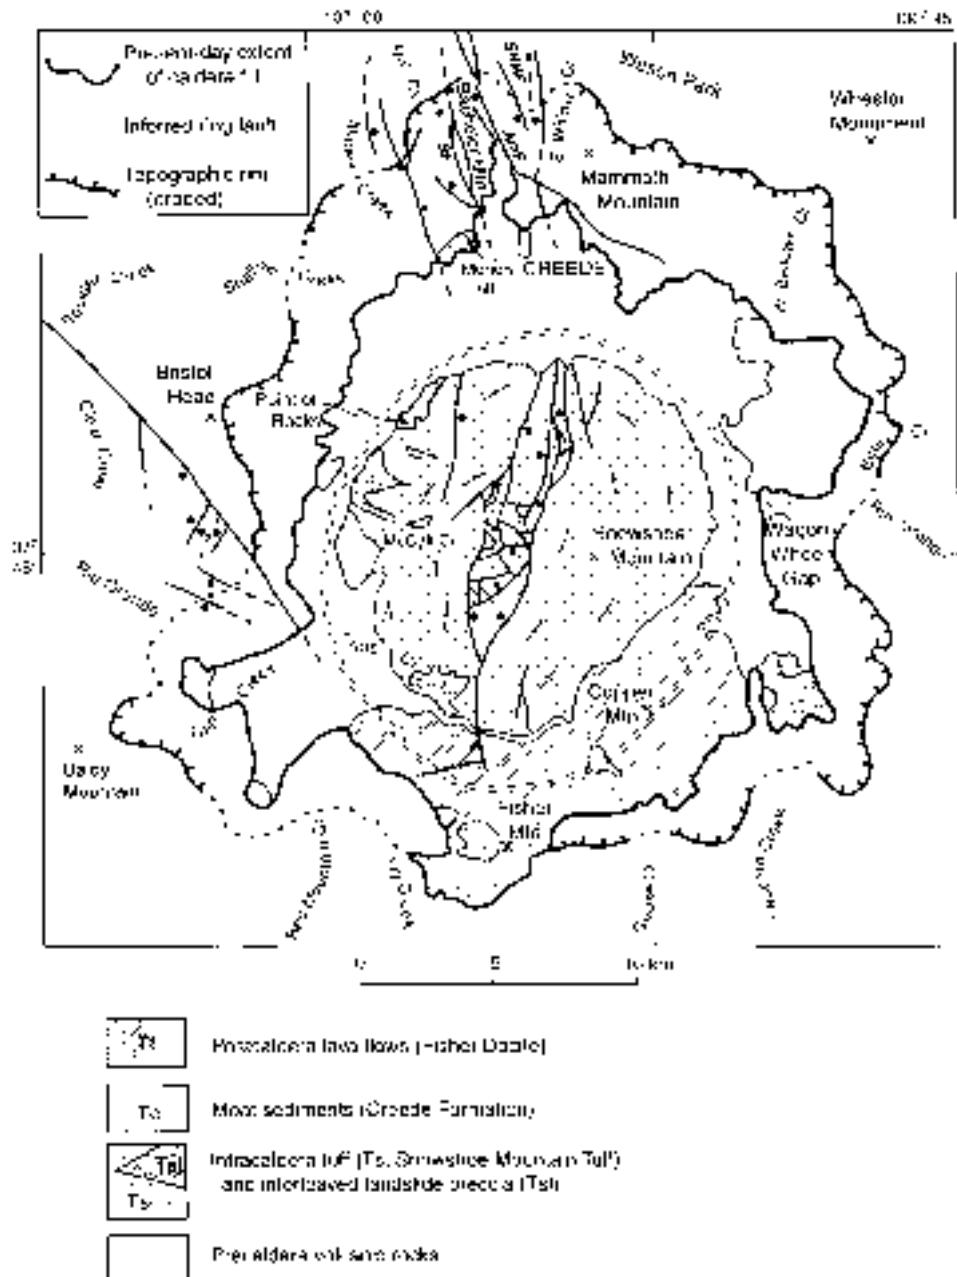

FIGURE 7 Generalized geologic map of the Creede caldera, United States, showing approximate location of eroded topographic caldera rim, present-day extent of moat-fill deposits, inferred buried ring fault, and late normal faults formed during resurgent doming and mineralization.

ronment and human society. Large explosive eruptions involve obvious hazards to people and property, while the volcanic ash generated by such events generates some of the world's most fertile soils and agricultural areas (cf. "Volcanic Soils"). Volcanic ash and aerosols generated on vast scales during caldera-forming events

can adversely modify global climate. Caldera structures are important loci for valuable metallic ore deposits (cf. "Mineral Deposits Associated with Volcanism") as well as for hydrothermal heat that can become valuable energy resources (cf. "Exploitation of Geothermal Resources").

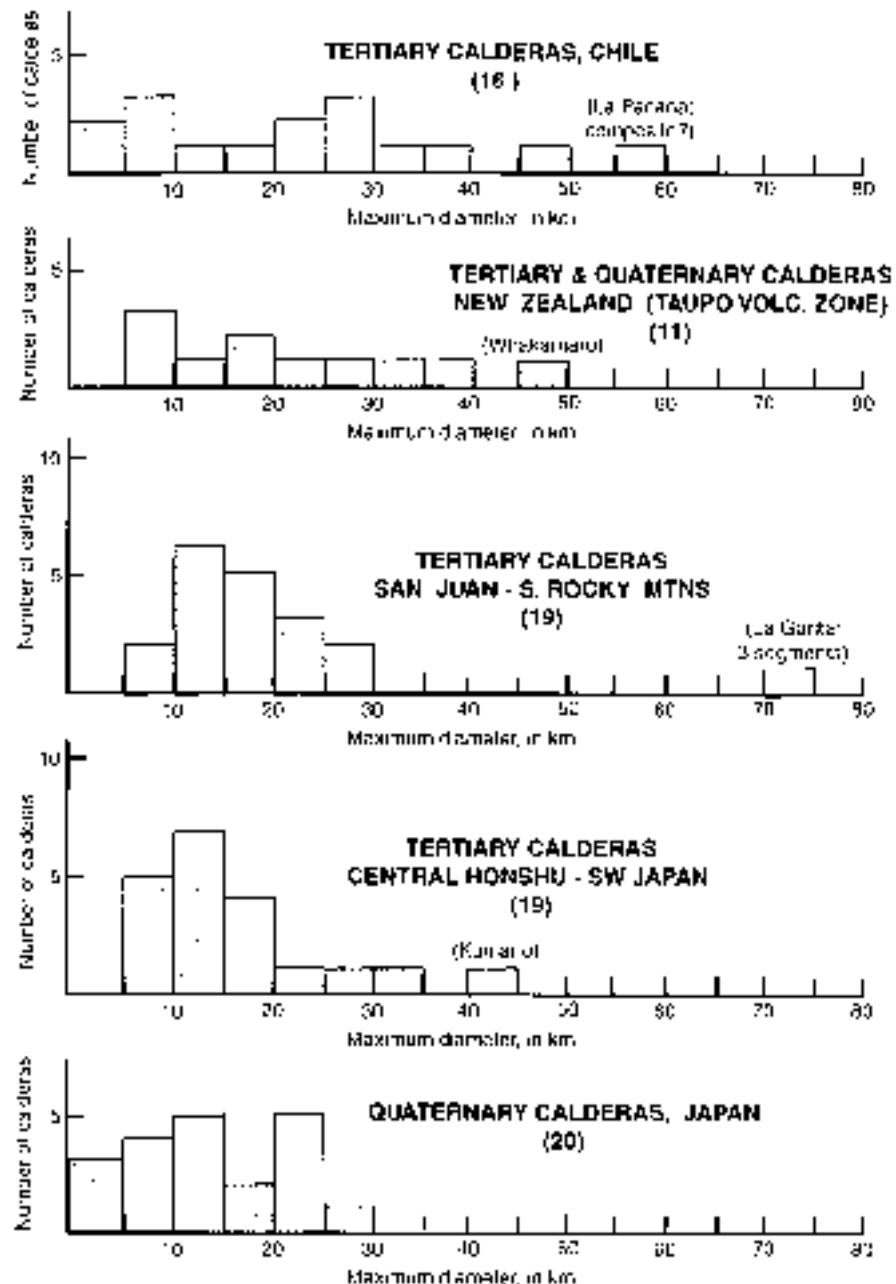

FIGURE 8 Diameters (maximum dimension) of calderas in diverse tectonic settings. Calderas in most regions have similar ranges of diameters. Smaller young calderas, as recorded in the Quaternary of Japan, probably tend to be obscured by erosion and cover by younger volcanic rocks in the older (Tertiary) volcanic fields. The largest calderas tend to be composite (multiple eruptions at La Pacana in Chile) or geometrically complex (successive subsidence of multiple segments during a single eruption at La Garita in the San Juan Mountains).

### A. Calderas and Volcanic Hazards

Large caldera-forming explosive eruptions probably represent the most catastrophic geologic events that affect the Earth's surface, other than rare large meteorite impacts. Krakatau in 1883 caused 30,000 deaths, mainly from tsunamis associated with the caldera eruption. The much smaller 1991 Pinatubo eruption in the Philippines could have been comparably deadly because of the high population density on its lower flanks had the onset of this eruption not been accurately forecast and large areas evacuated successfully. The potential societal impact of a future eruption comparable in size to large prehistoric events, should it involve a heavily populated area such as Napoli in Italy or Kagoshima Bay in Japan, are so enormous as to defy comprehension.

In recent years, relatively intense unrest has occurred at Long Valley in the United States (1980 to present), Campi Flegrei in Italy (1983 to present), and Rabaul in Papua, New Guinea (1971–1994). The unrest at Rabaul culminated in 1994, when two volcanoes erupted simultaneously along opposite sides of the ring-fracture system defined by current seismicity, but no large ignimbrite eruptions or caldera-wide subsidence were involved. Both Campi Flegrei and Rabaul have already experienced multiple caldera-subsidence events associated with large eruptions, so additional caldera-forming events are a significant long-term hazard for any existing restless caldera. One of the most important future tasks for volcanologists will be to recognize precursors for potentially devastating caldera-forming eruptions, as contrasted with the more frequent small eruptions at previously active volcanoes. Most future caldera-forming eruptions can be expected to occur at sites of existing calderas, but any cluster of active volcanoes should be evaluated as a potential site of a growing upper crustal magma chamber that could fuel a future caldera eruption. Because calderas form so infrequently, present understanding is woefully inadequate concerning the variety of potential precursors, the proportion of precursor events that lead to major eruptions, and especially the characteristic time intervals between precursors and eruption.

### B. Caldera-Forming Eruptions and Global Climate

Large pyroclastic eruptions that generate caldera collapse carry fine-grained ash and sulfur aerosols into the upper atmosphere. Historical caldera-forming eruptions

such as Tambora in 1815, Krakatau in 1883, and Pinatubo in 1991, although several orders of magnitude smaller in eruptive volume than the largest prehistoric eruptions, appear to have modified global climate, including visible atmospheric effects such as strange colors and halos on the sun and moon, vivid sunsets and sunrises, and anomalously cold weather. The dominant influence is believed to be injection of sulfur aerosols into the stratosphere, a process whose efficiency varies in relation to magmatic sulfur content and height of the eruption column. As a consequence, some exceptionally large silicic eruptions such as the 0.6-Ma Yellowstone event, characterized by relatively low sulfur contents, may have affected global climate less than smaller eruptions of more mafic sulfur-rich magma. The overall impact of explosive volcanic eruptions on global climate, in comparison to other influences such as polar ice cap volumes and deep ocean currents, remains uncertain.

## GLOSSARY

**composite volcano** Relatively large, long-lived constructional volcanic edifice, comprising lava and volcaniclastic products erupted from one or more vents, and their recycled equivalents.

**compound volcano** Volcanic massif formed from coalesced products of multiple, closely spaced, vents.

**debris avalanche** Catastrophic landsliding of gravitationally unstable volcano flanks resulting in a widely dispersed deposit at the foot of the edifice, typically characterized by a hummocky surface.

**edifice** Constructional volcanic mass.

**planezes** Triangular, flat-faced, facets on volcano flanks formed by the intersection of two master gullies in the upper reaches of a cone.

**ring plain** Region surrounding a volcano beyond lower topographic flanks, over which tephra and mass-wasting products are radially distributed.

**satellite (or flank, or parasitic) vents** Small monogenetic

volcanic features (domes, cinder cones) distributed over the flanks of a larger composite edifice.

**steady-state or equilibrium profile** Shape of the edifice (cone) once an active volcano has become well established—follows the initial cone building, precedes long-term erosional degradation, and represents a balance between construction through mass addition (eruption) and degradation through erosion.

**topographic inversion** Process whereby through time valleys become ridges and vice versa—can occur on volcanoes as volcanic products such as lavas are channeled down valleys, focusing subsequent erosion along their edges.

**vent** Surface opening at which volcanic material is erupted.

**A** SK A SMALL child to draw a volcano. Chances are that child will draw a composite cone. These are the most common types of volcanic edifice, the sites of the most well-known historic eruptions, and the sources of a wide array of volcanic products. Composite volcanoes occur in all regions of volcanic activity across the Earth. Human populations are drawn to composite volcanoes, attracted by the fertile and frequently renewed volcanic soils generated by the volcanoes, while at the same time threatened by the hazards associated with their frequent eruptions.

## I. INTRODUCTION

### A. Definition of Composite Volcanoes

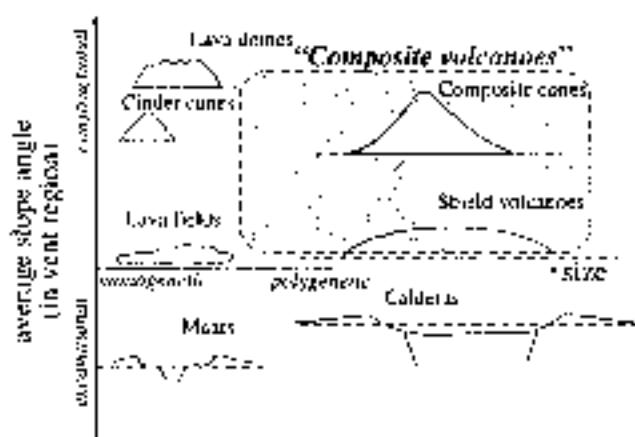

Surprisingly, the definition of a composite volcano is neither straightforward nor uniformly agreed upon. Most volcanoes are constructional features—they build an edifice from erupted material that extends above the original topography in the region of the vent. Exceptions to this are maars and calderas. Among constructional edifices, there are variations in shape and size (Fig. 1). Shape is largely a function of slope angle; at the one extreme are very shallow slopes that characterize shields, and on the other are the steeper slopes that characterize cones and domes. Among the smaller edifices are cinder cones and domes, which are typically monogenetic (formed from a single eruption episode). Shield volcanoes and composite cones are the products of multiple eruptions spanning tens to hundreds of thousand of years, and, as a result, are larger and more diverse in terms of their products (types and compositions). Composite volcanoes are therefore defined as relatively large and long-lived volcanic edifices comprising both lava and volcaniclastic erupted products. Note that our definition is intended to be descriptive and not a rigid classification; composite volcanoes clearly overlap with many other edifice types and may incorporate smaller volcano types (cinder cones and lava domes) in their architecture. Composite cones are commonly taken as synonymous

with stratovolcanoes; the latter term is preferred in many introductory texts. We choose to avoid the term stratovolcano, as it conveys an implication (albeit not necessarily intentional, but certainly perpetuated in diagrams from introductory texts) of regularly interlayered pyroclastic deposits and lavas. The term “composite” has been used to describe volcanic cones from the Andes that have a composite growth history, punctuated by one or more episodes of sector collapse, and the term “compound” to denote edifices comprising multiple cones, resulting from limited vent migration over time within a restricted area. Both composite and compound volcanoes in these senses are included under our definition of composite cones.

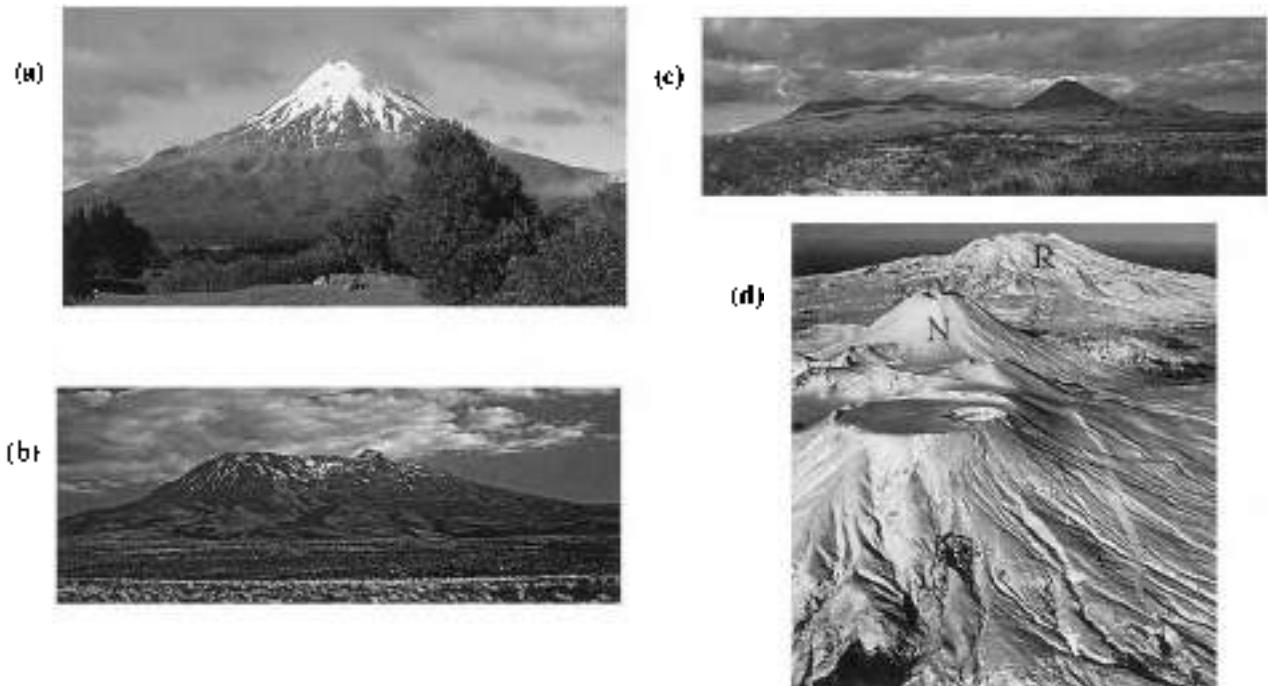

### B. Distribution of Composite Volcanoes

Composite volcanoes are found globally in nearly all regions of volcanism, although their abundance relative to classic shield volcanoes, lava fields and domes, calderas, and cinder cones varies considerably. At convergent plate margins, composite volcanoes are arguably the type edifices (Fig. 2). Indeed subduction zones are perhaps most dramatically characterized by classic cone-shaped basaltic andesite to andesite volcanoes such as Mount Fuji in Japan. In fact, most well-known historic eruptions have occurred at composite cones located along convergent plate margins (Table I). Although some convergent margin environments where extension occurs in intra-arc grabens or backarc rifts are dominated by cinder cone fields, the magmatic expression of a convergent plate margin is generally a chain of composite volcanoes, subequally spaced, comprising a volcanic arc. The arc is subparallel to the trench and constructed on the upper plate approximately 100–150 km above the upper surface (known as the Wadati–Benioff zone—see “Plate Tectonics and Volcanism”) of the subducted slab. The spacing of the volcanoes along the arc is subregular, varying from 30 to 100 km among different arcs, although most arcs may be characterized by an average spacing. The control on volcano spacing is unclear and may reflect the spacing of Rayleigh–Taylor diapiric instabilities in a melt zone above the subducted slab or periodic variations in the stress state of the upper plate lithosphere that impede or allow melt ascent.

Composite volcanoes are not common at divergent plate margins, although examples can be found. Along oceanic divergent margins (mid-ocean ridges) they are effectively absent, although on Iceland, where the mid-ocean ridge lies over a mantle plume, composite cones

**FIGURE 1** Variations in volcanic landforms as a function of size and “steepness.” The diagram is intended for illustrative purposes rather than a rigorous classification. The composite volcanoes discussed in this article are constructional features, each with a reasonably protracted history of eruptions. The erupted products typically comprise both lavas and pyroclastic materials, associated with reworked deposits.

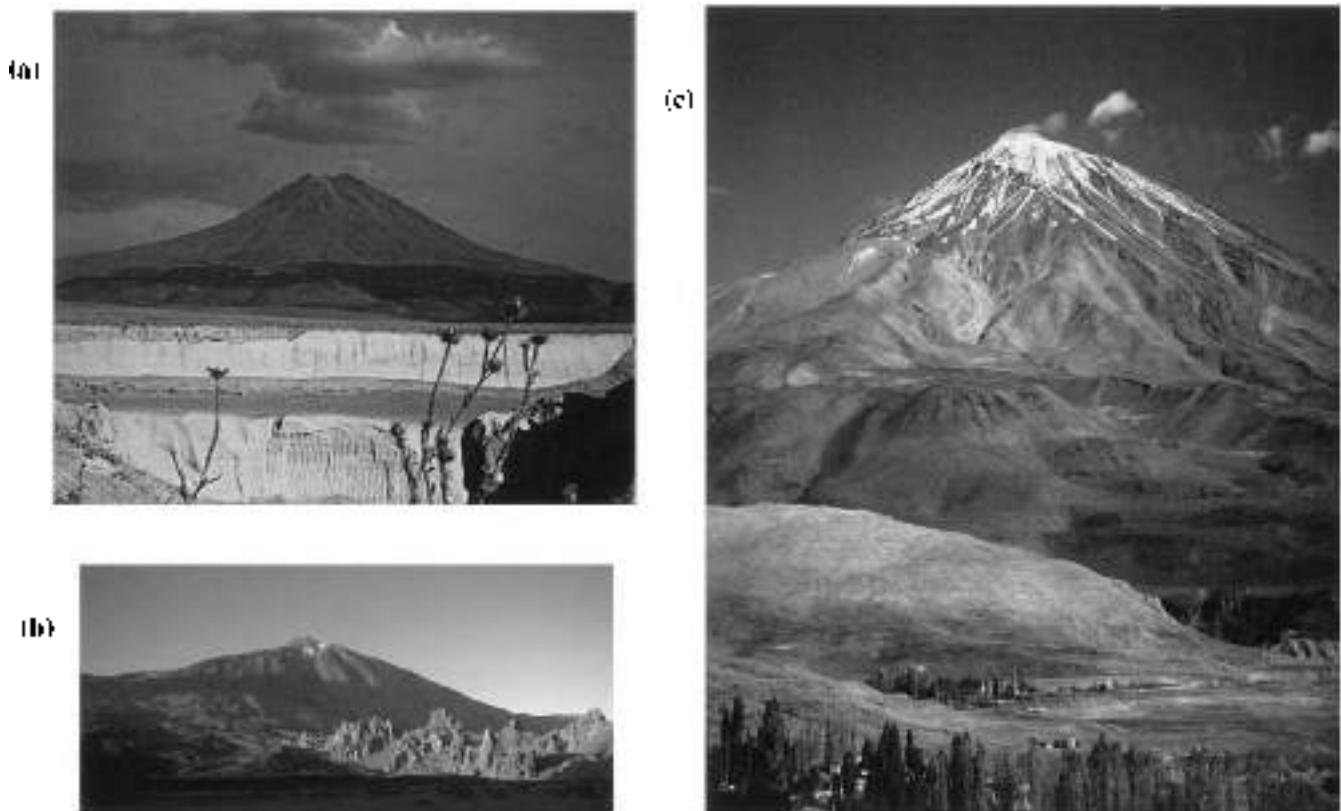

**FIGURE 2** Examples of different composite volcano forms from a convergent plate margin setting, the North Island of New Zealand: (a) Mount Taranaki, a “classic” cone shape; (b) Mount Ruapehu, a compound volcano; (c) Tongariro, a compound volcano with numerous Holocene vents (the youngest being the symmetrical cone of Mount Ngauruhoe with a single active vent). Photograph d is an aerial view of Tongariro (N = Ngauruhoe) looking south to Ruapehu (R) in the distance, for comparison. The variation from (a) to (c) reflects an increasing tendency for vent location to migrate over time. Although they are cluster or composite edifices (Table II), Ruapehu and Tongariro might be considered twin volcanoes (to each other) in a broad sense.

are present, such as Hekla and Askja. In the early stages of divergent margin development (continental rifting), composite volcanoes do occur, although they are typically off-axis. Along the East African Rift, for instance, huge composite volcanoes (e.g., Mount Kilimanjaro) are found at the rift shoulders. Intraplate volcanism, perhaps by virtue of the high heat (and therefore magma) flux over a protracted time period, typically gives rise to large composite volcanic edifices. Many, particularly in the ocean basins, are dominated by basaltic effusion and are classic shield volcanoes. Composite intraplate volcanoes may, however, be found in both oceanic and continental environments. They are effectively indistinguishable morphologically from those found at convergent plate margins (Fig. 3), differing only in terms of the rock chemistry and petrography.

What factors determine the surface expression of magmatism, that is, the construction of composite volcanoes rather than other volcano landforms? Two factors at least promote the formation of composite volcanoes: (1) the composition of magma erupted and (2) the style of eruption. Magma compositions at convergent plate margins are largely the result of differentiation and vola-

tile concentration. These factors are, of course, not unconnected, as volatile concentration is typically a consequence of differentiation (cf. “Volatiles in Magmas”). Styles of eruption are controlled more by the physical structure and stress environment of the lithosphere through which magmas ascend (although this also influences the extent of magma differentiation). In order to produce compound volcanoes, eruptions at a given vent are frequent and small to moderate in size.

Differentiation increases  $\text{SiO}_2$  content and increases magma viscosity, leading to high aspect ratio lavas and impeding lateral distribution. Thus there is a distinction between shield volcanoes, at which low-viscosity basalts can flow large distances from the vent, and cones, at which lava flows are shorter and construct a steeper sloped edifice around the vent. The combined increase in volatile content and magma viscosity also increases the propensity for explosive eruption and the production of pyroclastic material. Convergent margin magmas are characterized by high  $\text{H}_2\text{O}$  contents, and, at least by the time they reach the surface, they tend to be differentiated (basaltic andesites and andesites). Because magma ascent is fundamentally dictated by the buoyancy con-

**FIGURE 3** Large composite volcanoes from intraplate settings: (a) Hasandag volcano, Cappadocia, Turkey; (b) Teide volcano, Tenerife; (c) Mount Damavand in northern Iran (5671 m) (see also color insert). Both continental (a, c) and oceanic (b) crustal substrates are represented.

trast between magma and the lithosphere, ascent through thick, low-density continental crust will be impeded unless extensive differentiation occurs to reduce the magma density. Protracted differentiation can ultimately produce large volumes of rhyolite in continental regions, which, in turn, may be erupted in caldera-forming events (cf. "Calderas").

The association of calderas with precursor composite volcanoes is common. Smaller, less differentiated caldera systems such as Crater Lake in Oregon may represent the cataclysmic evacuation of a silicic magma chamber from beneath a simple composite cone. Larger caldera-forming eruptions (such as at Long Valley in California and Valles in New Mexico) are typically preceded, albeit by a few million years, by magmatism expressed as clusters of composite volcanoes concentrated in the region of the future caldera. Composite volcanoes and calderas may also be contemporaneous, varying only slightly in location along and across zones of magmatism, such as the Taupo Volcanic Zone of New Zealand. These associations suggest a further complex

balance between magma/heat flux and the rheological state of the crust in determining the morphological expression of volcanism.

In summary then, relative to shield volcanoes, composite volcanoes are characterized by the eruption of more differentiated, silica- and volatile-rich magma. Compared with caldera systems, composite volcanoes erupt smaller volumes more frequently and less explosively, which likely inhibits the long-term extreme differentiation, which typifies caldera-forming magmas.

## II. MORPHOLOGY OF COMPOSITE VOLCANOES

### A. Introduction

Morphology is one of the most fundamental properties of a volcano, and yet surprisingly little work has been

TABLE I Selection of Notable Eruptions from Composite Volcanoes Since A.D. 1500 Involving 1000 or More Fatalities<sup>a</sup>

Volcano	Country	Year	Explosive eruption	Lava flow	Debris flow	Tsunami	Famine

done since the seminal work of Cotton in the 1940s. One of the reasons for this may be the general perception that the morphological evolution of a composite volcano is simple; they are positive (constructional) topographic features, with steep flanks and a general conical shape, and they result from local accumulation of erupted products. However, this simple view ignores the fact that while many composite volcanoes are simple cones with a single summit vent and radial symmetry, many are more complex, compound volcanoes with convoluted histories involving cone collapses, rebuilding, and changing vent locations through time (Table II). Nevertheless, they still display a conical profile normal to the length axis, suggesting a consistency to the “normal” conical shape of a single composite cone.

Another fact that is ignored is that the simple conical shape is the result of a complex evolution that is controlled by the interplay of aggradation and degradation. Short-term aggradation by constructive processes of

eruption and emplacement of volcanic materials is opposed by degradation as the longer period destructive processes of erosion, punctuated by catastrophic events such as gravity-driven avalanching (cf. “Debris Avalanches”) and posteruption mass wasting. The fact that active composite volcanoes maintain a simple conical shape suggests that the average rate of aggradation must exceed the “punctuated equilibrium” of degradation.

## B. Evolution of Morphology

Most composite volcanoes around the world have very similar characteristics. These volcanoes are characterized by a concave-upward profile, which should be considered as the equilibrium or steady-state profile of an active composite cone. Classic textbook volcanoes such as Mount Mayon in the Philippines, Mount Fuji in

TABLE II Summary of Morphological Types among Composite Volcanoes

Morphological type	Description	Examples
Simple cone	Classic “textbook” radially symmetric shape; tend to be young	Fuji (Japan), Klyuchevskoy (Kamchatka), Mount Mayon (Philippines), Osorno (southern Chile), Shishaldin (Aleutians, United States), Taranaki (New Zealand), Cotopaxi (Ecuador)
Shieldlike	Shallow-sloped flanks, common craters/calderas in summit region, greater diversity of magmas (include evolved types such as dacite/rhyolite)	Newberry (Cascades, United States), Okmok (Aleutians, United States), Gorely (Kamchatka)
Compounds	Limited vent migration—typically resulting in an elongate ridge, more occasionally a large equant massif	Ruapehu (New Zealand), Zhupinovsky (Kamchatka), Lascar and Irruputuncu (northern Chile), Tatara–San Pedro (southern Chile)
Twins	Distinct neighboring volcanoes, considerably closer together than average volcano spacing along an arc; typically there is an age difference between the two edifices (a younger active and an older cone)	Avachinsky–Koryaksky (Kamchatka), Parinacota–Pomerape and San Pedro–San Pablo (northern Chile), Colima (Mexico)
Clusters	Groups of more than two distinct polygenetic edifices	Tongariro (New Zealand), Bromo (Java)
Collapse-scarred	Severe recent modification of morphology by sector collapse, resulting in large summit bowl or amphitheater	Mount St. Helens (Cascades, United States), Bezymianny (Kamchatka), White Island (New Zealand)

Japan, and Mount Taranaki (formerly Egmont, New Zealand) exemplify this (Fig. 4). While this is a useful general observation, it is instructive to note that more youthful or nonequilibrium volcanoes have a more pure conical shape with a more restricted base (Fig. 4b). At most composite volcanoes, it is clear that this shape is produced by early lavas being more voluminous and extensive than later lavas (Fig. 4b, parts iii and iv). Certainly, there is a slight concavity to the flanks, but these volcanoes lack the extensive aprons of talus that accentuate the concavity of the slopes. This suggests that mass transfer through destructive processes modifies the shape of a volcano with time from a cone with simple slopes and a restricted base to one with a more concave-upward profile and a wider base (Fig. 4c). Most active volcanoes are equilibrium or steady state.

### C. Factors Controlling Morphology

Notwithstanding the complexities discussed above, the primary shape of a composite volcano is conical. Many of the controls on this shape can be understood by considering the geometry of a cone. The volume  $v$  of a simple cone is given by

$$v = \frac{1}{3}\pi r^2 h, \quad (1)$$

where  $r$  is the radius of the base and  $h$  is the height of the cone. For a typical steady-state volcano with the concave-upward profile, a more complex exponential form is needed:

$$r = Be^{Mh}. \quad (2)$$

$B$  and  $M$  are constants and the volume has to be found by integration. Below we address the main factors that control the morphology of composite volcanoes.

### D. Aggradation

While there is a strong dependency of edifice height on the volume of a composite cone, there also appears to be a limit to the size of composite cones. Edifice heights (base to summit) of composite volcanoes rarely exceed 3000 m and the vast majority of arc-related composite volcanoes are between 2000 and 2500 m. Volumes are similarly restricted; notwithstanding the difficulty in measuring accurate volumes, maximum volumes for arc-related composite volcanoes are around 200 km<sup>3</sup> (e.g.,

Mount Adams and Mount Shasta in the Cascades of the United States). Intraplate composite cones may attain larger volumes.

One explanation for this is that the conical form exerts a fundamental control on the growth of a volcano. The relationships in Eqs.(1) and (2) suggest that if the conical form is to be maintained, every additional increment in height requires a huge additional increase in volume—the additional volume has to be distributed all over the cone. At some point, this becomes prohibitive to further growth. However, closer examination of volcanoes reveals that the height increment does not necessarily always involve the large volume increment suggested by the relationships described in Eq. (2), because in many cases the increase in height is achieved by adding material to the uppermost parts of the edifice only. In many cases the uppermost parts of composite cones are characterized by small and stubby lava flows or domes reflecting their evolved nature and attendant high viscosity and yield strength (Fig. 4c, part iv). Effusion of these lavas builds up the edifice without much new volume being added and results in the steep slopes that characterize the uppermost slopes.

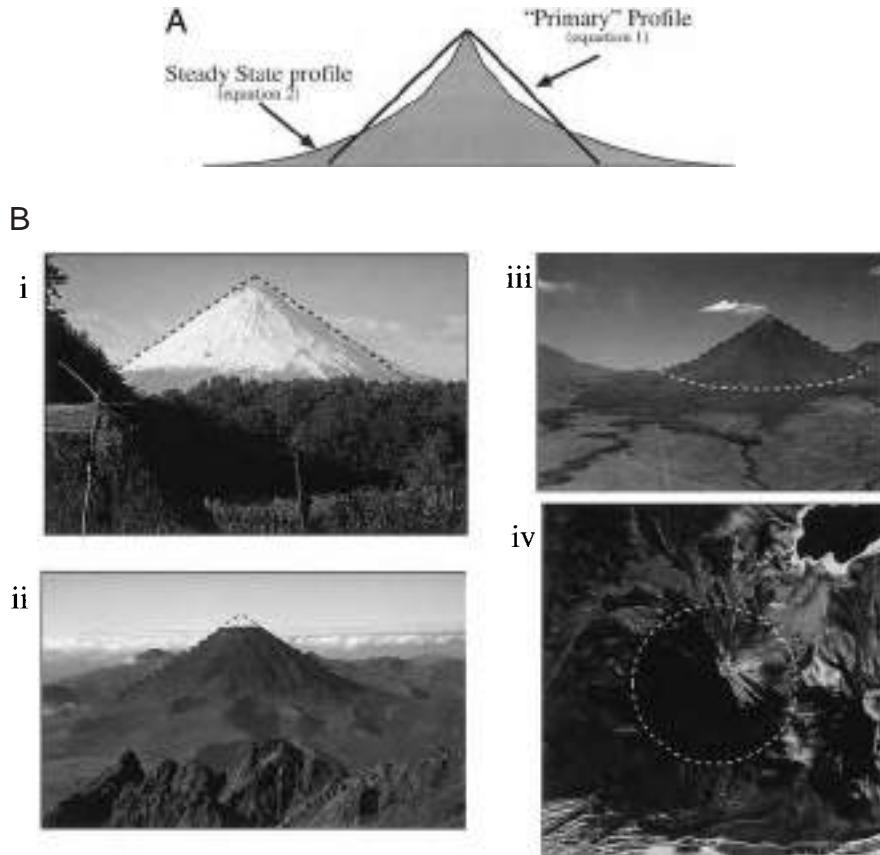

The consistency of edifice heights and volumes in comparable tectonic settings around the world suggests that some simple geophysical relation must exist to limit the size of composite volcanoes. Several factors can affect the height to which a composite volcano can grow. Among these are the nature of the volcanic products, the duration of magma supply, differentiation of the magmas, and the crustal density profile. Magma supply is certainly an important control because the largest composite volcanoes are intraplate volcanoes such as Mount Ararat, Turkey; Mount Damavand, Iran; and Mount Kilimanjaro, Kenya. Here magma production and supply rates are higher than those associated with arcs and the resulting edifices are much larger. However, even though magma supply rates and other factors are likely to be different between regions or arcs, they may be close to constant for a given region, arc, or portion of an arc. Mature composite volcanoes in comparable tectonic settings are still similar in size the world over.

Most eruptions from composite volcanoes are driven by the hydrostatic “head” or, more appropriately, the overpressure (that in excess of lithostatic (Fig. 5)) in the magma reservoir. Geophysical studies of active volcanoes commonly reveal the presence of shallow (5–10 km) magma storage zones beneath active volcanoes. Petrologic studies confirm shallow reservoir depths as most composite volcanoes are characterized by eruptions of porphyritic magmas dominated by plagioclase. Furthermore, most volcanic products also show evidence of

extensive magma mixing—a phenomenon that is best understood in the context of shallow magmatic systems. While it is debatable whether a shallow magma reservoir exists throughout the entire lifetime of the volcano, it is clear that one must exist during the actively erupting stages. Therefore it is reasonable to assume that most eruptions from composite volcanoes occur from shallow magma reservoirs and therefore that the overpressure required to erupt material from the chamber is unlikely to vary much. The consistency of the ballistics of volcanic bombs from composite volcano eruptions supports this contention.

As a volcano grows, two factors may conspire to decrease the eruption rate. First, the growing mass of the volcano increases the lithostatic load on the shallow magma chamber and eventually overcomes the hydrostatic head. Inflation and deflation of volcanic edifices are often modeled as the result of a shallow source of deformation (a Mogi source), suggesting strong feedback between the edifice and the magma reservoir. Second, the distance the magma has to ascend to the surface increases. It should be clear from Fig. 5 that if  $h$  and the load are increased, there will be a limit (observational evidence suggests this is about 3000 m of edifice height) above which it will be physically unlikely that further lava can be erupted from the summit. Two general observations support this reasoning. First, early lavas tend to be more voluminous and extensive than later lavas. Second, early lavas are commonly less evolved than later lavas. The first directly relates growth to changing effusion rate, and the second implies that the critical overpressure ( $P_{ex} > P_{lith}$ ) can only be maintained if the reservoir magma becomes more evolved and consequently less dense, but more viscous as the volcano grows. Only the higher viscosity of the lower density, evolved lavas permits the condition  $P_{ex} > P_{lith}$  to be maintained—the more evolved lavas typically have lower magma densities due to removal of dense crystalline phases and can sustain greater overpressures on vesiculation since the higher viscosities impede volatile outgassing.

This control is well illustrated in Fig. 4b, parts iii and iv. Here, the youthful cone of Licancabur is built from shorter younger flows radially disposed around the vent, overlying older more extensive flows. The true equilibrium profile has not yet developed because there has been insufficient time to significantly degrade the flanks and develop a talus apron. A dramatic decrease in density (with consequent increase in overpressure) can also be achieved by vesiculation of the magma. This condition will depend on magma composition (volatile species, solubility, and content) and on its capacity to achieve supersaturation through depressurization, which isulti-

**FIGURE 4** (A) Idealized evolution of the shape of a composite volcano. Initially, a pristine volcano will form a pure conical form with constant slopes and a volume given by Eq. (1). Mass wasting results in transfer of mass from the upper parts of the edifice to the lower flanks, building out a talus apron. The edifice evolves to a steady-state profile with concave-upward slopes and a volume given by Eq. (2). Compare with examples of profile evolution given in (B) and (C), respectively. (B) Young nonequilibrium conical profiles: (i) Klyuchevskoy volcano, Kamchatka, one of the world's most active subduction zone volcanoes and <10,000 years old (view from north); (ii) Ngaruuhoe cone (ca. 2500 years old), New Zealand (cf. Fig. 2); (iii) Licancabur volcano, view from west together with (iv) Landsat TM image of Licancabur. Photographs iii and iv show the early more extensive lava flows around the base and a more restricted cone formed from later more restricted lavas, outlined in a white dashed line.

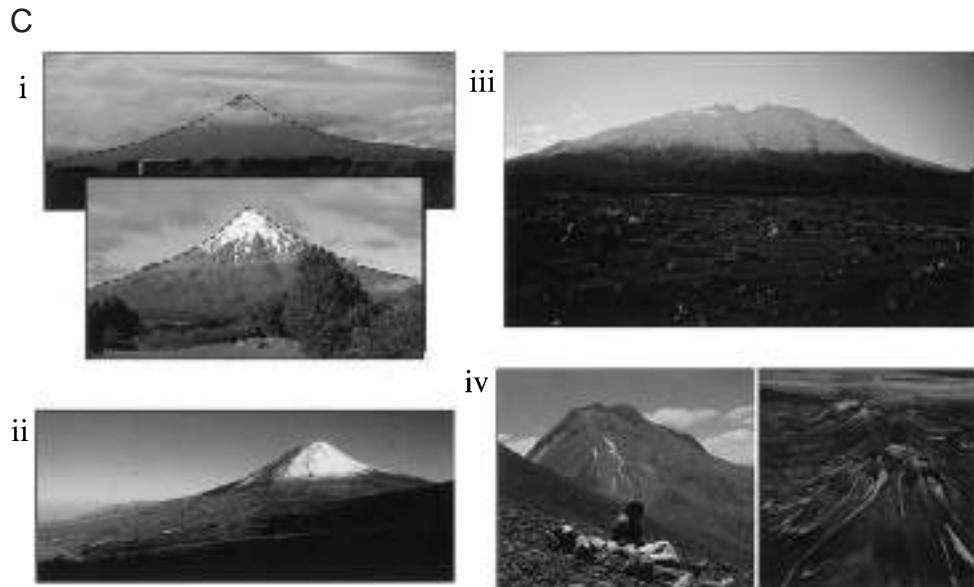

mately also controlled by the parameters illustrated in Fig. 5.

### E. Degradation

In a heuristic and phenomenological sense, the history of a composite cone can be thought of as the interplay of short-term eruptive phenomena that construct volcanoes periodically and the longer term erosive processes of degradation that conspire to bring them down (Table III). However, while this is a useful working hypothesis, it is important to recognize that the while the averaged rate of degradation on composite volcanoes suggests longer term equilibrium, in reality degradation is highly

variable, consisting of a regional “background” rate modulated by more rapid erosion and mass-wasting events. The high degradation rates often accompany and closely follow eruptions and punctuate the equilibrium. For instance, observations after the 1980s eruptions of Mount St. Helens in the USA and the 1991 eruption of Mount Pinatubo in the Philippines showed that peaks of erosion follow closely on peaks of eruption as pyroclastic material is rapidly (months to years) removed from the cone. Catastrophic processes such as landsliding/avalanching further conspire to accelerate degradation.

Long-term erosion depends on climate and the composition of the volcanic edifice. Given comparable rates of production and cone growth, volcanic cones are better

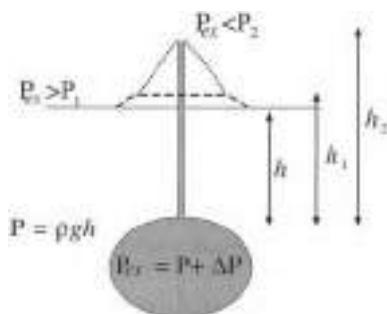

**FIGURE 4 (continued)** (C) Equilibrium profiles: (i) Taranaki volcano, New Zealand (two views from the north emphasizing classic extensive equilibrium profile of concave-up flanks); (ii) Volcan Misti (Peru) from southeast showing extensive ring plain or talus apron and a developing equilibrium profile; (iii) lahar deposits of the ring plain or talus apron (foreground) of Mount St. Helens. Low-angle aprons of this type of material extend out to several kilometers from the base of the cone. View is from the southeast. (iv) Aguas Calientes from Lascar (central Andes), showing the short, stubby lava flows that have built up the steep upper portions of the cone.

preserved in arid/cool climates rather than humid equatorial climates. For instance, climatic differences between the hyperarid central Andes and the tropical northern Andes are highlighted by pristine morphologies of Pleistocene volcanoes in the former and degraded morphologies in the latter. In response to eruptive

events that produced large volumes of unconsolidated material and greatly disturbed local topographic equilibria, at Mount St. Helens, 10-m-deep gullies were cut into the pyroclastic deposits within a few months of the

**TABLE III** Stages in the Erosional History of Composite Volcanoes

**FIGURE 5** Schematic diagram showing the relation between lithostatic pressure  $P$  and eruption driving overpressure  $P_{ex}$  in the magmatic system of an active volcano. The lithostatic pressure  $P$  changes with the mass of the growing volcano and the depth to the magma chamber  $h$ . Eruption can take place as long as  $P_{ex}$  remains greater than  $P$ . At  $h_2$ , the edifice has grown to the critical height beyond which  $P_{ex}$  is less than lithostatic and therefore eruption from the summit is no longer viable.

Stage	Geomorphic signature
1	Fresh, young cones, often dark, pristine lava flows and summit crater visible, sharp profile; not glaciated
2	Small gullies on flanks, lavas visible and crater may exist, but degraded; cone still sharp, dark apron gone; moraines present
3	Individual lava flows barely visible, no crater, well-established gullies, constructional surfaces dwindling; planezes initiated
4	No lava flows visible, deeply incised gullies, large planezes, little original cone surface left; considerable relief; major U-shaped glacial valleys in glaciated regions
5	Barely recognizable, low relief; radial symmetry the only clue to volcanic origin

eruption. At Mount Pinatubo, the 1991 pyroclastic flows had similar gullies within a matter of days. On the other hand, pyroclastic deposits at Katmai (Alaska), where the climate is somewhat cooler and drier, are only moderately eroded nearly 100 years after eruption.

The composition of the edifice is an equally important control on degradation styles and rates. Clearly, unconsolidated pyroclastic material will be more readily eroded. Lava is less porous than scoria and will encourage runoff. Porosity and permeability will therefore be important in controlling if runoff or percolation dominates. Since extensive gullying is common on composite volcanoes, we can surmise that runoff dominates. Gullying is the most common indication of degradation of composite cones and occurs in several stages. One of the most significant stages of gullying involves the formation of planezes (Table III). These are the result of two master gullies intersecting in the upper reaches of a cone and isolating a triangular, flat-faced, facet.

The biggest single obstacle to the growth of a volcano is gravity and the hackneyed cliche “what goes up must come down” is nowhere better exemplified than in the catastrophic debris avalanches (cf. “Debris Avalanches”) that are now recognized as being part of the normal mode of activity of composite volcanoes. The mass transfer associated with these events is largely responsible for modifying the shapes of volcanoes to the steady-state concave-upward profile as the deposits from these events extend the talus apron of the lower flanks out to several tens of kilometers from the summit.

As a volcano grows, its slopes become steeper and therefore gravitationally unstable. Further, asymmetry resulting from unequal distribution of mass on an edifice adds to the instability. Edifices built on slopes are inherently unstable. Gravitational collapse requires a trigger, and many events of this type probably involve earthquake-triggered flank failures (e.g., Bezymianny, 1956; Mount St. Helens, May 1980). The growing volcanic load may reactivate local basement faults that may penetrate up into the volcanic edifice (e.g., Socomopa, Chile, 7500 a). Finally, inflation of the cone due to a recharge event or degassing may trigger the collapse of an unstable flank (e.g., Tata Sabaya, Bolivia).

The most spectacular examples of gravitational collapse involve the failure of 25–30% of a volcanic cone in a matter of minutes.

The morphologic signatures of collapse are invariably a collapse amphitheater and hummocky topography on the avalanche deposit; the May 18, 1980, eruption of Mount St. Helens (see “Debris Avalanches”) provides a typical example. Several other amazing examples have also been recognized around the world, but nowhere more so than in the central Andes. The studies in the

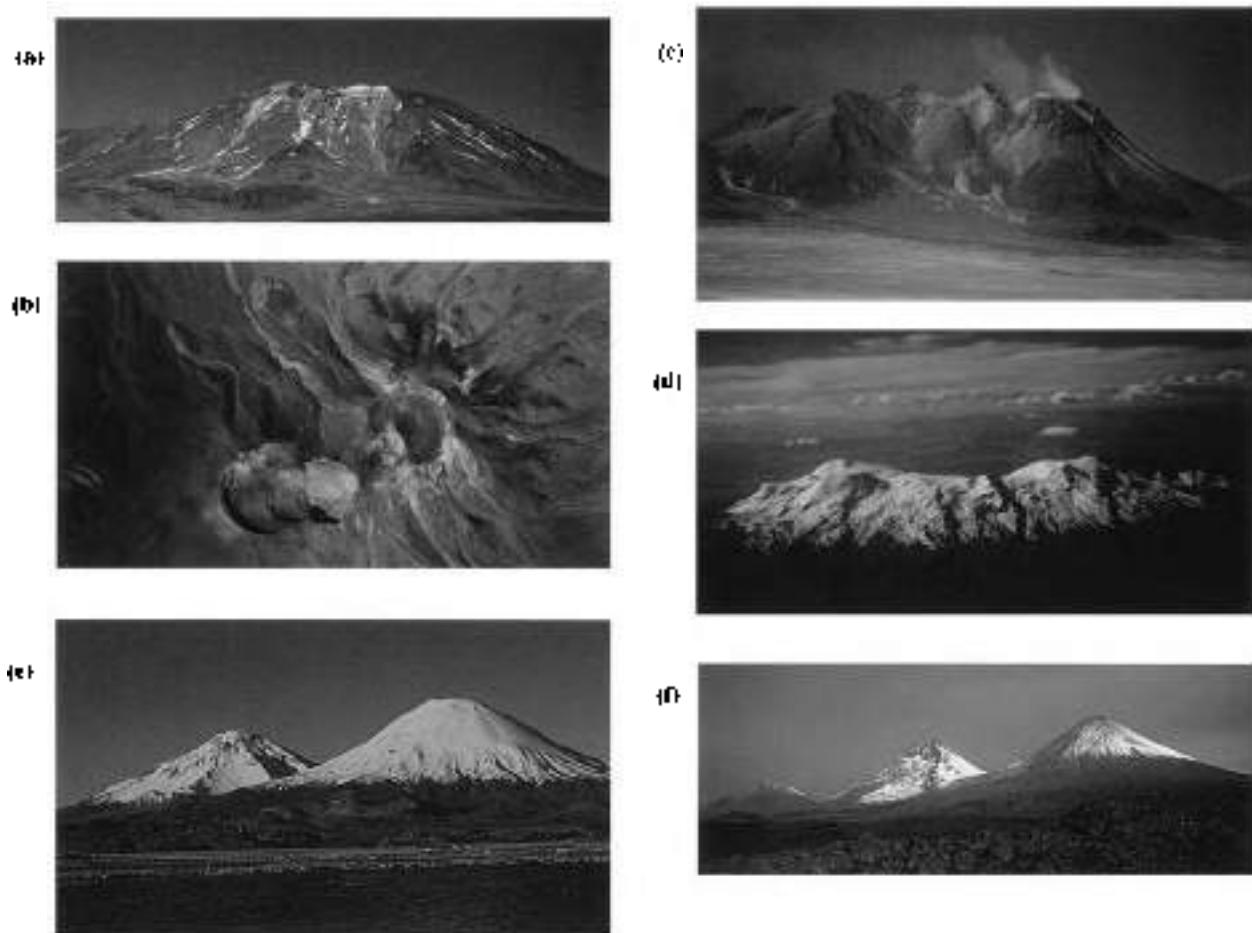

central Andes highlight several key features. First, collapsed portions may vary in scale from relatively small (10–15%) portions of the edifice as at Irruputuncu on the Bolivia/Chile border to quite large (30%) portions of the edifice as at Tata Sabaya in Bolivia. Second, regardless of how extensively an edifice is eviscerated, the conical shape is reestablished very rapidly. This may explain why there are currently few clear examples of collapse-scarred volcanoes (Table II). At Parinacota in Chile, reconstruction since a massive collapse 13,000 years ago has virtually rebuilt the entire edifice (Fig. 6e; see also color insert). Only very careful examination of aerial photographs reveals the trace of the amphitheater. At Bezymianny in Kamchatka, a dome growing since the 1956 sector collapse has nearly filled the amphitheater (Fig. 6f). Third, the deposits from these collapses can form a significant portion of the talus apron of volcanoes (e.g., Volcan Misti, Peru).

Gravitational collapse is therefore a significant mechanism of mass transfer on composite volcanoes. The reduction of steep slopes of the upper and middle flanks by collapse and deposition of these materials far from the flanks results in extensive low-angled aprons (commonly referred to as *ring plains*; *vide infra*) extending to several tens of kilometers out from the edifice. Subsequent “healing” of the cones results in reestablishment of steep middle and upper flanks, perpetuating the steady-state profile.

Also important in determining the volcano morphology resulting from degradation are the effects of hydrothermal alteration. Mature conduits can provide a sufficient heat flux to drive groundwater through a hydrothermal circulation system, with the consequence that the rock volume affected by the system is altered and weakened, making it more vulnerable to erosion by both long-term, slow-mass-wasting, glacial or fluvial processes and catastrophic failure. In volcanoes with well-established hydrothermal systems, the vent region can occupy an enormous bowl of altered volcanic material (such as Mutnovsky volcano, Kamchatka) that may resemble—or on occasion coincide with—a sector collapse amphitheater. The occurrence of hydrothermal activity and the influence of consequent alteration can extend long after magmatic addition to the edifice has effectively ceased and exert considerable control on its morphological degradation.

#### F. Changes in Vent Locations through Time

The classic conical shape owes its form to the constancy of vent location over a protracted period of time. This

**FIGURE 6** More complex or compound composite cones, illustrating effects of local vent migration through time. (a) Lascar from the north, an extensive composite cone that is elongate east to west due to migration of the vent region. (b) Aerial photograph of Lascar clearly showing the nested craters resulting from vent migration (north to top of page). (c) Irruputuncu (Chile/Bolivia), another typical nonconical, ridgelike composite cone (view from the west). The oldest part of the cone is the left. (Photograph courtesy of Gerhard Worner; see also color insert.) (d) Coropuna, Peru, a compound volcano made up of at least five different overlapping cones. (e) Nevados de Payachata, central Andes, comprising twin volcanoes (view from southwest). The older glaciated Pomerape cone is to the north (left), while Parinacota is the young, more symmetrical cone. The hummocky terrane in the foreground is a debris avalanche deposit. (See also color insert.) (f) Klyuchevskoy group volcanoes, Kamchatka, view from the south east. The symmetrical Klyuchevskoy cone in the foreground and the vapor-shrouded Bezymianny volcano (which collapsed in 1956 and now consists of a large active dome in the amphitheater) in the distance are both active, while the central peak (Kamen), which shows the scarp of a collapse event, is inactive.

ensures that volcanic products, and therefore mass, are always added from the summit area and decrease radially away from it. However, many volcanoes show evidence that activity has migrated with time (Table II, Fig. 6). Several interesting questions arise. For instance, it is not clear whether activity migrates in the same direction with time throughout the region, in response to migration of the volcanic front as a whole, or whether it is segment specific or even random.

Some volcanoes are twin systems comprising two

quite distinct but neighboring composite volcanoes. Examples include San Pedro–San Pablo and the Nevados de Payachata in the central Andes (Fig. 6e). Typically, twin volcanoes reflect a vent shift such that one of the two is active, leaving its twin extinct. Examples are found, however, such as Bezymianny and Klyuchevskoy volcanoes in Russia (Fig. 6f), where neighboring volcanoes are concurrently active. Others are elongate amalgamated edifices with a migrating summit complex. Examples of these include the following: in the central

Andes, Aucanquilcha, Lascar (Figs. 6a and 6b), Irruputuncu (Fig. 6c), Coropuna (Fig. 6d), and Ojos del Salado, the world's highest active volcano; in New Zealand, Ruapehu (Fig. 2); in Turkey, Ararat; in Kamchatka, Zhupinovsky. Tongariro (Fig. 2) is an extreme example of this as it is a cluster of as many as 30 relatively small edifices. These compound volcanoes offer even greater challenges of interpretation than on "simple" cones. The complex geometries of nested and overlapping cones make determination of individual cone volumes difficult as we commonly do not see basement exposed and the preexisting topography is unknown. Volcanic stratigraphy is similarly problematic to unravel, particularly in light of the close proximity (in both space and time) of potential source vents.

Subsidiary vents, commonly called satellite, parasitic, or flank vents, are common features at many composite volcanoes. The general use of the term parasitic should, however, be discouraged as it implies an often-false dependence on the main volcano. These subsidiary vents are typically in the form of small monogenetic volcanoes like cinder cones or domes (Figs. 1 and 7). Such features are commonly arranged along lineaments and are inter-

preted as reflecting the influence of faults along which magma can migrate laterally away from the main magma chamber or, more commonly, vertically from a separate magma batch. In some cases, these satellite vents occur as part of an areally extensive field spatially associated with the main volcano as at Mount Adams in Washington state or Payun Matru in Argentina. Geochemically, the erupted products of flank eruptions are commonly found to be significantly different from those of the main vent. Typically, they are more primitive but they can show a wide range in compositions—those of the main vent tend to be more restricted in their range. These observations suggest that in these systems the main vent is supplied by a steady-state magmatic system, whereas flank eruptions might be supplied by separate small magma batches that do not intercept the main magma chamber. In the case of the volcanic fields peripheral to the main cone (e.g., Mount Adams, Washington, U.S.A.; Payun Matru, Argentina; Mount Ararat, Turkey), the more mafic magmas that typically erupt from the satellite vents are probably prevented from ascending beneath the main cone by its subjacent magma storage system.

### III. LIFETIMES OF COMPOSITE VOLCANOES

It is important at the outset to distinguish the active life of a volcano from its longevity as a topographic entity. A volcano can exist as a topographic entity for a considerable time after its active life—defined as the time span over which volcanic eruptions occur—is over. The time span over which it remains recognizable is largely a function of degradation rate (the “background erosion” of Section IIIE), which is a function of climate. In arid regions such as the central Andes, 20-Ma-old volcanoes are well preserved and easily recognizable. In more temperate climates, this time span is considerably shorter. The discussion below focuses on the active lifetime of a composite volcano.

The general impression from the sparse and largely poorly constrained geochronological data on composite volcanoes is that these are long-lived. Observational evidence suggests that during this long lifetime periods of rapid aggradation punctuate the slow background of degradation. Unfortunately, these data do not address more detailed questions that are critical to really addressing the time scales over which volcanoes operate. For instance, does a composite volcano form in one

continuous episode or multiple episodes with periods of repose? How long are the eruptive episodes and the repose periods? What are the rates of eruption that characterize periods of aggradation? To answer these questions, one must address issues such as eruption rates during eruptive episodes vs background eruptive rates, episodic cone growth rates vs average long-term cone growth rates, length of repose intervals, eruption recurrence time scales, time–volume–composition relationships, and even the meaning of “active” and “dormant.”

The paucity of knowledge exists because addressing these questions requires detailed high-precision geochronology tied to detailed stratigraphy and few studies that have attempted this. The seminal work on the Mount Adams volcanic field in the USA distinguishes itself as a standard, which has recently been complemented by studies of Tatara–San Pedro in central Chile and Tongariro on the North Island of New Zealand. These detailed studies afford a general framework (see Table IV) within which many of the questions above can be addressed. Some of the main observations are

1. *Composite volcanoes grow in spurts.* The main cone of Mount Adams was built in three main episodes between ~520–490, 460–425, and 40–10 ka at eruption rates of 1.6–5 km<sup>3</sup>/ka. At Tatara–San Pedro the two youngest

TABLE IV Volume–Time Relationships for Well-Studied Active Composite Volcanoes

	Volume (km <sup>3</sup> )	Inception of activity of the volcanic system (ka)	Age of cone-building events (ka)	Peak eruption rates (km <sup>3</sup> /ka)	Background eruption rates (km <sup>3</sup> /ka)
Mount Adams	~200	940	520–490 460–425 40–10	1.6–5.0	0.05–1.0
Tatara–San Pedro	~55 <sup>a</sup>	930	183–83, Pellado 90–19, Tatara–San Pedro	0.2–0.3	0.06 <sup>b</sup>
Tongariro	~50	250–275	0–2.5, Ngauruhoe 65–110, Tongariro Trig 70–115, SW Oturere 120–190, Pukekaikiore 200–210, Tama 2 90–250, NE Oturere 215–275, Tama 1	0.88 0.27 ± 0.11 0.11 ± 0.05 0.09 ± 0.02 1.00 ± 0.02 0.37 ± 0.07 <sup>c</sup> 0.03 ± 0.02	0.17–0.2

<sup>a</sup> Volume of lavas preserved. Original volume assuming 50–95% of material erupted between 930 and 200 ka has been removed by erosion due to glaciation is much higher.

<sup>b</sup> Based on preserved volume. If no erosion is assumed, rate would be 0.2–0.3, which is similar to peak rates.

<sup>c</sup> Applies to main period of cone growth, 110–130 ka.

composite cones of Pellado and Tatara–San Pedro formed between 188–83 and 90–19 ka, respectively. So these two composite cones formed during  $\sim$ 100 ka of eruptive activity at a minimum rate of  $\sim$ 0.2–0.3 km $^3$ /ka. At Tongariro, seven large cones of 2–17 km $^3$  were built in periods ranging from 2.5–270 ka (or 2.5–70 ky) at rates of 0.09–1 km $^3$ /ka. These data suggest that the length and rate of cone-building episodes are quite variable.

Less comprehensive data from other places confirm this variability. The 250-km $^3$  Kluchevskoy volcano (Kamchatka) has been built in the past 7000 years at an extremely high rate of 8–35 km $^3$ /ka, whereas the similarly symmetric cone of Mount Fuji (Japan) appears to have been constructed in two phases from 80 to 10 ka and from 5 ka to the present. At Mount St. Helens the 79-km $^3$  cone has been built in the past 40 ka at a rate of 2 km $^3$ /ka, whereas the 76-km $^3$  cone of Parinacota (Chile/Bolivia) is thought to have formed in the past 250 ka at peak rates of around 0.6 km $^3$ /ka. Santa Maria and Fuego (Guatemala) are thought to have been constructed entirely in the past 100,000 years.

These reasonably short (generally  $<$ 100 ka) cone-building episodes might be considered the typical timescales to reach “maturity”—an approach to the steady-state equilibrium after which overall size is maintained roughly constant by the opposing effects of construction and erosion discussed earlier and the physical controls outlined in Fig. 5. Increases in the volume of the overall edifice beyond this are typically a function of subsequent vent migration.

2. *Composite volcanoes stay active for periods of up to 500 ka.* Mount Adams in the Cascades dates back to  $\sim$ 520 ka and appears to be typical of other large composite cones in the Cascade arc of North America. Although the data are sparse, Mounts Baker, Rainier, Hood, Jefferson, Mazama, and Shasta are thought to have lasted  $>300$  ka. Once a steady-state edifice has been constructed, there appears to be no clear relationship between volume and longevity.

The observations from the Cascades are ratified from other regions. Tongariro (New Zealand) had been active since  $\sim$ 250–275 ka. In the southern volcanic zone of the Andes, composite volcanoes are thought to have been active for periods of up to 300 ka. Volcan Parinacota, in the central Andes, was initiated  $\sim$ 250 ka, after the vent shifted slightly southward from its older twin cone Pomerape (Fig. 6e).

3. *Volcanic systems may remain active between widely spaced pulses of peak activity.* At Mount Adams, the main volcanic field remained continuously active from 940 to 10 ka with an average rate of eruption of 0.05–1 km $^3$ /

ka with breaks in activity up to 30 ka. At Tatara–San Pedro, the system was active from  $\sim$ 930 to 19 ka at an overall eruption rate of 0.09–0.12 km $^3$ /yr (adjusted for glaciation associated volume reduction). At Tongariro, the background rate of activity since inception  $\sim$ 250–275 ka is 0.17–0.2 km $^3$ /ka and the background rates of activity are considerably lower than the peak rates of activity discussed earlier (Table IV).

4. *Recurrence time intervals between eruptions at historically active composite volcanoes display a wide range.* Volcanoes such as Sakurajima (Kyushu) and Sangay (Ecuador) have been erupting persistently, on an almost daily basis for decades. More typically, composite volcanoes erupt on the 0.1 to 10-year timescale, as exemplified by Fuego (Guatemala), Klyuchevskoy (Kamchatka), Lascar (Chile), Pavlof (Alaska), and Arenal (Costa Rica). Activity at these volcanoes consists of clusters of minor outbursts, commonly vulcanian, of varying frequency. The next characteristic timescale is the hundred to hundreds of years timescale that characterizes many of our best-known recently active volcanoes such as Mount Pinatubo (Luzon), Mount St. Helens (Cascades), and Mount Fuji (Honshu). Lastly, volcanoes such as Mounts Baker, Hood, Rainier, and Adams that have had few true eruptions in the Holocene may typify a class of composite volcanoes that operate on the timescale of millennia.

No doubt our understanding of composite volcano behavior and evolution is biased by the historical record (Table IV), which may be too truncated relative to the timescales of cyclic volcanic activity to be representative.

---

#### IV. CHARACTERISTICS AND DISTRIBUTION OF VOLCANOGENIC PRODUCTS AT COMPOSITE VOLCANOES

##### A. Introduction

Composite volcanoes are characterized by a greater diversity of volcanogenic products than any other volcanic landform (Fig. 8). The controls on the nature and distribution of erupted products are twofold—magmatic differentiation processes and syneruptive modulation by interaction with the surface environment. In the former category are included the melting and differentiation processes discussed earlier in this volume (e.g., “Composition of Magmas,” “Origin of Magmas,” “Volatiles in Magmas,” and “Magma Chambers”) that determine

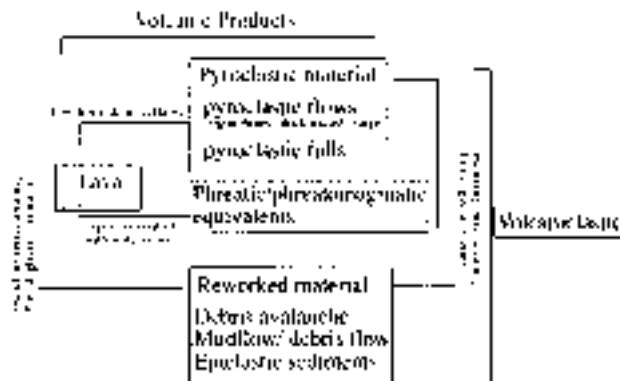

FIGURE 8 Broad classification of volcanogenic products (lavas vs volcaniclastic rock types, distinguished by shading of boxes) at composite volcanoes.

the physical properties—density and viscosity—of the magma. In this respect, the role of volatiles is critical (“Volatiles in Magmas”). High volatile concentrations increase the propensity for eruption as fragmented magma (pyroclastic) relative to lava, although the influences of effective magma viscosity and ascent rate will ultimately determine the occurrence and extent of explosivity. In the latter category, the surface morphology controls the distribution of lava flows. As gravity-driven phenomena, both pyroclastic and lava flows are typically channeled into valleys, producing a complex interplay of erosion and construction that leads to frequent topographic inversions on volcano flanks.

The morphology of the summit region can have a significant effect in directing volcanogenic flows, particularly if there are distinct crater breaches. Lava domes, a common feature of evolved composition volcanoes, may dominate vent region morphologies over long periods of time—occupying either craters (e.g., Soufrière and Montserrat) or sector-collapse scar amphitheaters (e.g., Mount St. Helens). The domes are commonly active, growing by slow addition of magma to the interior and periodically gravitational collapse—which may or may not be accompanied by explosions. Dome talus landslides or avalanches may on occasion supply more extensive block-and-ash flows. Lava flows in steep summit regions or on upper flanks may also sustain gravitational instability collapse of their flow fronts, producing hot block avalanches. Sustained dome growth can result in a significant fraction of the upper part of a composite cone being formed entirely of one or more domes (e.g., Bezymianny).

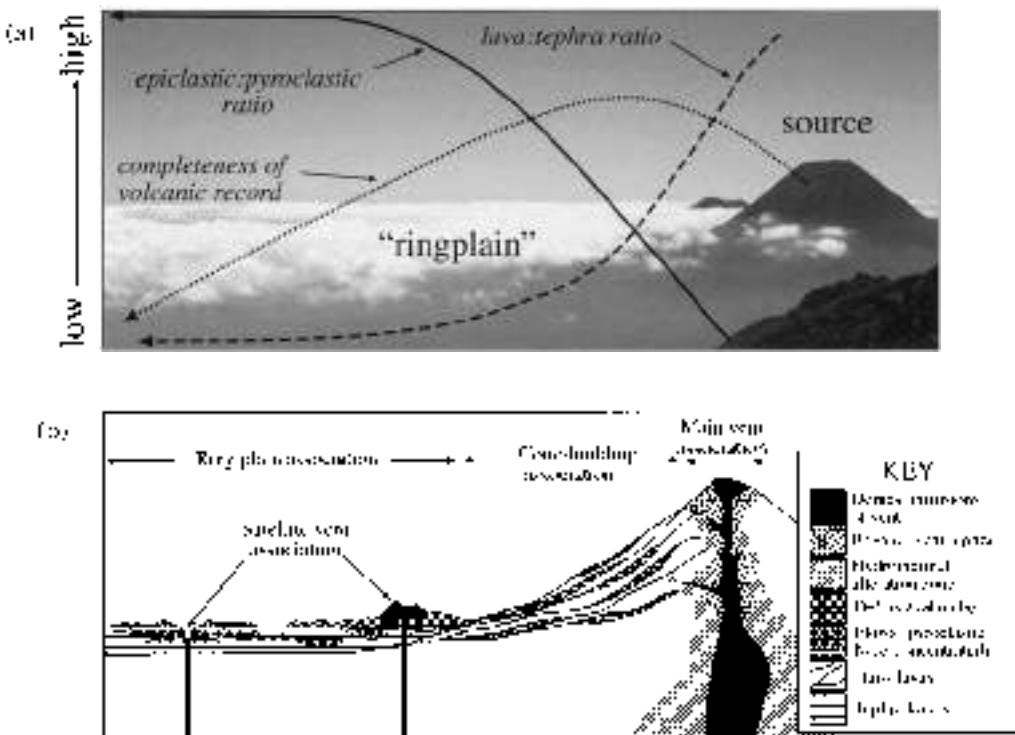

Finally, the effects of surface conditions (climate/weather), discussed in the previous section, will have a profound effect on the redistribution of volcanogenic

material. In fact, perhaps the single most important element in defining volcano morphology is the balance between construction (a function of magmatic flux to the surface) and erosion/weathering (a function of local climate). The control on the distribution of volcanogenic products is largely a result of this competition and is illustrated schematically in Fig. 9a.

While Fig. 9a usefully summarizes the distribution of volcanogenic products around a composite cone, perhaps the most helpful way to discuss the materials themselves and how they vary in nature and distribution relative to vents and topography is by use of the facies concept traditionally used to describe sedimentary environments. The specific associations that characterize a composite cone can be defined largely on the basis of distance from the vent, which accounts for both the relative predominance of immediate volcanic products near the vent, versus recycled or mixed (with water) volcaniclastic material, and topographic effects with slope steepness typically decreasing away from vents (Fig. 9b). A summary is provided in Table V.

## B. Main Vent Association

This association is defined as lithologies related to long-term vents at which volcanic products are erupted to the surface. Typically, for a simple cone this would be a central/summit vent, but in cases where compound cones have been developed, this may be an inaccurate description. The most important defining characteristic is that it is a long-term feature, and for a given volcano, it may change location several times during the history of activity. At the cone surface, the lithofacies found associated with the main vent are of two main types. On the one hand, if the vent takes the form of a crater, it is commonly surrounded by (1) vent-filling breccia comprising disaggregated wall rock material from the vent and (2) coarse primary tephra, commonly welded due to proximity to the vent. The distribution of this material is concentric to the vent, thinning rapidly away from the vent region, where it may simply pinch out (interfingering with proximal cone-building facies association) or grade into well-defined tephra layers or even lava flows of the upper cone. In cases where the vent crater is filled by a crater lake, additional deposits such as lacustrine sediment, intracrater lahars, and phreatic/phreatomagmatic deposits may be an important element of the main vent lithofacies. On the other hand, the vent at the cone surface can be occupied by a lava plug or dome that forms a steep-sided morphological feature

**FIGURE 9** (a) Schematic illustration of the distribution of deposits relative to vent for a composite volcano. “Completeness of volcanic record” refers to the number of events recorded in a succession at a given location. The most complete record is preserved in tephra that are deposited over wider areas. However, on the slopes of the volcano, tephra are rapidly reworked and may be washed away. Thus a more complete, albeit condensed, section is typically found in the region immediately surrounding the volcano—the ring plain. (b) Schematic illustration of lithofacies associations for a typical composite cone, showing types of deposits—compare with *distribution* of deposits in (a).

occupying or completely overfilling and obscuring a pre-existing crater depression. Main vent domes are vulnerable to collapse if they overfill the summit crater [e.g., Mount Unzen (Japan), Soufrière (Montserrat)]. They are also vulnerable to destruction during later eruptions when located over the volcano’s main vent. The lava dome itself is commonly surrounded by carapace breccia and breccia aprons—which again may be continuous with upper cone slope facies. In either case, the subsurface vent association is defined by a concentration of brecciated material and by an intensity of hydrothermal alteration. The latter reflects both the intense supply of heat and volcanic gases that define the vent and the permeability of the vent lithologies to vapors and fluids over long periods of time—commonly extending beyond the period of eruptive activity for the cone. Shallow intrusions comprising various geometries, including plugs, dikes, and sills, reflect the focusing of magma into the vent conduit and its movement upward through

the edifice. The main vent association at shallow subvent depths (referred to as “hypabyssal”) may also host concentrations of metal ores (cf. “Mineral Deposits Associated with Volcanism”), which can be exposed by modest erosion in the deeper portions of the edifice and in the subedifice basement between the surface and the original magma chamber.

### C. Cone-Building Association

The lithofacies of this association are those that build and define the edifice itself. They include a diverse array of volcanic products ranging from lava flows to pyroclastic flows to the products of flow transformations or reworking, involving mixing of water with volcaniclastic material. The relative distribution of lithofacies is largely dependent on (1) the style of activity—which we

TABLE V Lithofacies Associations for Typical Composite Volcanoes

Association	Main lithofacies and architecture	Other features
Main vent	Coarse tephra, commonly welded; breccia Poorly bedded, commonly disturbed/slumped Domes may fill vent at surface	Hydrothermal alteration common Shallow intrusives below vent
Cone building	Lava flows, pyroclastic flows, hyperconcentrated flows Radial from main vent—may grade into vent facies or not be connected Ribbon-like bodies to narrow wedges	Distribution of deposits strongly influenced by erosional topography
Ring plain	Fall tephra, debris fans from lower cone slopes, laharls, debris avalanche deposits Deposits tend to be more continuous and widely dispersed than on cone	Distribution of tephra strongly influenced by wind Preservation of deposits/completeness of record decreases if ring plain is restricted/eliminated by encroachment of surrounding topography
Satellite vent	Cinder cones, with lava flows and tuff ring/maar associations Dome/coulees Distribution may be controlled by basement structures—e.g., aligned along faults	Phreatomagmatic features more likely on lower flanks and ring plain

have seen is determined mainly by the composition of the magma supplied to the volcano—and (2) the balance between the supply of volcanicogenic material (eruption frequency) and the rate of erosion. If erosion is able to produce a well-developed drainage pattern between eruptions, then many of the erupted products will be channelized and form ribbon-like bodies radial to the main vent(s). As a result, there may be common stratigraphic inversions—younger flows occupy valley floors while older flows form the canyon walls at higher elevations. Topographic inversions may also occur—if valleys are effectively filled by lava flows that are resistant to erosion, then subsequent incision may take place on former ridges.

If erosion is less effective and the edifice is a relatively smooth-surfaced cone, then, at least for low-viscosity erupted products (basaltic lavas, pyroclastic flows, and hyperconcentrated flows), more widely distributed wedge-shaped veneers will form, again focused at the vent(s) of origination. The distribution of fall tephra is less influenced by the cone topography, but rather will form a veneer with a thickness that is greatest near the vent and strongly influenced by wind directions during eruption.

Lava flows, and their associated autobreccias, originate principally from the main vent, where, in the case

of basaltic flows, they are typically the result of quiet effusion from a summit crater (overspill of a lava lake) or rapid accumulation and congelation of fire fountain spatter (clastogenic flows). More silicic andesite and dacite flows form more prominent radial ridges by virtue of their greater viscosities and tend to be topography-formers rather than topography-filters, as in the case of their more fluid basaltic counterparts. They may be short, stubby coulees, connected to main vent domes, or may be rootless if the steep uppermost portions of the cone cause detachment of the main mass of the flow from its source.

Pyroclastic flows are also dispersed radially from the main vent. Given a well-established topography—that is, deep radial valleys—they will tend to become valley fills; otherwise they may form veneers over quite large angular segments of the flanks. Such flows may originate as column collapse from vulcanian or plinian eruptions or as dome/plug collapses in the vent region. Mixing with stream water in channels or snow and ice on the cone surface may lead to flow transformations, so that the ratio of primary pyroclastic flow deposits to hyperconcentrated flows (lahars and debris flows) typically decreases away from the vent (Fig. 9a). Unmodified pyroclastic flow deposits, as with pyroclastic fall tephra, are also rapidly reworked and removed from the upper

parts of the cone to be redeposited low on the cone or on the ring plain.

#### D. Ring Plain Association

The lithofacies of the ring plain are dominated by fall tephra and by the tephra that has been rapidly reworked from the cone. The ring plain is defined as the area immediately surrounding the volcano, but not including the constructional edifice itself. In cases where the cone is isolated from neighboring volcanoes or other mountainous terrain (e.g., Taranaki and Ruapehu, Fig. 2), the definition is quite obvious. However, in many volcanic terranes, individual edifices merge with their neighbors, including ancestral degraded volcanoes, and the surrounding topography is far from flat so that classic “ring plain” deposits as discussed here will rather be concentrated into drainages, reworked and removed from the system quite rapidly. Furthermore, for many oceanic composite cones such as those of island arcs, the immediate edifice is surrounded by ocean and a true ring plain does not exist—although quite complete records of activity can be recovered from the tephra mantling the nearby ocean floor.

As emphasized in Fig. 9, the ring plain is potentially where the most complete record of explosive activity is preserved. It is sufficiently close to the volcano that the products of volcanism are not too widely dispersed, yet it is beyond the edifice, which, through its topography, has the effect of promoting rapid removal of volcanic products and concentrating them into narrow drainages. Lithofacies include numerous tephra layers—pyroclastic fall material that may be correlative with flow-forming events on the cone but that has been dispersed over much larger areas. The thicknesses of individual tephra layers reflect both the flux and duration of an eruption and the dispersal control by wind. Lateral variations in the thicknesses of individual layers (isopachs) and in the grain sizes of tephra within the layers can be used to accurately reconstruct eruption histories (cf. “Plinian Eruptions” and “Tephra Fall Deposits”).

Interbedded with fall tephra are the fluvial and laharic deposits, which may form the distal edges of wedgelike fans of debris from the lower cone slopes or may be concentrated along well-established drainage channels through the ring plain. The distal edges of the most extensive of flows (lava and pyroclastic) from the cone may also reach as far as the ring plain (e.g., Fig. 4b, parts iii and iv).

A typical, albeit occasional, product of composite vol-

cano activity is the debris avalanche—the widely dispersed large-volume product of large-scale gravitational instability, or sector collapse (cf. “Debris Avalanches”). Debris avalanche deposits are a common ring plain lithofacies, distinguished by a hummocky topography, with the size of hummocks decreasing away from the edifice from large toreva blocks at the slope base to the more subtle topography of flow transition lahars and debris flows that drain the deposit far out on the ring plain (e.g., Fig. 6e). The hummocks consist of blocks mobilized from the cone slopes, which have suffered various degrees of disruption. At the base of the deposit, the lithologies are strongly disrupted and smeared, whereas in the interiors of many blocks disruption is minimal and a jigsaw texture is observed among the components reflecting intense fracturing but no turbulent mechanical mixing.

#### E. Satellite Vent Association

While by no means ubiquitous at composite cones, satellite vents are nevertheless common. As pointed out above, the magma compositions erupted at such vents are commonly distinct from those of the main vent that characterize the bulk of the edifice. The eruptions are also typically monogenetic—a single eruptive episode rather than prolonged and repeated eruptions of the main vent. It should come as no surprise then that there may be distinct lithofacies associations at satellite vents.

Scoria cones are defined by the steep piles of scoria that are accumulated at the angle of repose about the vent crater. A high flux of pyroclast accumulation around the vent can lead to the formation of spatter ramparts or even limited clastogenic lava flows. However, most lava flows associated with scoria cones (and some may be quite extensive; Fig. 7b) breach the cone and may raft large fragments of the cone walls along on the flow.

If a basaltic satellite vent interacts with near-surface water, then maars and tuff rings may form during phreatomagmatic eruptions. The water may occur as shallow groundwater reservoirs or in standing bodies of water such as lakes. In either case interception of shallow water by ascending magma is more likely to occur on the shallow slope lower reaches of the edifice, or on the ring plain, rather than on the cone itself. The common occurrence of accretionary lapilli in such phreatomagmatic deposits is also consistent with the important role for water.

Lava domes may also occur as monogenetic eruptions at satellite vents (e.g., Figs. 7c and 7d). These occurrences, by virtue of their location, have a higher preservation potential than those emplaced at the main vent. Silicic magma batches supplied to flank locations are typically small and degassed, resulting in slow and passive effusion of lava. The earliest phases of emplacement may be volatile-charged, resulting in emplacement within a pumice cone—an effect analogous to effusion of basalt lava from a cinder cone. As with basaltic equivalents, tuff cones of silicic tephra may also be found where silicic magma supplied to flank vents intercepts shallow near-surface water reservoirs.

#### V. CONCLUDING REMARKS AND FUTURE RESEARCH DIRECTIONS

We are only beginning to understand the complex behavior of composite volcanoes through detailed studies of their histories (erupted products), their subsurface conduits (geophysically imaged), and their occasionally witnessed eruptive activity. In recent years, physical volcanology has made considerable advances enabling the characteristics of individual deposits to be interpreted in terms of eruption styles and magnitudes. At the same time, geochemical techniques examining both rocks and volatiles have enabled us to better understand magma generation and evolution from source to eruption. A major challenge of the next decade is to integrate geological, geochemical, and geophysical approaches in order to decipher the processes occurring in magma chambers, the timescales over which they occur, and the consequences for volcanic eruptions. Such an understanding not only will enable us to address important aspects of magmatism such as mass fluxes between the mantle, lithosphere, and atmosphere but will also have tremendous predictive value, aiding the mitigation of volcanic hazards.

## GLOSSARY

**accretionary lapilli** Tightly bound, approximately spherical aggregates of ash particles. They form in eruption clouds, by raindrops falling through the eruption cloud or by electrostatic attraction.

**achneliths** Juvenile ash- to lapilli-sized volcanic particles with smooth, glassy surfaces. They are interpreted to form from chilled lava spray.

**armored lapilli** Lithic fragments or crystals forming solid nuclei surrounded by fine ash. They form during hydrovolcanic eruptions.

**diatremes** Funnel-shaped breccia pipes that reach as much as 2500 m in depth. Diatremes are thought to form by hydrovolcanic fragmentation and wall rock collapse. Diatremes may underlie maars and grade at depth into dikes.

**fire fountains** Fire or lava fountains are highly fluid mix-

tures of basaltic magma and gas that are common in hawaiian eruptions as in Kilauea volcano.

**fuel-coolant interaction (FCI)** Intense mixing of hot liquids (fuel) with cooler liquids (coolant) may result in thermal explosions, known as fuel-coolant interactions. Explosive interaction of magma with external water has been interpreted in terms of FCIs.

**hydrovolcanic eruptions** Hydrovolcanic (hydroclastic, hydromagmatic, phreatomagmatic) eruptions are caused by the mixing of magma with water.

**strombolian eruptions** Discrete explosions at periodic intervals of a few seconds to minutes or hours, named after Stromboli, a volcano in the Aeolian Islands, Italy. Deposits consist of lava spatter, vesicular bombs, scoriaeuous lapilli, and ash.

**surtseyan eruptions** Hydrovolcanic explosions dominated by jets of wet tephra, as observed at Surtsey (1963), Iceland. They result in tuff cones. The term "surtseyan" is mostly used for volcanoes erupting through seawater.

**vesicular tuff** Tuffs containing millimeter- to centimeter-sized, irregular to round pores. The cavities are interpreted to form during trapping of air or vapor in wet ash deposits or after deposition of muddy rain.

**S**CORIA CONES are the most common volcano type on land. Hydrovolcanic tuff rings, tuff cones, and maars are second in abundance to scoria cones.

These volcanoes are small compared to shield volcanoes or stratovolcanoes. Here we briefly review the particle morphologies and fragmentation processes, deposits, environments, and eruption style of strombolian/hawaiian scoria cones and hydrovolcanic tuff rings, tuff cones, and maars. Explosive fragmentation results from (a) rapid exsolution and decompression of magmatic volatiles (pyroclastic fragmentation), (b) explosive interaction of magma with external water, or (c) simultaneous interaction of both processes. Pyroclastic eruptions resulting in scoria cones and “wet” hydrovolcanic tuff cones are end members in a wide spectrum of explosive fragmentation.

## I. DEFINITIONS

*Scoria cones*, also called cinder or tephra cones, are relatively small but common volcanoes that form by the eruption of low-viscosity, generally basaltic magma in strombolian or hawaiian eruptions. They commonly occur in groups or fields, some consisting of hundreds of eruptive centers. The volcanoes are truncated, cone-shaped, or horseshoe-shaped. Bowl-shaped craters at the top are filled by debris reworked from the cone rim and younger deposits. Elongate cones are built above fissures with more complex vent systems. Deposits of scoria cones consist of bombs, scoriaceous lapilli, and minor ash whereas spatter cones and scoria-agglutinate cones consist largely of welded lava spatter. Well-known examples include Heimaey (Iceland), Paricutin (Mexico), and Stromboli (Italy). Shallow marine scoria cones constructed by submarine lava fountaining are rare.

*Tuff rings*, *tuff cones*, and *maars*, formed subaerially and/or in shallow water, are second in abundance to scoria cones. They result from phreatomagmatic eruptions due to mixing of ascending magma with groundwater or surface water. Deposits are composed of juvenile (or essential) pyroclasts, derived from the erupting magma, accessory (or cognate) clasts of comagmatic volcanic rocks from earlier eruptions, and accidental clasts, derived from the subvolcanic basement. Magma–water interactions occur in shallow water, beneath ice, or where lava flows or pyroclastic flows enter the sea. The term phreatic eruption is used when explosive eruptions eject exclusively preexisting rocks but no juvenile fragments.

Hydroclastic volcanoes can be subdivided into three different morphological and structural types: (1) tuff rings, (2) tuff cones, and (3) maars. Differences between

these volcanoes are mainly controlled by the magma/water ratio, the degree of magma/water mixing, and the depth of fragmentation.

*Tuff rings* are commonly less than 50 m high. They are defined by craters with small depth to width ratios at or above ground level and low ejecta rims of hydroclastic debris, with beds dipping <25°. The deposits consist of a mixture of juvenile and accidental clasts. Juvenile pyroclasts are the main constituent of the well-stratified deposits.

*Tuff cones* are characterized by higher profiles than tuff rings and maars and steeper external slopes with bedding dips >25°. Their crater floors are generally above the land surface. Deposits are composed mainly of juvenile clasts and subordinate amounts of accidental clasts. Rim beds are massive and interpreted as having been emplaced laterally by turbulent particle-laden surges, fall, and remobilization processes.

*Maars* are defined by bowl-shaped craters cutting about 10 m to more than 500 m deep into the pre-eruption surface. Maars are surrounded by low ramparts of well-bedded ejecta (beds dipping <25°) that decrease rapidly in thickness away from the rim. Maar deposits are distinguished from those of tuff rings/tuff cones by the abundance of nonjuvenile components (country rock). The deposits are mainly emplaced by base surges and fallout.

Hydroclastic volcanoes and scoria cones are commonly termed monogenetic because they may form in a single eruptive episode with nearly constant eruptive conditions during rapid cone growth within a few days, months, or, at most, years. This results in a simple stratigraphy that differs from that of large, long-lived polygenetic shield volcanoes and stratovolcanoes. More detailed studies of scoria cones have revealed complex structures due to alternating magmatic and phreatomagmatic eruptive conditions over long time intervals. Some volcanoes evolve from a maar, tuff ring, or tuff cone phase to a scoria cone phase, followed by lava flows, resulting in a composite volcanic complex.

---

## II. PARTICLE MORPHOLOGY AND FRAGMENTATION PROCESSES

### A. Particles Resulting from Dry Magmatic Eruption

Strombolian and hawaiian eruptions producing scoria cones are caused by near-surface expansion and explo-

sive disruption of gas bubbles within fluid, low- to moderate-viscosity magma. During strombolian eruptions, magma becomes fragmented to clasts with moderate to high vesicularity at periodic explosive intervals of a few seconds (e.g., Heimaey, Iceland) to minutes or hours (e.g., Stromboli, Italy; Paricutin, Mexico). Deposits are generally coarse-grained and composed predominantly of lapilli- to bomb-sized particles larger than 2 mm. Common clasts are scoria, vesicular basaltic to andesitic glass less inflated than pumice and mostly composed of tachylite, a nearly opaque basaltic glass. Minor ash-sized particles are more vesicular. Particles with elongate and ragged shapes are common.

Hawaiian lava fountains, in contrast, are produced by nearly homogeneous turbulent mixtures of gas and magma. Hawaiian lava fountains produce spatter, bomb-sized fragments of molten clots, commonly stuck together to form agglutinate deposits or lava flows, glassy achneliths, droplike Pele's tears, and long threads of Pele's hair. Clast shapes are fluidal or ragged.

## B. Particles Resulting from Hydroclastic Eruption

In hydrovolcanic explosions, thermal energy is efficiently converted into kinetic energy (Fig. 1). Strong hydrovolcanic explosions generate fine particles by an optimum water to magma mass ratio ranging between 0.2 and 0.3. Larger particles result from explosions with higher or lower mixing ratios. The explosivity of magma–water interactions (analogous to fuel–coolant interactions) is highly controlled by (a) the geometry and location of the vent and contact zone, (b) the depth

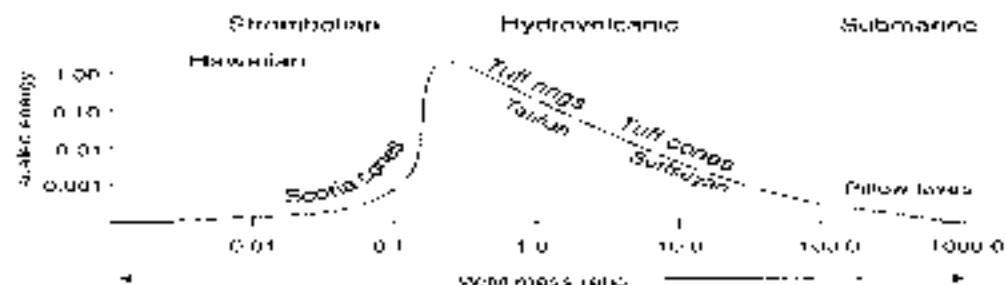

of interaction, (c) the water/magma mass mixing ratio and premixing mass ratio, (d) the magma ascent rate and the pressure regime between magma and water, (e) the processes by which energy is transferred from magma to water, and (f) the propagation of shock waves through the mixing zone.

The grain size of hydrovolcanic deposits is dominantly in the ash- and lapilli-size range; bombs and blocks are subordinate. Juvenile, glassy particles show fracture-controlled surfaces with blocky-equant shapes. Fine-grained particles with ragged and fluidal surfaces can form during inefficient mixing of magma with water. The vesicularity of hydrovolcanic clasts is strongly influenced by the ascent history of the magma. Clast vesicularity commonly ranges widely from nonvesicular (0–5 vol% vesicles) to highly vesicular (60–80 vol% vesicles), which reflects the relative timing of vesiculation and water-induced fragmentation. Armored and accretionary lapilli, cored ash aggregates, commonly form in wet hydrovolcanic eruptions. Clasts with contrasting vesicularity, clast morphology, and mud coating are interpreted as recycled particles. They may have been generated by fallback or collapse into the crater during an eruption and later reejection.

## III. DEPOSITS

### A. Scoria Cones

Strombolian deposits are distinguished from deposits of hydroclastic volcanoes by their coarser clast sizes and massive to coarsely bedded structures, the general pau-

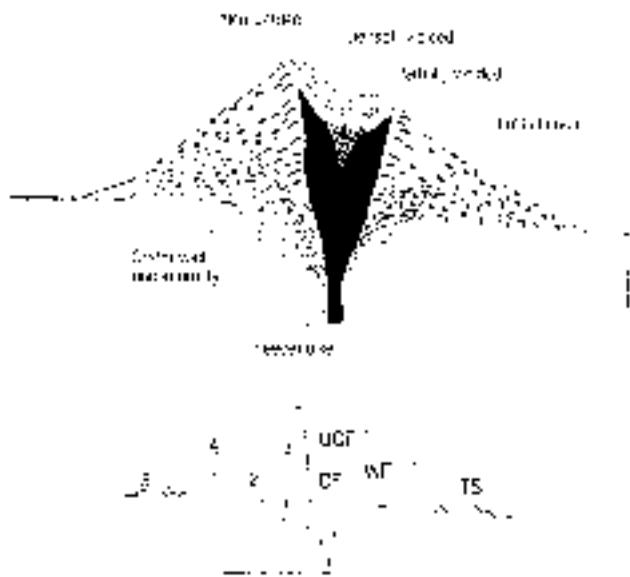

**FIGURE 1** Diagram of water/magma ratios. Water/magma (W/M) ratios are an important control on the eruption style and the mode of transport and deposition of ejecta. Scoria cones result from low W/M ratios or dry magmatic eruptions. With increasing W/M ratios, the eruption style changes to hydrovolcanic fragmentation. Tuff rings result from eruptions with relatively low W/M ratios, known as taalian eruptions, and tuff cones from eruptions with relatively high W/M ratios, known as surtseyan eruptions. (Modified from Wohletz, K. H., and Sheridan, M. F. (1983). Hydrovolcanic processes: II. Evolution of basaltic tuff rings and tuff cones. *Am. J. Sci.* **283**, 385–413. Copyright © 1983 Kline Geology Laboratory.)

city of lithic clasts, and higher depositional temperatures. Strombolian deposits are framework supported and mostly well sorted. Bedding may consist of alternating coarser and finer fall beds. Variable sorting may result because of eruptions of fragments with different vesicularities and densities, particle aggradation of ashes, or mixing of clasts transported by flow and fall. Clasts in strombolian deposits have vesicle volumes up to 80 vol%. Angular fracture-bounded clasts with poor to moderate vesicularity (e.g., Rothenberg scoria cone, Germany) in strombolian deposits may have been generated by magma ponding in and around the vent that led to simultaneous eruption of gas-rich magma together with degassed magma.

Massive scoria breccias commonly form as result of submarine lava fountaining in shallow water. Scoria clasts are irregular to amoeboid with up to 60 vol% vesicularity. Intercalations of stratified lapilli tuffs in these scoria cones suggest a change from magmatic to hydrovolcanic fragmentation, caused by significant mixing of water into the fire fountain.

Two main facies can be distinguished from each other in a scoria cone: (a) an inner crater facies and (b) an outer wall facies (Fig. 2). The deposits of the crater

**FIGURE 2** Morphology and internal structure of a scoria cone: 1, initial phreatomagmatic eruptions; 2, strombolian eruptions with phreatomagmatic intercalations; 3, strombolian eruptions forming main cone; 4, poststrombolian talus slides; 5, distal fallout; CF (crater facies), agglutinates, feeder dike; UCF (upper crater facies), round bombs set in matrix of lapilli, redeposition and slumping from the walls; WF (wall facies), scoria breccias, partial welded bombs in proximal units and unflattened bombs in distal units; TS (talus slope), redeposition because of slope failure.

facies are more heterogeneous than those of the wall facies. The lower crater facies consists of erupted lava spatter, which was hot on landing and became welded to form an agglutinate. In a transitional area, passing outward toward the crater wall facies, scoria fragments may be welded together but can still be recognized as individual clasts. In the crater interior, lava lakes or lava flows can develop. The upper crater facies characteristically consists of round bombs set in a poorly sorted matrix of lapilli, overlain by well-sorted lapilli layers up to several meters thick. The lapilli layers can extend much farther than the actual scoria cone.

The outer wall facies may begin with basal fine ash layers rich in accretionary lapilli overlain by coarse-grained, poorly sorted breccia layers extremely rich in accidental fragments. These deposits result from initial phreatomagmatic explosions during reaming out of the conduit. The inner wall and lower crater facies may contain similar deposits. Coarse-grained scoria bombs and lapilli beds dominate the outer flank facies and may be moderately welded close to the crater rim but become increasingly less welded, uncompacted, and finer grained in the distal facies. Single, denser, in part spindle-shaped bombs are found in wall facies deposits, together with moderately to highly vesicular juvenile lapilli. Wall-rock lithics are sparse. The outer flanks of many scoria cones are covered by fall layers of well-sorted lapilli. Vertical and lateral transitions in scoria cones may reflect common changes in eruptive conditions, distance from the vent, and/or phreatomagmatic influence.

Later redeposition of the products is a major process, especially during the mature stages of scoria cone growth, when the outer slopes become unstable and the clasts slide to the foot of the cone. Redeposition may occur by oversteepening of the cone, where the slope angle is higher than the angle of repose, or when deformation associated with ascending magma leads to cracking and partial collapse. Deposits on steep cones may be mobilized downslope as debris flows, grain flows, or mudflows, commonly resulting in inversely graded beds.

## B. Hydroclastic Volcanoes

Typical deposits of hydroclastic volcanoes are rich in accidental lithics. Coarse- to medium-grained fallout deposits may contain up to 90 wt% wall-rock lithics and minor juvenile clasts (e.g., from Ukinrek maar, Alaska), and contain important information on the make-up of the subvolcanic basement and on the depth of the hydro-

lastic explosions. Most tuff rings, tuff cones, and maars are dominated by surge deposits generated during explosive hydrovolcanic eruptions, as shown by historic eruptions such as Surtsey (Iceland, 1963–1967), Taal (Philippines, 1965), Capelinhos (Azores, 1957–1958), and Miyake-jima (1983), where base surges and cock's tail jets were observed. Fall deposits of better sorted lapilli tuffs, mostly grain-supported openwork and crudely interstratified with fine ash layers, and ballistic fall breccias are common intercalations in hydroclastic deposits. Fine-grained fallout tuffs may be derived from ash clouds accompanying the base surges.

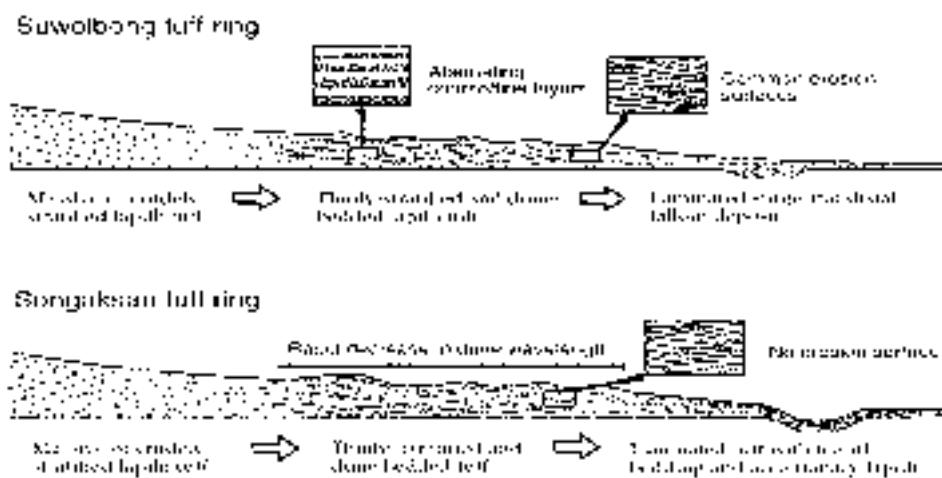

Base surges are gravity-controlled, low-concentration, turbulent pyroclastic density currents with gas (steam) as a continuous phase. Downcurrent flow transformations and variable flow regimes and degrees of wetness result in complex lateral and vertical facies changes (Fig. 3). Base surges may be dry (superheated steam as the fluid phase) or wet (condensing steam as fluid), leading to rapid facies variations. Surges range in transport and emplacement temperatures from cool to 200–300°C. Surge deposits are generally thin bedded, fine grained, and poorly sorted. Bedforms are planar, wavy, or cross-bedded, and bed thickness decreases rapidly in the direction of transport.

Tuff rings and maars are characterized by progressive lateral and vertical facies changes of mostly dry surges. Near-vent deposits may be inversely graded, massive to bedded lapilli tuffs changing with distance from vent into crudely bedded lapilli tuffs, planar-bedded lapilli

tuffs, and more distal cross-bedded lapilli tuffs. Outward-dipping deposits may begin with disorganized and scour-filled lapilli tuffs, replaced by stratified lapilli tuffs and dune-bedded lapilli tuffs. Lateral facies sequences for both imply deposition from high-concentration turbulent surges near the vent. Lack of tractional transport leads to unstratified, massive and crudely bedded deposits. Further downcurrent, surges become more diluted through deposition of clasts and mixing with ambient air, forming thinly stratified and laminated deposits. Dilution of surges may also cause cooling and condensation of steam, leading to moistened ash, vesiculated tuffs, and accretionary and armored lapilli.

Lateral facies variations in tuff cones differ from those of tuff rings, because of the higher wetness of the eruption clouds. Ash-coated lapilli in mainly crudely stratified deposits are interpreted as having been deposited by radially propagating dense, wet surges, which do not extend far from the vent. Tuffs containing millimeter-to centimeter-sized, irregular to subspherical pores up to 1 cm around may have developed in wet surges and mudflows on proximal rim beds. The vesicular tuffs are interpreted to form during (a) trapping of air or vapor in wet cohesive fall or surge deposits, (b) sedimentation of viscous mudflows, or (c) gases given off by hot pyro- and hydroclasts. In most examples described, vesiculated tuffs are associated with accretionary lapilli due to steam condensation.

Reworking is commonly a subordinate process in tuff rings and maars because of low slope rims but depends

**FIGURE 3** Lateral facies variations of base surges, Cheju Island, Korea. In the Suwolbong tuff ring, proximal lapilli tuffs are crudely stratified or massive with inversely graded bases. In medial parts, thinly stratified beds or dune-bedded lapilli tuffs dominate. Segregation of coarse and fine grains into distinct layers reveals cohesionless transport. In distal sections, thinly stratified and wavy-bedded tuffs are present. The Songaksan tuff deposits show similar facies variations, although accretionary lapilli, plastering of deposits on vertical obstacles, and absence of erosion structures suggest wetter surges. (Adapted from Sohn, 1996.)

strongly on the ambient environment. Redeposition is more common in more steeply bedded tuff cones, resulting in lenticular, massive or chaotic bedded lapilli tuffs emplaced by debris flows, grain flows, slides, and/or slumps.

### C. Mixed Deposits

Fall and surge deposits of complex magmatic/hydrovolcanic origin are characterized by juvenile clasts with (a) highly variable clast densities, (b) sorting coefficients between strombolian/hawaiian and hydrovolcanic deposits, and (c) angular to blocky clast morphologies with low vesicularities (hydrovolcanic) to ragged (strombolian) and fluidal (hawaiian) with high vesicularities. Mixed deposits may represent mixing of pyroclastic/hydroclastic clasts from simultaneous eruptions of a multiple-vent system.

---

## IV. MORPHOLOGY AND INTERNAL STRUCTURE

### A. Scoria Cones

The morphology of scoria cones depends on numerous factors, including (1) total volume of erupted material, (2) range and median ejecta velocity, (3) ejection angles, (4) wind speed and direction, (5) nature and size of particles, (6) occurrence of lava overflows, (7) phreatomagmatic intercalations, and (8) vent geometry.

Scoria cones range from 0.25 to 2.5 km in basal diameter ( $W_{co}$ ), with a median of 0.8 km (Fig. 4). Cone heights equal  $0.18W_{co}$ , varying from a few meters and rising to as much as 424 m such as Paricutin volcano, Mexico. Crater diameters equal  $0.4W_{co}$  (data from 910 cones). Some spatter cones and scoria-agglutinate cones show basal diameters less than 0.2 km. The crater diameter increases not only by ejection of pyroclastic material but also by slumping into the vent, for example, during seismic shocks. Most cones are initially built during high rates of strombolian or hawaiian activity. The main eruptive center migrates repeatedly during growth of scoria cones and several conduits may be active along a fissure. Late eruptive activity modifies the cone morphology only slightly. Many cones produce lava flows, which mainly extrude after explosive activity has ceased. Lavas may be fed by lava fountaining or are erupted

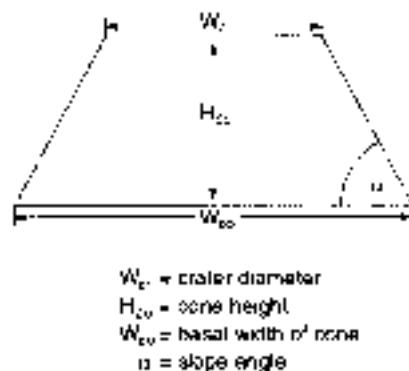

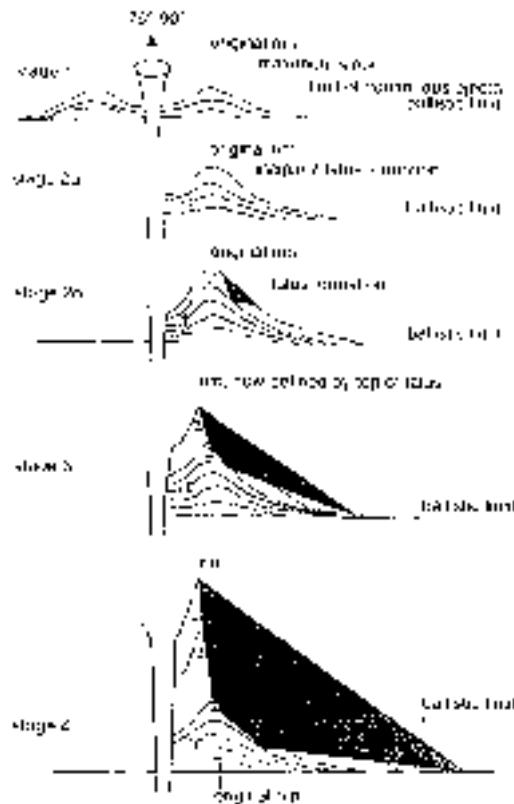

FIGURE 4 Simple model of cone parameters. Scoria cones range from 0.25 to 2.5 km in basal diameter ( $W_{co}$ ), with a median of 0.8 km. Cone heights equal  $0.18 W_{co}$ ; crater diameters equal  $0.4W_{co}$ . Slope angle is less than angle of repose and ranges between 25 and 38°, depending on the nature of the ejected material.

from base-of-cone vents or fissures. Fifty percent of observed scoria cone eruptions lasted less than 30 days, and 95% ended within 1 year. Volumes of cone plus flows range between  $10^5$  and  $10^9$  m<sup>3</sup>, similar to total volumes of tuff cones and rings. Lava flow volumes are generally higher than associated cone volumes. Coarse pyroclasts (scoriaceous lapilli, bombs) fall near the vent but may move downslope until reaching a position where the slope angle is less than the angle of repose (about 30°) (Fig. 5). Spatter cones and scoria-agglutinate cones can present steeper sided slopes because fragments are welded together. During the last phase of eruptive activity, cones grow only slightly and lava flows dominate over pyroclastic eruptions, resulting in submergence of the base of the cone by its own lava flows. Multiple destruction and rebuilding occurred during the extended growth period of the famous scoria cone Paricutin (Mexico). Well-exposed scoria cones may show several conduits. The spatial arrangement and morphological structure of scoria cones may suggest eruption from a fissure or en-echelon feeder system. Several different eruptive processes can occur simultaneously at different parts of a fissure system, for example, mixed magmatic/phreatomagmatic deposits from Crater Hill (Auckland, New Zealand), or can alternate with each other, leading to the formation of complex volcanic structures (e.g., from Herchenberg and Rothenberg cones, Eifel, Germany).

Cone height, height/diameter ratio, and slope are reduced systematically by erosion with time. The mode of degradation seems to be similar for all scoria cones but is strongly influenced by rainfall, climate, and cementation rates. Scoria cones in New Guinea showed

**FIGURE 5** Growth stages of scoria cones. Stage 1: Initial phreatomagmatic deposits form a tuff ring with shallow dipping rim beds. Mean ejecta angles range between 75 and 90°. Stage 2: Continuous strombolian eruption activity leads to the growth of a steeper sided cone. Slope instability results in talus formation (Stage 2b); as volume increases, the cone rim migrates outward. Stage 3: Inward migration of the exterior talus pile and destruction of the older rounded rim occur. Collapse of the vent, talus formation of the inner slopes, and destruction by larger eruptions modify the original cone. The cone rim migrates inward. Stage 4: During continuous growth of cone, talus extends beyond ballistic limit of ejecta. (Adapted from McGetchin *et al.*, 1974.)

significant gully erosion 5 years after eruption, in contrast to more arid regions, where erosion is negligible after thousands of years. Cone morphologies and degradation rates are thus useful indicators of ancient climatic regions and changes. The systematic degradation of scoria cones has been used to estimate the approximate ages of undated scoria cones within a single field.

### B. Tuff Rings, Tuff Cones, and Maars

The morphology, shape, and size of hydrovolcanic cones and rings are described by the parameters (1) rim diameter,

(2) maximum height, (3) height/rim ratio, (4) excavation depth, and (5) maximum bedding dip.

Tuff rings and maars are morphologically similar. In maars, the crater is cut into the pre-eruption surface (Fig. 6). Both have crater diameters averaging 0.7–0.8 km and range from 0.2 to 3.0 km (e.g., Kilbourne Hole, New Mexico). Rim sequences are commonly less than 50 m thick but may reach more than 100 m in height (Joya Honda maar, Mexico; El Cuchillo tuff ring, Lanzarote, Canary Islands). Height/rim diameter ratios range between 0.13 and 0.05. Morphologically asymmetric volcanoes form during strong winds [e.g., Cerro Colorado maar (Pinacate Volcanic Field, Mexico)]. The well-bedded and fine-grained deposits of tuff rings and maars dip gently around 20° near the rim to less than a few degrees outward. They generally lack spatter and agglutinates deposited hot. The maximum diameter of country rock fragments may exceed 3 m. Accidental clasts may reach up to 90 vol% in maar deposits but make up only a minor component in tuff ring deposits. The fragmentation level in tuff rings is generally more shallow than in maars based on the higher abundance of moderately vesicular essential clasts.

Tuff cones vary in rim diameter from <100 m to 1.5 km in length (e.g., Udo tuff cone, Cheju Island, Korea), the height varying between 50 and 330 m (e.g., Koko Crater, Hawaii). The base of tuff cone craters may rise up to 130 m above the surrounding plain (e.g., North Menan tuff cone, United States). Typical height/rim ratios of tuff cones range from about 0.5 to 0.2. Beds of tuff cones dip more steeply (10–30° and up to 45° near the crater rim) compared with tuff rings and maars. Intercalated channels, which may form after slumping of unstable crater walls, commonly dip steeper (between 20 and 50°) than primary bedding. Unstable steep crater walls produce large, funnel-shaped faults (e.g., Surtsey, Iceland; El Golfo, Lanzarote, Canary Islands), with faults dipping about 50–90°, and shear displacements along larger blocks that may subside up to >50 m.

---

### V. TECTONIC SETTING AND CHEMICAL COMPOSITION

Scoria cones and hydrovolcanic cones and rings occur in all tectonic environments such as rift zones, uplifted blocks, subduction zones, and oceanic islands. The volcanoes occur mostly in (a) groups, roughly of the same age, and (b) volcanic complexes, several nested volcanoes of roughly the same age that can be distinguished from

**FIGURE 6** Diagram of maar volcano showing different stages of rim evolution controlled by continued excavation of the crater. The rim beds consist of lithic-rich ashes and lapilli deposited by pyroclastic surges and fall. Sectorial distribution of the surges and the influence of wind velocity on the fall deposits produce asymmetric rim beds. O, outward-dipping rim bed; I, inward-dipping rim bed; C, funnel-shaped conduit formed by explosive interaction of magma with groundwater; A, groundwater aquifer; L, crater filling, consisting of fallback tephra, reworked tephra from the rim beds, and lake sediments. [Adapted from "Pyroclastic Rocks," Fisher, R. V., and Schmincke, H.-U., p. 259, 1984, copyright notice of Springer-Verlag.]

each other by structure and types of deposits and contain their own individual vent system.

#### A. Volcanic Islands

Hydrovolcanoes characteristically form during the shoaling to emergent stage of a seamount where hydrostatic pressure is low. A classic example of the growth of a new island is Surtsey, Iceland. Surtsey formed on a shallow insular shelf by phreatomagmatic explosions caused by the interaction of rising magma with seawater. The island is about 1.5 km in diameter and has an area of 2.8 km<sup>2</sup>. The deposits are crudely bedded to massive lapilli tuffs consisting of blocky, nearly equant vesicular clasts. Pyroclastic fragmentation followed after sealing of the vent system against external water and growth of the cone above sea level. Alkali basalt flows extended to the south and protected the cone from wave erosion. Surtsey subsided about 1.1 m between 1967 and 1991 because of compaction of the loose hydrovolcanic deposits and/or compaction of the underlying seafloor sediments.

In oceanic islands, scoria cones are commonly restricted to inland areas whereas tuff cones, tuff rings, and maars are mostly distributed along the coastal regions, as on Cheju Island, Korea, where >300 scoria cones are distributed in the inland area and about 10 tuff cones, tuff rings, and maars erupted along the shoreline in the transition between submarine and subaerial environments. Tuff cones on Cheju Island formed by direct flooding of seawater into the vent or where subaerial lavas with pervasive joints acted as permeable aquifers, allowing intrusion of coastal seawater or mixed seawater/groundwater. Tuff rings and maars may also

form by explosive eruptions in inland areas when aquifers, streams, lakes, or wet sediments are intruded by rising magma (e.g., Bandama and Marteles maars, Gran Canaria, Canary Islands). Historic basalt eruptions on Lanzarote, Canary Islands, in 1730–1736 and in 1824 covered about 20% of the island (Fig. 7). Thirty scoria cones of nephelinite to olivine tholeiite formed during five eruptive phases along a fracture 14 km long. Pleistocene hydrovolcanic tuff cones and tuff rings, distributed along the western coast of Lanzarote and directly controlled by the interaction of seawater or wet lagoonal sediments with ascending magma, were partly buried by lava flows.

#### B. Rift Areas and Subduction Zones

Scoria cones are the most characteristic subaerial volcanoes in continental rifts. Although scoria cones and tuff cones and rings are numerous, total erupted volumes are small compared to convergent plate boundaries. Extensional stress in the lithosphere is released by rifting or faulting and influences the development of volcanic fields, which are commonly associated with extensional uplifted intraplate plateaus. Continued extension produces graben subsidence, graben shoulder uplift, and thinning of the underlying lithosphere. Single volcanoes and volcanic groups form within the grabens and on the uplifted graben shoulders. Volcanic complexes in intraplate plateaus may consist of hundreds of volcanoes, for example of up to 1000 volcanoes over an area of 60,000 km<sup>2</sup> in the TransMexican Volcanic Belt, often with separate volcano clusters of 20–150 volcanoes within areas of 100–5000 km<sup>2</sup>, (see "Basaltic Volcanic Fields"). Well-known examples of Tertiary to Recent

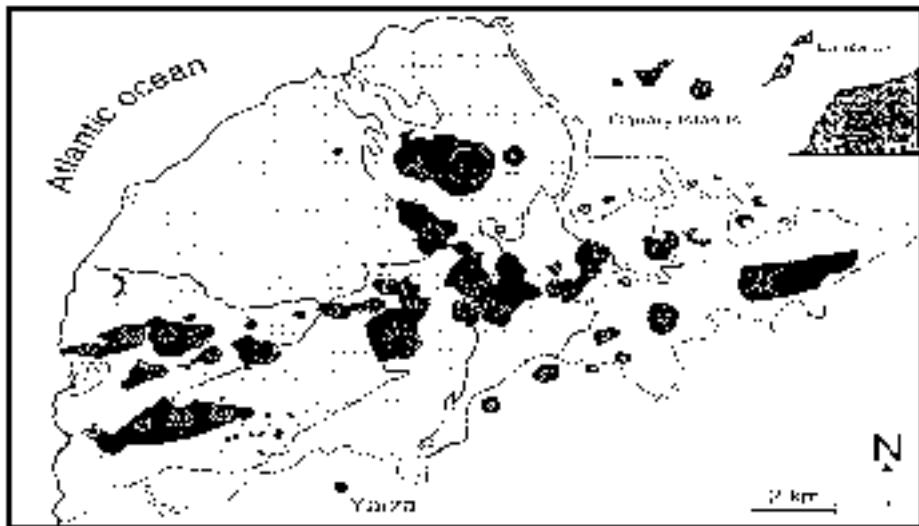

FIGURE 7 Volcanic field, Lanzarote. Map of the 1730–1736 eruptive sites on Lanzarote showing scoria cones (black) and lava flows (gray). Hydrovolcanic cones (white) are Pleistocene in age and are restricted to the former coastline. [Modified from *J. Volcanol. Geotherm. Res.* 53, Carracedo, J. C., Badiola, E. R., and Soler, V., The 1730–1736 eruption of Lanzarote, Canary Islands: a long, high-magnitude basaltic fissure eruption, 239–250 (1991) with permission from Elsevier Science.]

volcanic fields in uplifted tectonic regions are the Eifel (Germany), Hoggar and the Tibesti Rift system (Algeria), the Rio Grande Rift system, and the Colorado Plateau (United States). Most of the Tertiary to Quaternary volcanic fields in western Europe are restricted to extensional and volcano-tectonic stress fields in grabens (Rhine Graben, Limagne Graben, and Eger Graben) or to associated uplifted graben shoulders (Westerwald, Eifel, and Auvergne). In rifts, cones are commonly alkalic to tholeiitic in composition and grow faster and higher than those erupted on associated rift shoulders. On graben shoulders cones are more alkalic in composition, suggesting a correlation between the rate of extension, the crustal thickness, the depth of the magma reservoirs, and the degree of partial melting of the upwelling mantle. Scoria cone fields may reflect localized mantle upwellings (plumes) beneath the continental lithosphere, for example, the Snake River and Yellowstone Volcanic Fields, United States, believed to be related to a hotspot trace or the Hoggar Volcanic Field, Algeria, which consists of maars and scoria cones. Uplift resulted from the ascending plumes that produced the erupted magmas.

Volcanic fields in compressional tectonic regimes along active continental margins are characteristically related to active fault systems and show cluster alignments (e.g., Wrangell Volcanic Field, Alaska, and TransMexican Volcanic Belt, Mexico). Most clusters of cones show alignments to the regional stress field. In

many volcanic fields, scoria cones, tuff rings, and maars, commonly more primitive in composition, are restricted to the vicinity of large, more silicic and evolved andesitic shield volcanoes. In the Tuxtla Volcanic Field, Mexico, of the 250 scoria cones, tuff rings, and maars surrounding a large composite cone, 210 are scoria cones with associated lava flows. The distribution of 40 tuff rings and maars was directly controlled by the ground-water table. Scoria cones are common in many basaltic settings, especially in well-drained areas with deep water tables. They mainly form when the ascending magma fails to intercept a hydrologically important aquifer, if aquifers are empty during dry seasons, or if the permeability of country rocks is limited. Scoria cones also form when the vent is blocked against water entry and the fragmentation depth is above the water table. Tuff cones, tuff rings, and maars predominate in wetter, more basinal fields, where external water is available. Maars and tuff rings often form in basinal lowlands, in playas with shallow ponds, and along ancient streams, where external water is limited such as the Hopi Butte Volcanic Field in New Mexico. Maars were earlier explained by CO<sub>2</sub> explosions, an interpretation still upheld by some workers. Surge and fall derived deposits in maars with juvenile particles showing mostly low to moderate vesicularity and blocky equant particle morphologies generally suggest hydrovolcanic fragmentation. Accretionary lapilli, armored lapilli, and vesiculated tuffs in surge deposits of maars are considered good evidence that the

surges were wet. A hydrostatic pressure barrier of about 20–30 bars is assumed to control the maximum depth level of explosive magma–water interaction and the downward migrating fragmentation zone (diatreme structures). Explosive eruptions producing tuff cones are closely restricted to water-rich subaerial environments, both lacustrine and fluvial, and to hydrogeologic environments with high replenishment rates such as alluvial fans. Sublacustrine tuff cones may be associated with pillow lavas, hyaloclastite deltas, and reworked volcanoclastic deposits.

## VI. SIGNIFICANCE

Although tiny with respect to individual erupted magma volume, scoria cones, tuff rings, and maars are much more widely distributed on continents and islands than any other type of volcano. They mainly occur not as isolated cones but in fields whose diameters, mostly around 30–50 km, resemble the basal diameters of large central volcanoes and that of many oceanic islands. Some fields may be hot spots in the sense that they reflect a deep-seated melting anomaly of which only a small part of the magma generated has leaked through the crust to erupt on the surface, commonly interacting with the uppermost crust and surface water or groundwater. The typical composition of scoria cones is alkali basalt generated by lower degrees of partial melting. The search for the depth and shape of the melting anomaly has resulted in the discovery of small plumelike areas as in central France. This aspect is also treated in the earlier article “Basaltic Volcanic Fields.”

Most seminal studies on xenoliths of mantle rocks, dominantly peridotite as well as fragments of the lower crust, commonly granulites, are based on the widespread occurrence of such xenoliths in maars and tuff rings worldwide but much less common occurrence in scoria cones. This has led to the model in the older literature that maars are the result of CO<sub>2</sub>-rich fluidized systems that start in the mantle and drill their way to the surface. A general consensus has emerged in the past few decades that maars and tuff rings are mainly the result of interaction of rising magma with groundwater.

The reason maars and tuff rings are especially rich in xenoliths is probably that high magma ascent rates and/or the large energy generated by the interaction of magma with groundwater resulted in the ejection of the fragmented magma before the xenoliths had time to sink back in the magma column as they seem to do in

the less energetic strombolian phases in scoria cones. This is corroborated by the fact that the roots of scoria cones in many Tertiary areas, for example, in central Germany, where at least 100 m has been eroded since the Oligocene, consist of lava lake and pluglike substructures that are commonly choked with xenoliths.

Scoria cone distributions show common orientations along fault zones and are grouped parallel or en echelon to the strike of the faults. The alignment of scoria cones and the orientation of the long axes of scoria cone fields are major surface features for deducing the current orientation of the stress field of the lithosphere and/or that of older reactivated zones of weakness. In a compressional regime as in the TransMexican Volcanic Belt, scoria cone alignments are induced by faults or fault zones, by which the ascent of magma is enhanced, although local volcanic alignments must not have been affected by fault zones. Scoria cones on the flanks of large central volcanoes have been used to map the stress fields that develop within a large volcanic edifice.

## VII. HISTORIC EXAMPLES

### A. Capelinhos, Azores

From September 27, 1957, until October 25, 1958, submarine hydrovolcanic and later strombolian/hawaiian eruptions formed a new island named Capelinhos, 800 m off the west coast of Fayal Island (Azores). Earthquakes preceded the eruptive activity. The eruption began at four submarine vents shooting steam and ash-laden eruption columns above the vent. The four vents coalesced during intermittent and continuous-uprush hydrovolcanic explosions, resulting in the formation of a tuff cone. The cone had grown to 80 m above sea level after 6 days and to 140 m in less than 1 month. The cone rim diameter was 300 m, with a 100-m-wide breach on the southwest side. During the horseshoe-shaped cone stage, seawater had direct access to the vent system. Seawater maelstroms flooding down the vent were recorded, which led to wet hydrovolcanic eruptions creating powerful jets and surges after mixing of seawater with hot magma. The eruption started with the spread of white steam clouds from the base of the emerging eruption column crossing the ocean surface, shortly followed by black, particle-laden cock's tail jets up to heights of 1000 m. Finally, the eruption column tumbled back, and a turbulent mixture of particles, gas, and water spread radially in dark surges to distances of up to 3 km

from the vent. The eruption clouds were water-rich as shown by the abundance of accretionary lapilli and armored lapilli. Wet mud was plastered onto vertical cliffs and the walls of a lighthouse at a distance of 1.3 km. The deposits are crudely bedded, caused by the wetness and high density of the surges, whereas dune bedding, very characteristic for surges, was rare.

The activity stopped on October 26, 1957, and the island was completely eroded within a few days. Eruptions resumed on November 6, resulting in a new tuff cone connected to the shore of Fayal. After sealing of the vent, activity generated a scoria cone in the center of the tuff cone. Intermittent ("strombolian") explosive activity gave way to hawaiian fire fountains and lava flows late in 1957. The eruption ended on October 25, 1958. The new peninsula Capelinhos had added more than 2.6 km<sup>2</sup> of new land to Fayal Island.

### B. Miyake-jima Eruption, Izu Island, Japan

In 1983, a fissure eruption occurred on the oceanic island Miyake-jima, 170 km south of Tokyo. During about 10 h of volcanic activity, 13 scoria cones, 1 tuff cone, and 4 lava flows were produced. This event was documented by aerial photographs and videos, representing a rare opportunity to better understand growth processes of oceanic islands. At 3 pm on October 3, some craters around the western flank of Oyama volcano erupted lava flows and scoria. Hydrovolcanic explosions started about 70 min after the initial fissure eruptions. These explosions are thought to have resulted from the explosive mixing of magma with seawater, lakewater, or groundwater, depending on the location of the vents.

Two eruptive sequences were recorded. During the first sequence, which lasted from 3 pm to 8 pm, strombolian and hawaiian eruptions produced highly vesicular scoria fall, fire fountains, and subsequent lava flows, interrupted by short hydrovolcanic phases. More than 95% of the eruptive products (0.012 km<sup>3</sup>) were erupted at this time. After a short interval of decreased activity, the second eruptive sequence began, lasting at least 1 h. Pyroclastic eruptions produced scoria fall, minor bombs, ash, and accidental clasts (0.0006 km<sup>3</sup>), while hydrovolcanic eruptions were recorded only from two craters. The eruption ceased in the early morning of October 4. The 13 scoria cones were aligned en echelon along the 4-km-long, north-south trending fissure system. Along the northern part of the fissure, scoria cones consist mainly of black, highly vesicular scoria fall and intercalated lava flows. The scoria cones show only minor

phreatomagmatic phases limited by the hydrodynamic regime of the country rocks. Along the southern fissure, hawaiian fire fountaining and strombolian eruptions were periodically replaced by hydrovolcanic explosions. Only one ring-shaped hydroclastic cone with a crater diameter of 150 m was formed during shallow aqueous eruptions at the southern end of the fissure as seawater entered a submarine fissure conduit. The surtseyan cone (see "Surtseyan and Related Phreatomagmatic Eruptions") started with initial explosions rich in breccia, water-chilled bombs, and sideromelane shards. In the second eruptive cycle, thin, stratified sideromelane layers were deposited in the waning stage of the eruption. Ballistic deposits comprising block sags and water-chilled bombs were found only within 300 m of the crater. These ejecta were interpreted as having been emplaced by cock's tail jets, leading to crudely stratified deposits with many bomb sag structures. Common planar bedding and dune bedding in more distal sections suggest emplacement by base surges. The change from the dominance of cock's tail jets in the earlier eruptions to base surges at later stages marked the transition from wetter to drier eruptions.

### C. Paricutin Volcano, Mexico

The new volcano Paricutin grew in the Trans Mexican Volcanic Belt, one of the largest scoria cone fields on earth, containing approximately 1000 scoria cones. The birth of Paricutin on February 20, 1943, in a cornfield and its formation by periodic strombolian eruptions until 1952, accompanied by seismic tremors, are well documented. The eruption of Paricutin was characterized by violent strombolian activity. Lava flows rich in granitic xenoliths began to erupt on the second day.

During the initial stage of eruption, the cone grew very rapidly from 5 to 40 m high in 1 day to 167 m within a week. It reached 336 m at the end of the first year. Cone growth rate rapidly increased from 10<sup>4</sup> to 4 × 10<sup>6</sup> m<sup>3</sup>/day and continued for the first 250 days, before slowly decreasing. After eruptions ceased in 1952, the final elevation of Paricutin was 424 m. The basal diameter of the cone was around 1 km. At least 1.3 × 10<sup>6</sup> m<sup>3</sup> of pyroclastic material and 700 × 10<sup>6</sup> m<sup>3</sup> of lava were erupted, ranging from early basaltic andesites to late andesites.

Strong strombolian eruptions generated ash plumes several kilometers high. The vent and conduit geometry of Paricutin changed during the eruption from two separate funnel-shaped vents aligned northeast-southwest

to one vent during 1949–1951. The southwest vent, 10 m in diameter, erupted ash- and bomb-laden clouds every few hours. Intervals of quiet steady gas emission and periods of explosions followed each other irregularly. Sliding, slumping, and mudflows caused modifications of cone and crater diameters. Ash-mantled slopes started to creep at 32°, which is the angle of repose of the ash. Major erosive unconformities caused by slumps were filled within days or weeks by strong ash-fall eruptions, regenerating the original cone morphology.

# EXTRATERRESTRIAL VOLCANISM

In the Space Age we have discovered that volcanoes occur on most of the rocky bodies of our Solar System, and future explorations of other worlds will without doubt reveal volcanism as an important feature of planetary evolution in the universe as a whole. The evidence for volcanism on other bodies of the Solar System is reviewed in the five following chapters in Part V of the *Encyclopedia of Volcanoes*, Extraterrestrial Volcanism.

Although just beginning, the exploration of extraterrestrial volcanoes has revealed some amazing surprises, as described in this part of the volume. We begin with the chapter Volcanism on the Moon, studying the volcanism of our nearest neighbor. When Apollo 11 landed on the Moon in 1969, it touched down on the surface of a basaltic lava flow. Ever since Galileo aimed his telescope at the Moon in 1610, we have wondered about the origin of its numerous and large craters. The lunar craters, however, turned out to be of impact origin, whereas the dark plains, which are clearly visible with the naked eye from Earth and were termed maria by Galileo, turned out to be made up of great floods of basaltic lavas. Studies of the rocks returned back to Earth laboratories have shown that the Moon has been extinct for over one billion years—a consequence of the small diameter of this rapidly cooling planetary body.

In contrast to our volcanically “dead” Moon, the Jovian satellite Io has a continuous display of spectacular eruptions, as described in the chapter Volcanism on Io. It is in fact the only body outside the Earth known to have large-scale active volcanism today. Io is indeed a strange and colorful world, with a surface decorated

with a wonderful mosaic of yellows, oranges, and reds and sulfurous volcanic plumes that rise over 300 km above its surface. We are accustomed to thinking of volcanic energy as largely derived from primordial heat in the planet, but Io's energy source is different. The intense and continuous volcanism of Io is due to heat from great tidal stresses generated by its giant neighbor Jupiter.

Venus—our nearest planetary neighbor—has volcanic features that are in several respects similar to the activity on Earth, as described in the chapter Volcanism on Venus. While there is no evidence of Earth-style plate tectonics on the Moon, Io, or Mars, there is indication that such global-scale processes may have been operating on Venus, and these may be reflected in its volcanism also. Here both lava flood plains and large central volcanoes occur. But Venus also possesses enigmatic coronae, enormous circular structures that are several hundred kilometers in diameter and found nowhere else in our Solar System.

The chapter Volcanism on Mars answers the question: how did a planet one-half the size of Earth generate volcanoes that are several times larger than the largest volcanoes on Earth? Mars has widespread volcanic plains, like the Moon, but the characteristic Mar-

tian volcanic features are huge central volcanoes that dwarf any terrestrial volcanoes. These immense lava shields are the result of hot spot activity, and the largest is Olympus Mons, 25 km high, 600 km diameter. Is the size of these volcanoes a reflection of a much thicker lithosphere and the absence of plate tectonics?

In the farthest reaches of our Solar System, on the moons of Uranus, Saturn, and Jupiter, a unique form of volcanism occurs, in which geyser-like plumes of nitrogen and water-rich “magmas” are ejected from volcano-like structures. The final chapter of this section, Cryovolcanism in the Outer Solar System, discusses this distinctive form of volcanism. Most of the moons around Jupiter, Uranus, and Neptune are made up of water ice and other volatiles. From time to time, heat generated within these satellites churns up a slush of ice and volatiles that are erupted at the surface, forming volcano-like manifestations of “dirty ices” mixed with ammonia, silicates, and other impurities. The discovery of nitrogen-rich and geyser-like plumes on Triton, Neptune’s distant moon, by Voyager 2 in 1989 shows that this type of volcanism occurs today.

## GLOSSARY

**albedo** The reflectivity of an object light and dark are high and low albedo, respectively.

**anorthosite** A slowly cooled rock made up almost solely of the calcium-rich mineral plagioclase feldspar.

**armalcolite** An iron titanium oxide mineral, found in lunar mare basalts and named for the crew members of the Apollo 11 mission.

**ash** Very small fragments of lava, sprayed out at a vent, cooled quickly, and deposited as a blanket of debris.

**basalt** A dark, fine-grained rock, rich in iron and magnesium, created by solidification of a lava rich in iron and magnesium.

**bombardment** The collision of a planet with asteroids repeatedly over a long time.

**caldera** Summit crater of a volcano; collapse depression found over a subsurface magma chamber.

**cinder cone** Hill produced by the buildup of ash or other pyroclastic (q.v.) fragments around a volcanic vent.

**collapse pit** Small depression associated with subsurface

collapse, as over a shallow chamber after lava has been drained from it.

**cone** Small volcanic construct, usually having relatively steep sides.

**dark mantle deposit** Large area of the Moon covered by glassy ash deposits.

**dome** Bulbous, hill-like volcano.

**fire fountain** Spray of lava from a vent, producing a dark mantling deposit.

**flow front** The terminal end of a lava flow.

**glass** Natural material that possesses no internal order, a liquid of high viscosity.

**igneous** Of or relating to material formed from a liquid state.

**igneous rock** Rock crystallized from a liquid (magma).

**ilmenite** Iron and titanium mineral found in mare basalts.

**impact dark halo crater** Crater with dark ejecta, caused by the exhumation of buried lava flows in the lunar highlands.

**KREEP** Acronym for potassium (K), rare-earth elements (REE), and phosphorus (P); a chemical component in lunar rocks, created as the last phase of the magma ocean (q.v.).

**lava** Liquid magma extruded onto a planetary surface.

**lava channel** A channel filled with a stream of flowing lava or the landform produced after such a process.

**lava tube** A lava channel (q.v.) that is partly or completely roofed over to enclose the lava stream; may form a cave after the flow has cooled.

**mafic** Geological property describing an enrichment in iron and magnesium at the expense of silicon and aluminum.

**magma** Liquid rock within the interior of a planet.

**magma ocean** State of the early Moon in which the entire globe was covered by a layer of liquid rock hundreds of kilometers thick.

**mantle** The part of a planet below the crust and above the core. Partial melting of the mantle is the source of magma in most planets.

**maria** (MAR-ee-ah) Dark areas of the Moon; Latin plural for “seas”; singular is *mare* (MAR-ay).

**olivine** A magnesium- and iron-rich silicate mineral, common in mafic (q.v.) igneous rocks.

**pyroclastic** Literally “fire-broken,” meaning fragmental rocks produced in explosive volcanic eruptions; includes ash.

**pyroxene** A magnesium- and iron-rich silicate mineral, an important constituent of mafic (q.v.) igneous rocks, such as basalt (q.v.).

**radiometric dating** Determining the age of formation of rocks and minerals by measuring their amounts of radioactive isotopes, which decay at known rates.

**rille** A linear or sinuous (snakelike) depression on the Moon. Sinuous rilles are lava channels in the maria.

**shield volcano** A broad, low-relief volcanic construct made up of flows of relatively fluid lava, usually basalt.

**sinuous rille** A lava channel or tube in the lunar maria.

**summit pit** Depression occurring at or near the top of a volcano.

**terrae** (TER-eye) Latin plural for “land,” the cratered highlands of the Moon; singular is *terra* (TER-ah).

**vent** Hole in a planet from which volcanic products (lava, ash) may be erupted.

**vesicle** Hole (frozen bubble) in a sample of lava rock that results from dissolved gas in magma coming out of solution.

**viscosity** The property of a fluid that causes it to resist flow or movement. Higher viscosity results in slower rates of flow.

**visible maria** The dark areas of the Moon, made up of lava flows erupted between 3.8 and about 1 billion years ago. Some mare deposits may not be visible, having been ground up into the cratered terrain of the highlands.

**volcanic rock** Rock formed by the cooling of liquid rock (lava) extruded onto a planetary surface.

**volcanism** The process of interior melting of, the movement of liquid rock bodies through, and the eruption of such liquids onto the surface of a planet.

**xenolith** (ZEE-no-lith) Literally “stranger rock,” a fragment of rock from great depth carried to the surface as a clast in a lava flow or pyroclastic deposit.

## 1. INTRODUCTION

The idea that the Moon is or was volcanically active was prevalent in the years before spaceflight. Astronomers tend to be very fond of volcanoes and the analogy was made between the craters of the Moon and calderas, the large, circular depressions found at the summit of terrestrial volcanoes. Detailed work on lunar craters and terrestrial analogs provided convincing evidence that the abundant craters of the Moon were formed by the collision of solid bodies with the Moon over geological time.

The few who studied the Moon largely ignored the dark maria, the low smooth plains that make up large fractions of the near side of the Moon seen through a telescope (Figs. 1 and 2). Most ideas about the maria related them to ancient sedimentary deposits, either water-laid or mass-wasted material derived from the surrounding highlands. However, in his landmark 1949 book, *The Face of the Moon*, Ralph Baldwin presented convincing evidence that the maria were floods of basalt, a common, dark lava rich in iron that is abundant on the Earth.

Although the debate raged during the 1960s during detailed examination of the Moon in preparation for the Apollo missions, the return of samples of the maria by the Apollo program settled the issue. The maria indeed are made up of floods of lava, but what is most striking from the returned samples is the age of these lavas. The

**FIGURE 1** Full Moon image showing the two principal terrains of the Moon: the light, rough highlands (or *terrae*) and dark, smooth lowlands (or *maria*). Study has shown that the maria are basaltic lava flows.

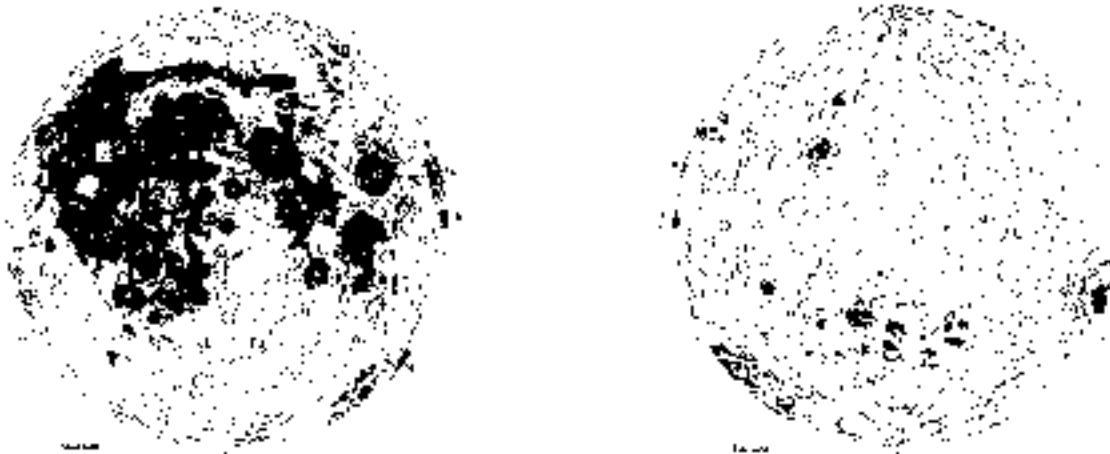

FIGURE 2 Simplified map of the lunar maria. Note extensive mare flooding on near side (left) as opposed to the far side (right). Despite appearances, the maria makes up only 16% of the lunar surface and much less than 1% of the volume of the crust.

basalts returned by Apollo range from 4.3 to 3.1 billion years old, as old as the very oldest rocks on the Earth. The lunar lavas also have some interesting chemical characteristics, including a complete absence of any type of mineral that contains water, minerals that nearly always occur in lavas on the Earth. These properties, determined during the initial examination of the Apollo samples, gave us a first-order understanding of the basic properties of the Moon. We discovered that the Moon has a crust, formed during global melting early in its history (the “magma ocean”). This differentiation produced not only the plagioclase-rich crust but also the mantle source regions for the later mare basalts. Thus, the volcanic rocks of the Moon contain important information about the Moon’s deep interior.

hot—in some places, hot enough to partially melt. These blobs of melt coagulate deep in a planet’s interior and slowly migrate upward, where they may force their way to the surface and be extruded onto a planetary surface as a lava flow.

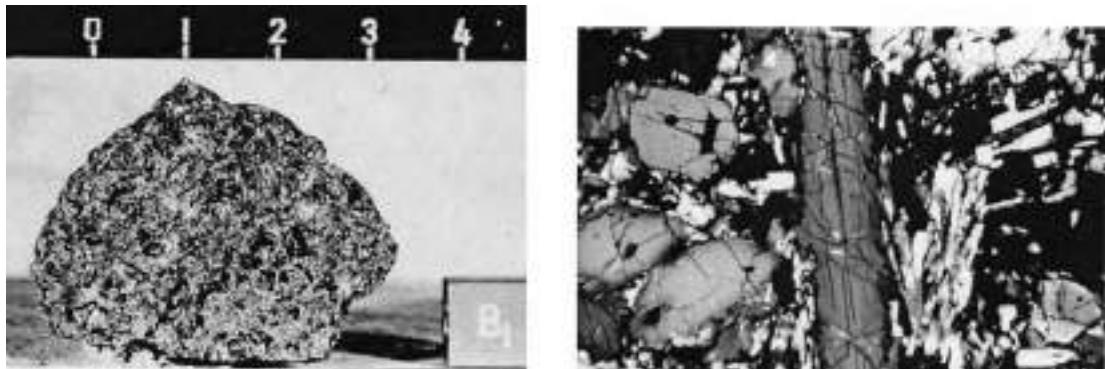

Unlike the Earth, we see little evidence for ponding of large amounts of lava at shallow depths in the crust and for its retention in deep, subsurface “holding chambers.” Most magmas appear to have migrated upward through the mantle and crust and erupted fairly quickly. The pyroclastic glasses are the most extreme examples of this phenomenon, as they appear to be completely unfractionated, suggesting rapid ascent from the mantle and violent, immediate eruption. Some mare basalts show slight evidence of assimilation of KREEP-like material. Such a process does not imply significant ponding, as KREEP would have a low melting point and could be assimilated easily during brief contact with the basaltic magma.

The chemistry of basaltic magmas tells us approximately where they formed within the Moon (at depths of 150–400 km) and what processes have affected them subsequently. Our study of the mare basalts tells us that many regions of the mantle underwent melting episodes at several depths over a very long period of time, a period at least 700 million years long and more likely over a time span of 1–2 billion years. These melted pockets found their way to the surface through cracks that they themselves propagated or through the fractures induced by the formation of the giant craters and basins of the highlands. However, only a very tiny fraction of the mantle has been melted to make basalt. Although

## II. MARE VOLCANISM ON THE MOON

### A. Origin of Mare Basalts

The samples of the maria returned by the Apollo missions are a form of common lava known as *basalt* (Fig. 3). As on Earth, basalt is created by partially melting mantle rocks composed mostly of the iron- and magnesium-rich minerals olivine and pyroxene. From the relatively high density of the mantle and sparse seismic velocity data, we know that the lunar mantle is largely made up of these minerals. Radioactive, heat-producing elements, such as uranium, made the early mantle very

**FIGURE 3** Mug shot (left; markings in cm) and thin section (right; FOV  $\sim 2$  mm) of Apollo 17 high-titanium mare basalt. Lunar basalts are made up predominantly of augite (Ca-rich pyroxene), olivine, plagioclase, and ilmenite. Mare basalts are depleted in volatile elements and show no evidence of any hydrous phases.

the maria appear prominent, the lavas are relatively thin compared with the volume of the crust as a whole. It is estimated that the mare basalts cover about 20% of the Moon by area but probably account for less than about 1% of the total volume of the crust.

### B. Apollo Mare Basalts

Like terrestrial basalts, the lunar mare basalts are made of mostly pyroxene and plagioclase and are rich in iron and magnesium. The grain size of basalt is very fine (usually less than 1 mm), a result of its very rapid cooling. Like some terrestrial basalts, some lunar lavas have small, bubble-like holes in them (*vesicles*), indicating that the magmas contained gas during eruption. As are basalts on earth, the lunar mare basalts are all formed by partial melting of the lunar mantle, a mantle made of mostly pyroxene and olivine.

The first basalts returned from the Moon were from the Apollo 11 landing site in Mare Tranquillitatis (Sea of Tranquillity). These rocks are remarkable in several respects. Mare basalts are not only devoid of water or any hydrous phase, they are depleted in all of the volatile elements (those that have very low boiling temperatures), including, for example, sodium, zinc, potassium, and phosphorus. Strangely (and surprisingly), the Apollo 11 basalts have large amounts of titanium, mostly in the form of the mineral ilmenite, an oxide of iron and titanium. The enrichment of the mare basalts in iron and their depletion in aluminum, the exact reverse of the composition of rocks from the lunar highlands, account for the relative darkness (low albedo) of the maria as opposed to the terrae.

Lavas from the Moon were found to contain some minor minerals that are not found in Earth rocks. One

of these, another iron–titanium mineral, was given the name armalcolite, named in honor of the Apollo 11 crew (the word coming from the first letters in the names of the crew, *Armstrong, Aldrin, and Collins*). The compositional properties of the lunar basalts reflect the unique chemical environment that they formed in—a small planet (resulting in low interior pressures), depleted in volatile elements, containing no water, and erupted onto a low-gravity surface in a vacuum.

Additional mare basalts from other Apollo missions largely confirm the initial impressions gathered from these studies, with some surprises and interesting variations. Lavas from the second mission, Apollo 12, are lower in titanium than the Apollo 11 basalts and 600–700 million years younger (Apollo 12 lavas formed about 3.1 billion years ago). Once again, these lavas are low in volatile elements and very rich in iron. The lower titanium and younger ages of the Apollo 12 basalts confirm that the maria were not erupted as a single, massive flood of lava across the surface all at one time but rather that the formation of the maria was an extended process that involved different batches of magma erupted in different places at different times. In short, the samples told us about the complicated volcanic history of a small planet with its own geological evolution.

Mare basalts from the other two mare landing sites extended our picture of mare volcanism, perhaps somewhat misleadingly. Apollo 15, which landed just inside the rim of the basin containing Mare Imbrium, returned low-titanium basalts of slightly older age than those from Apollo 12; these lavas crystallized about 3.3 billion years ago. Apollo 17, landing on the edge of Mare Serenitatis, returned very high titanium basalts (Fig. 3), similar to those from Apollo 11, but of slightly younger ages, about 3.7 billion years old. These results led some to conclude that the Moon had a fairly simple volcanic

history, with early eruptions of high-titanium lavas and late eruptions of low-titanium lava. The conclusion was also drawn that the Moon "died" volcanically after the Apollo 12 lavas were erupted at 3.1 billion years, a totally unwarranted conclusion that even today is widely believed and recounted.

In addition to the basalt samples returned from the mare landing sites, little fragments of lava have been found in samples from the highlands as well. These basalts occur in two principal ways: as small rocks in the regolith of highland sites and as fragments of volcanic lava in highland breccias. The former occurrence of mare basalt is likely to result from the deposition of a ray from a crater on the maria, distant from the highland site. Examples are several fragments of mare basalt from the Apollo 16 regolith. Because secondary craters from the large impact crater Theophilus occur near the site, we infer that these rocks were thrown to the site by the formation of this crater and that they represent a sample of the distant Mare Nectaris. Thus we can characterize the rocks of distant maria, if plausible candidate craters can be identified.

In contrast, mare basalt fragments found as clasts in highland breccias offer clues to the variety and ages of the earliest phase of lunar volcanism. These breccias from the highlands were assembled before 3.8 billion years ago; therefore, the lava fragments within them must be older than this. Some of these mare basalts large enough to date were extruded well before 3.9 billion years ago. The oldest mare basalt yet found is about 4.2 billion years old, only slightly younger than the age of the solidification of the crust! Other fragments date from between 4.1 and 3.9 billion years and display a variety of chemical compositions. Curiously, most of the ancient mare basalt fragments tend to have relatively high contents of aluminum compared to the basalts from the "main phase" of mare eruptions, although a few groups of high-aluminum basalt date from this later era as well.

### III. STYLES OF VOLCANISM AND ASSOCIATED LANDFORMS

#### A. Lunar Lava Flows

From pictures taken by telescopes on the Earth, the maria appear smooth and dark. The impression is that these plains fill in the holes and depressions of the Moon, suggesting a fluid emplacement. At close-up scales, small, lobe-shaped scarps can be seen; such scarps are

very common in the lava flows basalt found on the Earth. These scarps can even be seen in some of the best telescopic pictures of Mare Imbrium (Fig. 4). Thus, we had direct evidence *before* the exploration of the Moon by spacecraft for emplacement of the maria by fluid flow.

We obtained our first detailed look at the maria from the robotic precursor missions sent to scout the Moon for Apollo. The Ranger 7 spacecraft was the first to return detailed, close-up pictures of the Moon. From these images, we learned that the scale of impact cratering continues downward to the limits of resolution and that the maria is covered by the regolith. Lunar Orbiter took detailed pictures, showing us a wide variety of landforms most easily attributable to volcanism, including a better view of the flow fronts, small domes and cones, snakelike rilles that served as conduits for molten lava (lava channels and tubes), and irregular craters, whose shapes are difficult to explain by impact origins. The Surveyor 1, 3, 5, and 6 craft all performed soft landings in the maria, giving us a close-up view of the surface and telling us about the nature of the mare surface, including the revelation of some dark rocks covered with small holes, a morphology typical of lava samples.

The chemical composition of the mare basalts has an interesting side effect. The *viscosity* of the lava is dependent on the composition and temperature of the magma. The low amounts of aluminum and alkali elements and high amount of iron in the lunar magmas, coupled with their relatively high temperature upon extrusion, result in lavas that have extremely low viscosity. The viscosity of erupted lunar lava was about the same as motor oil at room temperature, about a factor of 10 more fluid than terrestrial lava. Such runny, fluid flows spread out great distances and this property, in addition

FIGURE 4 Flow fronts in Mare Imbrium (FOV ~ 150 km). Large mountain at top right is Mons La Hire, a pre-mare basin massif. Flows here are up to 800 km long, 20–40 km wide, and 20–60 m thick.

to the low lunar gravity, accounts for the great lengths (up to hundreds of kilometers) that lava flows can reach on the Moon. Such a fluid character to the lava also explains the tendency of mare lavas to form low, broad structures rather than steep-sided volcanoes and to be erupted in lava channels, as are many basalt lava flows on Earth, such as the volcanoes of Hawaii.

Discrete, single flows of mare basalt appear to be rare. Although many units in the maria have a uniform density of impact craters (denoting continuity of age) and single color, they appear to be made up of many thin, small lava flows. High-resolution photographs sometimes reveal scarps or moats occurring around impact craters that may delineate very thin flow lobes (less than a couple of meters thick). The spectacular lava flows within the Imbrium basin (Fig. 4) are often used in textbooks to illustrate the volcanic nature of the maria, but these flows are unique on the Moon and their appearance probably indicates a specialized set of eruption circumstances (e.g., the rapid inflation of the crust and discharge of a large magma body over a short period of time). For the most part, the maria appear to be a smooth, nondescript surface and discrete flows are not visible. It is likely that they consist of a complex series of relatively thin lava flows, in which subsequent regolith production and impact erosion have completely destroyed any original volcanic texture.

Smaller volumes of lava that come out from a narrow, more localized vent (such as a single-pit crater) can produce a variety of other interesting landforms. If the volume of lava erupted cools on timescales similar to the rate of magma supply to the vent, small volcanoes form and may assume a variety of different shapes (Fig. 5). Typically, lunar volcanoes form domes of low relief,

a few hundred meters high and a few kilometers across. Such landforms resemble the small basaltic shields found in certain volcanic regions of the Earth, such as Iceland and the Snake River plain of Idaho.

Other domes appear to be slightly larger and steeper. One of the most spectacular areas in the maria is the Marius Hills, a complex area of many small domes in Oceanus Procellarum (Fig. 5). The domes of the Marius Hills appear to be slightly steeper than the basalt shields mentioned above. On the Earth, such differences in shape are caused by differences in the composition of the lava, steeper domes containing more silica and less iron and magnesium than the low, broad shield volcanoes. The causes for steep domes on the Moon are less well understood but appear to be related to styles and rates of extrusion, rather than to lava composition. Eruptions of shorter duration, possibly mixed with minor interludes of ash eruption, would build up a construct with steeper slopes than would the quiet effusion of the very fluid, low-viscosity lavas.

Domes and cones on the Moon seldom are found in isolation but often occur as fields of volcanoes within the maria. The Marius Hills display many domes and cones, which occur on the summit of a broad topographic swell. The complex is several hundred meters high and has a blister-like profile, suggesting that it may be the lunar equivalent of a shield volcano, as are found on the Earth, Venus, and Mars. The Rümker Hills in northern Procellarum is another volcanic complex, similar in appearance to the Marius Hills, but smaller. Small basaltic shields, such as those found near Hortensius, occur in several locations near the margins of Maria Imbrium, Nubium, and Serenitatis. The last type of central vent volcano on the Moon is the cinder cone,

FIGURE 5 Central vent volcanoes on the Moon. Marius Hills (left; FOV ~ 150 km) occurs on a gentle topographic swell and exhibits numerous cones, domes, and rilles. Isolated cone in Mare Serenitatis (right; FOV ~ 20 km) is low albedo, steep sided construct. It may be a lunar stratovolcano.

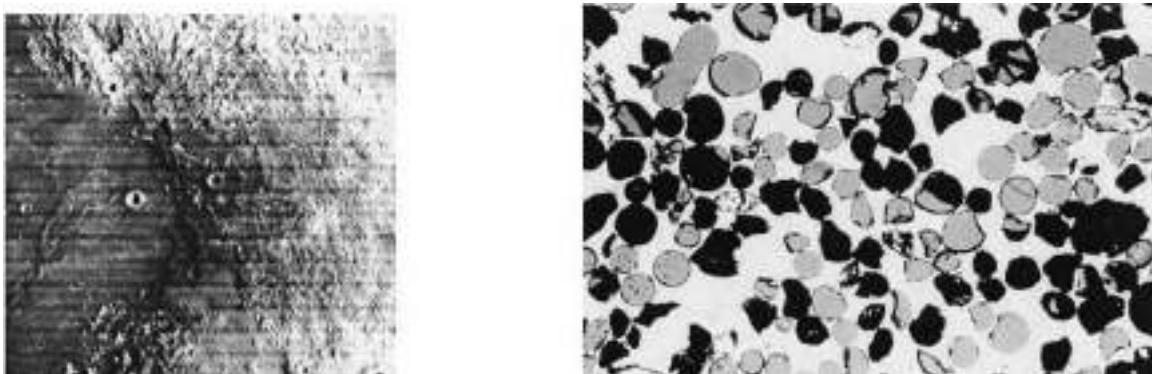

FIGURE 6 Regional view of dark mantling deposits near Rima Bode (left; FOV  $\sim$  180 km), an irregular rille and vent system. Such deposits are made up of basaltic glass of pyroclastic origin, such as the Apollo 17 orange glass (FOV  $\sim$  2 mm).

typified by irregular dark halo craters found along fractures in some crater floors. These features are surrounded by ash deposits (as shown by remote-sensing data) and are often associated with the volcanic modification of large craters that originally formed by impact.

### B. Pyroclastics

Both the Apollo 15 and 17 missions returned some unexpected and surprising material. Small glass beads were found in abundance at both sites: clear emerald green glass at the Apollo 15 site and black and orange glass from the Apollo 17 site (Fig. 6). These glass beads are homogeneous, with a basaltic composition, and do not contain the debris of mineral fragments that characterizes the impact-melted glasses from the regolith. The surfaces of these glass beads have small mounds of a variety of volatile elements, including lead, zinc, and halogens such as chlorine. The Apollo 15 green glasses are very rich in magnesium and extremely low in titanium (an unusual composition for a lunar magma), whereas the orange and black Apollo 17 glass is very rich in titanium. Once these glasses were recognized from these two sites where they occur in abundance, small spheres of similar material were recognized from every landing site. More than 20 varieties of this type of glass are known.

These glasses are of volcanic, not impact, origin and they represent the products of a fine spray of low-viscosity lava into space. During some basaltic eruptions on Earth, lava effusion is sometimes accompanied by large sprays of magma from the vent. Such spray eruptions are called fire fountains and result in a deposit of ash around the eruptive vent. The ash from Hawaiian eru-

tions consists of glass that has basaltic composition and is frequently coated by a layer of volatile elements. On the basis of similar characteristics, the lunar glasses represent the products of fire fountains that existed on the Moon over 3 billion years ago. One difference between the lunar and Hawaiian ash deposits is that so far, no samples of lava with compositions corresponding to the lunar ashes (presumably derived from the same magma) have been recognized.

In addition to their presence in the samples, the glasses are also evident as regional deposits. It was noted during the pre-Apollo systematic mapping that parts of the highlands and maria are blanketed with very dark material (Fig. 6). In the early days of lunar mapping, darkness was often equated with geological youth and these regional dark deposits were thought to represent the ash deposits of young volcanism. In fact, such a concept was responsible in part for the selection of the Apollo 17 landing site near the margin of one of these regional deposits. It was predicted that this material was volcanic ash because it typically occurs in the vicinity of irregular craters of volcanic origin and indiscriminately covers all previous terrain. The principal occurrences of these regional deposits are around the margins of filled mare basins, such as those on the Aristarchus plateau, Sulpicius Gallus, Rima Bode (Fig. 6), and Taurus-Littrow (the Apollo 17 landing site). The Apollo 17 ash is indeed of volcanic origin, but it is old (3.5 billion years), not young.

Several large craters on the Moon have deformed and fractured floors. Along some of these fractures, small (typically a few kilometers in size), irregular craters are found that are surrounded by dark, smooth material. These craters are probably volcanic vents, surrounded by ash deposits. They are the lunar equivalent of *cinder*

*cones* found in terrestrial volcanic fields. To create a cinder cone, magma charged with volatiles is squirted out through a very narrow conduit. The release of the low-viscosity lava under high pressure through a small vent causes the lava to spray into a “mist” of liquid rock droplets. The spray of droplets quickly cools in flight and each droplet lands back on the Moon as a small bead, thrown on a ballistic path. Millions of such beads are made during an eruption, building up a deposit of dark ash that surrounds the vent.

Phase chemistry allows us to determine which minerals can coexist at certain temperatures and pressures. Studies of the phase chemistry of volcanic glasses have given us a great deal of insight into the very deep interior. It appears that these glasses were generated by the partial melting of an olivine-rich mantle at depths of about 400 km within the Moon. Moreover, unlike all of the mare basalts, the glasses appear to be largely unmodified from their chemical composition at their point of origin. Such a relation indicates that the magmas from which the glasses formed must have ascended very rapidly up through the Moon from deep in the mantle, with little chemical modification from their point of origin. The glasses then erupted into a violent spray at the surface. As such, lunar volcanic glass is our best sample of the deep interior and is an important material for determining the bulk composition of the Moon.

Both the fountain nature of the eruption and the small coatings of volatile materials on the glass surfaces indicate that pockets of gas and other volatile elements existed deep with the Moon during the main era of mare volcanism over 3 billion years ago. Such an inference is also supported by the presence of the vesicles (holes) that are found in some samples of mare basalt. The composition of this gas phase is something of a mystery. It certainly is not water vapor (which accounts for almost all of the volatile phase in terrestrial volcanoes) because there is a total absence of water-bearing phases and oxidized material in the mare basalts. The reduced chemistry of lunar lavas makes us think that the gas phase might have been carbon monoxide. A detailed search for trapped bubbles of ancient gas within the glass spheres has not been successful to date, but the quest continues.

### C. Sinuous Rilles

One common landform of the maria deserves special mention, if only because the Apollo 15 mission (July

FIGURE 7 Cluster of sinuous rilles around the ancient flooded crater Prinz ( $D \sim 50$  km). Studies have shown the lunar sinuous rilles are lava channels, in some cases roofed over to form lava tubes.

1971) was sent specifically to investigate one of them. Sinuous rilles are narrow, winding valleys that occur primarily within the maria (Figs. 7 and 8). Some originate in highlands terrain, but all trend downslope and empty into mare material. Many rilles begin in irregular craters, some of which are surrounded by dark mantling

FIGURE 8 Orbital view of the Apollo 15 landing site region (FOV  $\sim 120$  km). Hadley Rille is long sinuous rille, trending NW along base of Apennine scarp. Light plains at left are the Apennine Bench Fm., a rare exposure of pre-mare KREEP volcanism.

material. Many ideas were advanced for the origin of these features before the Apollo missions, including their origin as water-cut stream channels. However, the absence of any water on the Moon, the basaltic nature of the maria, and their irregular shapes all have led to the consensus that these features are lava channels, some of which were partly roofed over to form lava tubes.

The Apollo 15 mission was sent to Hadley Rille, just inside the rim of the Imbrium basin (Fig. 8). Hadley is one of the largest sinuous rilles on the Moon, being over 100 km in length, 1–3 km wide, and up to 1 km deep. The rille begins in an elongate, irregular crater in the Apennine mountains and winds its way through the maria, snaking back and forth through the mare, finally becoming shallow and appearing to merge into a complex set of fractures north of the Apollo 15 site. The rille was examined at its rim near the landing site, where the rille is 1.5 km wide and 300 m deep. Samples of basalt collection on the rille edge are probably the only samples in the Apollo collected that were taken from bedrock. A ledge of bedrock seen in the orbital photographs probably consists of this mare basalt unit. Layers of mare lava are exposed in the walls of Hadley Rille, all confined to the upper 60 m of the rille. Color data from the Clementine mission confirm that the walls of sinuous rilles on the Moon expose mare basalt.

Although all workers agree that sinuous rilles are lava channels and tubes, their exact mode of formation remains contentious. On Earth, lava channels are created when a flow extruded at moderate rates cools from the margins inward; this cooling tends to confine the molten, active part of the flow along a central axis. This axis becomes the channel and in some cases is bridged over to form a lava tube. In this mechanism, lava channels are primarily *constructional* features, where the overflow of lava builds up levees and raises the topographic level of the flow axis. Lava can accumulate laterally on the walls of the channel, narrowing the channel width; in fact, such narrowing away from the vent is a common feature both of lava channels on Earth and of sinuous rilles on the Moon. Another concept that has emerged in the past few years holds that lava channels are primarily *erosional* features. The claim is that the eruption of very high temperature, fluid lava would flow turbulently and would soften, melt, and then remove underlying material, forming a lava channel by erosion. In such a model, the sinuous depression in the maria consists of material removed by the flow of liquid lava and incorporated into the mare deposits.

The occurrence of rille source craters in the highlands that are connected to sinuous rilles by channel segments in terra material indicates that some erosion has oc-

curred. This eroded segment may have been enlarged by collapse, a process common in lava channels. In general, however, geological evidence indicates that sinuous rilles and terrestrial lava tubes and channels are formed dominantly by construction. The large size of sinuous rilles, argued by some as evidence for erosion, can also be a result of the filling in of pre-existing depressions, as clearly shown by Hadley Rille, where the lava channel merges into pre-existing valleys north of the Apollo 15 landing site.

#### IV. NONMARE VOLCANISM

During the pre-Apollo mapping of the Moon, many highland landforms, including smooth plains, wormy textured materials, and steep domes, were interpreted to be of volcanic origin. The Apollo 16 mission in 1972 was specifically sent to the Descartes highlands to sample these highland volcanic rocks. The rocks from this mission were all impact breccias, however, and the idea of highland volcanism (specifically, evolved rocks of higher silica and/or lower iron than the mare basalts) was viewed as being discredited by the results of the Apollo 16 mission.

A regional exposure of light plains near the Apollo 15 landing site is the Apennine Bench Formation (Fig. 8). These plains predate the basalts of Mare Imbrium, but postdate the impact that created the basin. As determined by a variety of remote-sensing techniques, these plains have composition identical to small fragments of relatively high-alumina basalts of volcanic origin, the KREEP basalts, so called because they are relatively enriched in potassium (K), the rare-earth elements (REE), and phosphorus (P). In major-element composition, they are fairly aluminous and iron-poor, compared to most mare basalts. Their origin is still debated, but the idea that they may be partial-melting products of an aluminous source (lower crust?) is still viable. This would make the Apennine Bench Formation a major surface manifestation of premare, “highland” (i.e., non-mantle-derived) volcanism.

Numerous domes and color anomalies occur in the highlands that have been suggested to represent different styles of highland volcanism. The blister-shaped Gruithuisen domes are red and occur along the main rim of the Imbrium basin. Spectral data suggest that these features are very low in iron, but otherwise unremarkable. It is still not certain that they are indeed of volcanic origin.

## V. THE BEGINNING AND END OF MARE VOLCANISM

The maria were not erupted all at once as a massive flood of lava. The Moon underwent a long and protracted volcanic evolution, characterized by different degrees of interior melting and different types of eruptions of different compositions and places over a long period of time. The production of magma through time is an important basis for reconstructing lunar thermal evolution. Such information allows us to compare the Moon with the other terrestrial planets to understand the many ways that planets lose their heat.

### A. Early Phase

The earliest extrusions of lava on the Moon may have been the outpouring of liquid rock onto the still-cooling, crusted-over surface of the early Moon. Indeed, the line between volcanism and crustal formation was probably indistinguishable in early lunar history. The oldest unequivocal volcanism on the Moon is represented by tiny chips of mare basalt from the Apollo 14 highland breccias. These fragments represent pieces of a lava flow extruded onto the surface 4.2 billion years ago, a time so remote that we can only guess at what conditions were like on the Earth. Volcanic eruptions probably were more or less continuous, though sporadic, throughout a period of heavy bombardment between 4.3 and 3.8 billion years ago. Traces of this volcanism can be found in the tiny fragments of lava in the highland breccias but may also be evident as a chemical signature in cratered terrains. Some regions of the highlands appear to contain relatively large amounts of iron. This iron could represent unsampled highland rocks but it is also possible that it represents flows of iron-rich mare basalt that have been ground up into regolith of the highlands by the intense impact bombardment of early lunar history.

During the final phases of the heavy bombardment, 3.9–3.8 billion years ago, several large, well-preserved basins formed. These basins still have recognizable ejecta blankets and the smooth, far edges of their debris layers appear to fill craters and other depressions in several areas. Such deposits have all the compositional properties of highland rocks and Apollo results tell us that the light plains of the highlands are an impact formation, associated with the large multiring basins. However, some of these plains display small (1- to 3-km

diameter) impact craters whose ejecta are relatively dark. Dark halo impact craters are found in highlands light plains and cluster in regional groups, such as in the Schiller–Schickard impact basin. Spectral observations of these craters indicate that their low albedo is caused by mare basalt lava making up the crater ejecta—yet this is an area of impact-made plains.

The dark halo impact craters are excavating *buried* deposits of mare basalt. Because the plains that bury the lava flows are themselves 3.8 billion years old, the basalt flows that they cover must be older than this. Thus, a map of the light plains of the Moon that display dark halo impact craters is a map of ancient maria—basaltic lavas that were emplaced before 3.8 billion years ago. This remote-sensing evidence for the regional extent of ancient maria complements the sample evidence of tiny fragments of lava in highlands breccias and indicates that the early Moon was a planet of active volcanism.

### B. Main Phase

This stage of mare volcanism began when the very high rates of cratering typical of early lunar history declined to the point where the lava flows were not destroyed and ground up into the megaregolith after they were extruded. This decline of the impact flux was very rapid between 3.9 and 3.8 billion years ago, leveling off after 3.8 billion years. From that time onward, the extruded lava flows were bombarded by impact, but the cratering did not destroy the flows. These flows make up the visible maria. The earliest lavas from this period are the high-titanium basalts of Maria Tranquillitatis and Serenitatis, returned by the Apollo 11 and 17 missions. These flows erupted between 3.8 and 3.6 billion years ago. The complete extent of early high-titanium lavas cannot be determined because they are partly covered by younger flows; they may be extensive over the near side.

A long period of eruption of lower titanium basalt followed, from 3.6 billion years to an undetermined time, certainly as late as 3.1 billion years ago, but perhaps much later. Some of the lavas from this time were of the high-aluminum variety, particularly in the eastern maria Crisium and Fecunditatis, as sampled by the Soviet Luna 16 and 24 sample return missions. These basalts date from 3.6 to 3.4 billion years and have moderate to extremely low titanium contents. Eruption of low-titanium lavas in Mare Imbrium at 3.3 billion years ago (Apollo 15) and Oceanus Procellarum at 3.1 billion years (Apollo 12) followed. The lavas from the Apollo 12 site are the youngest mare basalts in the sample collection.

Eruptions of mare basalt were rare events, even at the

height of lunar volcanic activity, between 3.8 and 3.0 billion years ago. Although the maria appear to dominate the Moon (Fig. 2), especially on the near side, the visible mare deposits make up very much less than about 1% of the volume of the crust. The total accumulated thickness of lava in most mare deposits varies widely but is typically less than a few kilometers and large areas of basalt may be thinner than about 100 m. In part, we know this because of the abundance of highlands debris mixed into the mare soils; this fraction may approach 60–70%. Because most of this debris is derived from rocks beneath the local bedrock, the implication is that the stack of mare flows is thin.

There is a tendency to think of the maria as a hotbed of geological activity on the Moon, at least in the past. Certainly there has been activity in the maria, but very long time spans separate times of activity. At the Apollo 11 site, several different lava flows are represented among the samples. The oldest flows are 3.86 billion years old, but samples of flows of similar composition have a variety of ages, some as young as 3.55 billion years. In addition, another group of lavas, of different composition, are also about 3.5 billion years old. Thus, at this one site, we have evidence for at least four (and perhaps more) separate lava flows, emplaced over a period of over 0.3 billion (300 million) years. This geologically “active” area of the Moon has been completely quiet for a period of time longer than vertebrate life has existed on the Earth.

### C. Late Phase

The only other source of information on the age of mare lavas is the relative age data provided by geological mapping. This mapping shows that many different kinds of flows spilled out onto the maria between the dated and sampled eruptions, providing for a continuous filling of the basins from 3.8 billion years ago onward. A key piece of information for lunar volcanic history is one we do not have—what is the age of the *youngest* mare basalt eruption on the Moon? This question has an important bearing on the thermal history of the Moon; if we know the age of the last eruption, we know when the Moon “shut down” thermally, at least to the point where no lava could get out of its interior.

Many areas of the maria have been identified that have a lower density of impact craters than the sampled flows of the Apollo 12 site (aged 3.1 billion years). The very young lava flows with well-developed scarps in Mare Imbrium have crater densities about a factor of two to three lower than the lavas of the Apollo 12 site.

Thus, these Imbrium flows may be 1.5–2 billion years old; we cannot estimate their absolute age any more precisely than this. Other relatively young flows are found from Oceanus Procellarum in the west to Mare Smythii in the east. One notable example is the Surveyor 1 landing site (the site of the very first American soft landing on the Moon back in 1966) within the lava-filled crater Flamsteed P in Oceanus Procellarum. Crater density suggests that these lavas are some of the youngest flows on the Moon, having an age possibly as low as 1 billion years. Interestingly, television images returned by Surveyor 1 show that this site has the thinnest regolith of any mare site ever visited, estimated to be between 1 and 1.5 m thick. For comparison, the regolith at the Apollo 12 site (which is underlain by the youngest *sampled* mare basalts) is about 4 m thick. As already mentioned, regolith thickness reflects the age of the bedrock upon which it forms. Thus, we have an independent way to estimate the relative age of the Flamsteed basalts from the Surveyor data. These images are consistent with an age for these lavas of about 1 billion years.

The very last gasps of volcanism on the Moon may have occurred about 800 million years ago. Ejecta from the crater Lichtenberg (about 20-km diameter) is covered by a lava flow, which is therefore younger than the crater. Lichtenberg has rays and is a member of the youngest class of craters on the Moon. Estimates of the absolute age of Lichtenberg are uncertain, but craters of this size tend to have their ray systems completely destroyed on timescales of 500–2000 million years. Thus, Lichtenberg, and its overlying lava flow, are probably *younger* than 2 billion years. This mare unit is the youngest lava flow currently recognized on the Moon.

The sum of the evidence suggests that the Moon has been volcanically active for most of its history. Massive extrusions of lava probably began in dim antiquity, during the era when the Moon’s crust was being ground to a pulp by very high rates of bombardment. Extrusion of basalt continued throughout the era of basin formation, including the eruption of the massive amounts of lava that now underlie the highland plains deposited by the Orientale basin. As basins ceased to form, large expanses of mare deposits began to be preserved, forming the complex series of overlapping lava flows and ash deposits that make up the visible maria. Slow, prolonged filling of the near-side basins continued for several hundred million years, gradually loading the crust and deforming the filled basins by interior compression and exterior extension. Some impact craters underwent volcanic modification, including interior flooding and the formation of cinder cones on their floors. Large-scale

regional deposits of ash were erupted along the margins of some maria. Younger lava deposits tend to be less voluminous than the older deposits, indicating that the intensity of volcanic activity has declined with time. The youngest lava flows are confined to Procellarum and Smythii. Some of these young eruptions may have occurred since 1 billion years ago, a time that seems remotely old, but, in fact, is "only yesterday" in the ancient and silent world of the Moon.

## GLOSSARY

**differentiation** The process by which planets and satellites develop layers or zones of different chemical and mineralogical composition.

**fly-by** Term used to describe the close approach of a spacecraft to a body, without the spacecraft going into orbit around that body.

**fountain collapse** Term used to describe the collapse of an eruption column, which can lead to the formation of a pyroclastic flow.

**Galilean satellites** The four largest satellites of Jupiter (Io, Europa, Ganymede, and Callisto), named after their discoverer Galileo Galilei.

**heat flow** Heat that comes out of a body from its interior and is ultimately radiated to space.

**hot spots** Regions of enhanced thermal emission on Io, a sign of volcanic activity. The term does not imply a particular eruption mechanism and does not have the same meaning as hot spots on Earth.

**IRIS** Acronym for Infrared Interferometer Spectrometer, an instrument aboard Voyager.

**NIMS** Acronym for Near-Infrared Mapping Spectrometer, an instrument aboard Galileo that obtains spectra in the wavelength range 0.7–5.2  $\mu\text{m}$ . The spectra are used to analyze the composition of Io's surface and to measure the temperatures of its volcanic regions.

**patera** A collective term for a variety of unusual, saucer-shaped, shallow volcanic constructs that often have a central caldera.

**pyroclastic materials** Fragmented materials ejected during a volcanic eruption, including ash, pumice, and rock fragments.

**SSI** Acronym for Solid State Imaging system, the CCD camera aboard the Galileo spacecraft.

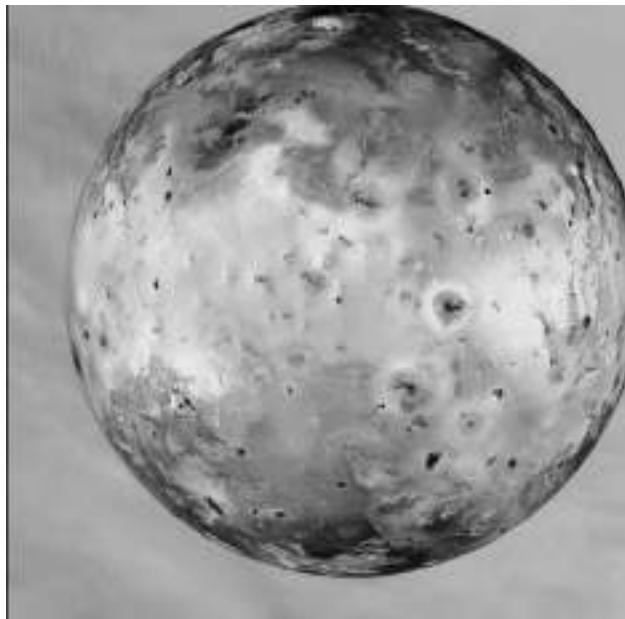

**sulfur allotropes** Sulfur cooled rapidly from different temperatures, resulting in different colors.

**thermal emission** Electromagnetic radiation produced by a body due to its temperature.

**volatiles** Chemical compounds or elements contained in magmas that are generally released as gases to the atmosphere during a volcanic eruption.

## I. INTRODUCTION

Io, the innermost of Jupiter's four Galilean satellites, is particularly important to the study of planetary volcanology because it is the only body outside the Earth known to have large-scale active volcanism. The discovery of active volcanism was made by the Voyager 1 spacecraft, which flew close to Io in 1979. Images showed volcanic plumes up to 300 km in height, and a vividly colored surface dominated by large calderas and flowlike features. The study of Io's remarkable volcanism has continued since then using observations by telescopes on Earth, by the Hubble Space Telescope, and, since 1996, by the Galileo spacecraft (Fig. 1). We now know that Io is the most volcanically active object in the Solar System, that its heat flow is much higher than the Earth's, and that several of its volcanoes erupt

**FIGURE 1** Io imaged by Galileo's camera (SSI) on September 7, 1996. Io's surface has a colorful appearance which is the result of its constant volcanic activity, depositing silicate materials and sulfur compounds. (For a color image, see <http://photojournal.jpl.nasa.gov/cgi-bin/PIAGenCatalogPage.pl?PIA00494>). Red and black deposits are thought to be the most recent volcanic deposits, probably no more than a few decades old. Just to the right of the image center is the Prometheus volcano, one of the most active hot spots on Io. Notice the dark flow snaking its way towards the right and the bright annulus surrounding the volcano, formed by plume deposits. The dark spot on the left edge just below the equator is the volcano Pele, which is surrounded by large red deposits.

TABLE I Facts about Io<sup>a</sup>

Orbital period	1.769 days
Rotational period	Synchronous with orbit
Mean radius	1821.3 km
Bulk density	3530 kg m <sup>-3</sup>
Mass	(8.9310 ± 0.0012) × 10 <sup>22</sup> kg
Gravity	1.80 m s <sup>-2</sup>
Global average heat flow	>2.5 W m <sup>-2</sup>
Radius of core	If pure iron, 656 km If iron and iron sulfide mixture, 947 km
Magnetic field	Perhaps
Geometric albedo	0.7
Local topographic relief	Up to 15 km
Active volcanic centers	>70
Hot spot temperatures	Up to at least 1600 K
Active plumes	15 observed
Surface composition	Sulfur dioxide frost mantle's surface Other sulfur compounds and probably silicates
Typical surface temperatures	85 (night) to 140 K (day)
Atmospheric pressure	10 <sup>-9</sup> bar or less, higher at locations of plumes

<sup>a</sup> Sources: McEwen et al., 1999; Matson and Blaney, 1998.

lavas that are hotter than any erupted on the Earth today.

Io's size and bulk density (Table I) are similar to those of the Earth's Moon and suggest a composition predominantly of silicates. We might have expected Io to be a cratered, dead world much like the Moon. However, even before the first close-up images of Io were returned by Voyager in 1979, there were hints that Io was remarkably different from the Moon. Earth-based telescopic observations made in 1974 by W. Wamsteker and colleagues first showed that the overall spectrum of Io closely matched that of sulfur, suggesting that sulfur and sulfur compounds might be abundant on the surface. It was also known that Io's spectrum lacked water ice, unlike those of the other Galilean satellites. Just prior to the Voyager encounters in 1979, two events presaged the discovery of active volcanism. F. Witteborn and colleagues reported a telescopic observation of an intense temporary brightening of Io in the infrared wavelengths from 2 to 5 μm. They explained it, although with some skepticism, as thermal emission caused by part of Io's surface being at a temperature of about

600 K, much hotter than the average expected daytime temperature of about 130 K. A few days before the Voyager encounters, a seminal theoretical paper by Stan Peale and colleagues was published in the periodical *Science*. They had studied the tidal stresses generated within Io as a result of the gravitational fields of Jupiter and Europa. Their calculations showed that the possible heat generated by tidal stresses was on the order of  $10^{13}$  W—much greater than heat that could be released from normal radioactive decay. Their prediction was that Io might have “widespread and recurrent volcanism.”

Active volcanoes were not immediately obvious in the first images returned by Voyager 1. The most striking aspect of Io shown in the first images was its colorful surface, with yellows, oranges, reds, and blacks. Scientists on the imaging team nicknamed Io the “pizza moon” and speculated about the presence of large quantities of sulfur on the surface. Another surprising aspect was the absence of impact craters. The obvious conclusion was that Io’s surface was very young and the craters must have been obliterated—but how? The answer came soon after, when a navigation engineer at the Jet Propulsion Laboratory, Linda Morabito, noticed a peculiar umbrella-shaped feature emanating from Io’s limb in one of the images that was taken to aid navigation of the spacecraft (Fig. 2). The pattern turned out to be an eruption plume rising about 260 km above the surface. A second plume was found on the same image, and more plumes were seen upon close examination of various other images. Additional evidence for active volcanism came from another of Voyager’s instruments, the Infrared Interferometer Spectrometer (IRIS), which detected enhanced thermal emission from parts of Io’s surface—some areas had temperatures of about 400 K, much higher than the rest of the surface, which has noontime equatorial temperatures of about 107–124 K. When one of the hot areas was found to coincide with one of the plumes, there was no doubt that active volcanism was taking place.

Eighteen weeks after Voyager 1’s dramatic discovery, the companion spacecraft, Voyager 2, flew close to Io. Intense activity was still taking place, but significant changes had occurred between the two fly-bys, including the cessation of the largest plume, Pele, and the altered shape of the deposits associated with this plume. An area of about 10,000 km<sup>2</sup> had been filled in, presumably by fresh material falling down from the plume (Fig. 3). It became evident that dramatic changes of Io’s surface could occur over short timescales.

Initial analysis of the Voyager data showed nine plumes and nine “hot spots,” though not all plumes coincided with hot spots and vice versa. Hot spot is a term used by Io researchers to define a region of en-

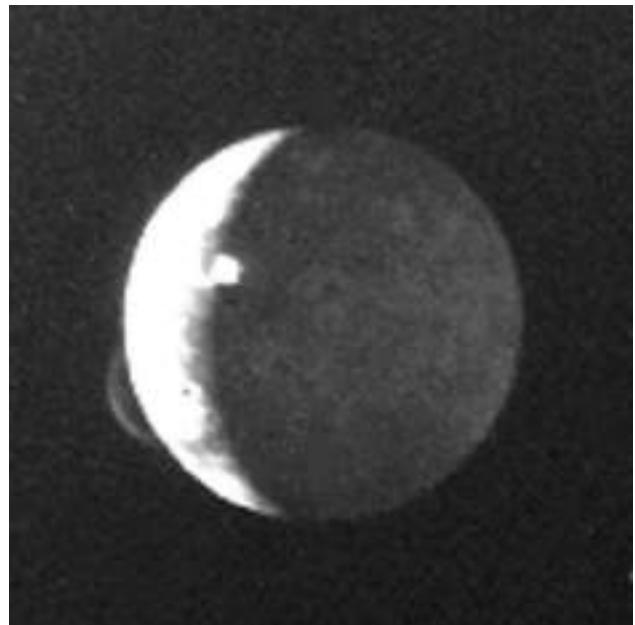

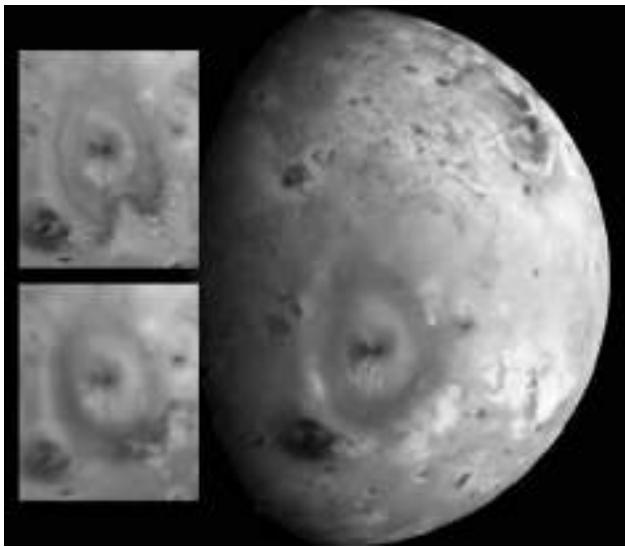

FIGURE 2 Volcanism on Io was first seen on this Voyager I image, taken on March 8, 1979. The image shows two plumes. The Pele plume is seen on the edge of the disk against the dark sky and it rises about 260 km above the surface. The other plume, Loki, is seen as a bright spot on the nightside of the terminator (the boundary between day and night). The plume is reaching above the darkness of the disk and catching the rays of the rising sun.

hanced thermal emission, a sign of active volcanism—it does not mean the same as a hot spot on Earth. The Voyager IRIS experiment did not observe all of Io’s surface, so it was suspected that other hot spots existed.

After the two Voyager space crafts left the Jupiter system on their way to Saturn and beyond, the study of Io’s volcanism was continued from Earth by astronomers using infrared detectors mounted on telescopes. These observations showed that brightenings and fading of hot spots occur, indicating variations in the level of volcanic activity. Observations by W. Sinton, R. Howell, J. Spencer, and other astronomers have shown that Io’s most powerful hot spot, Loki, has brightenings that switch on in one month or less and last several months before fading. Telescopic observations were also used to analyze the reflected light from Io’s surface to determine surface composition, confirming that it was dominated by sulfur dioxide (SO<sub>2</sub>). Io was also observed by the International Ultraviolet Explorer satellite and more recently it has been observed by the Hubble Space Telescope.

The first spacecraft to orbit Jupiter is Galileo, which has been able to image Io and monitor its volcanic activi-

**FIGURE 3** Changes in the bright red deposits around the Pele plume. The larger image was taken by the Galileo camera in June 1996 and shows Pele just below the center of Io's disk. The upper inset is an image from Voyager 1 taken in March of 1979, while the lower inset was taken by Voyager 2 in July of 1979. Note the dramatic change in the shape of the annular deposit in the four months between the two Voyager encounters. The differences in the shape of the deposit are thought to reflect the changing shape of the vent from which the plume emerged. For a color image, see <http://photojournal.jpl.nasa.gov/cgi-bin/PIAGenCatalogPage.pl?PIA00718>.

ity since June of 1996. Galileo was inserted into orbit around Jupiter in December 1995 and flew close to Io at that time. Unfortunately, a problem with the on-board tape recorder prevented any close-up images and other remote-sensing observations to be obtained. However, all was not lost and extremely valuable information was gained using the fields and particles instruments aboard the spacecraft.

Since the radiation environment near Jupiter and Io is extremely hostile to spacecraft and instruments, no other close passes of Io were planned, and Galileo began a series of 11 orbits making close passes to the other satellites (Europa, Ganymede, and Callisto) and observing Io from distances much greater than Voyager had done in 1979. However, Galileo has been unique in that it can monitor Io's volcanoes from Jupiter orbit and thus map their distribution on the surface and detect changes in their activity (Fig. 4). The two major instruments on Galileo that monitor the activity of Io's volcanoes are the camera (Solid State Imaging system, or SSI) and the Near-Infrared Mapping Spectrometer (NIMS). To make up for the loss of data from 1995, three close fly-bys of Io are planned in late 1999 and early 2000.

If Galileo and its instruments survive, we should be able to answer many of the questions that have been asked since Io's volcanism was discovered.

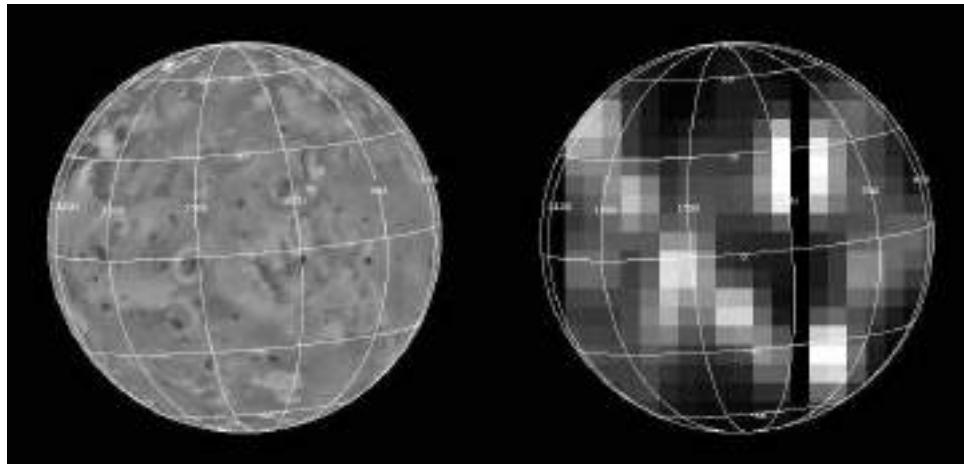

## II. INTERIOR AND HEAT FLOW

When Galileo approached Io in December 1995, the magnetometer experiment detected a disturbance in Jupiter's magnetic field. A likely explanation for the disturbance is that Io produces its own magnetic field, but this cannot be confirmed until Galileo obtains further measurements from a close pass over the south pole of Io, planned for the end of 1999. Another interesting result was obtained by radiotracking of the spacecraft as it came close to Io. Variations in the spacecraft's motion revealed distortions in Io's gravitational field, which provided evidence that Io is differentiated. Io has a large metallic core with a radius of about half of its total radius, made up of iron or a mixture of iron and iron sulfide. Given Io's intense volcanic activity and high heat flow, it is possible that the metallic core is at least partly molten and may be circulating. This would generate a magnetic field, consistent with the initial indications from the magnetometer experiment. However, if the tidal energy is mostly dissipated within the upper mantle, as recent results from the global distribution of hot spots suggest, then convection in the core might not occur.

Io's heat flow is very large compared with that of the Earth and other planets. The heat flow is measured at infrared wavelengths and the portion due to reflected sunlight is calculated and subtracted, taking into account Io's surface albedo. The difference is the heat flow due to volcanism and originates in Io's interior. The current best measurement of Io's heat flow is  $10^{14}$  W. For comparison, the Earth's total heat flow is  $4.42 \times 10^{13}$  W. Averaged over the whole of Io's surface, the value is about  $2 \text{ W m}^{-2}$ , high even compared to geothermal and volcanic areas on earth. Io's heat flow is about 200 times what could be expected from heating due to the decay of radioactive elements and illustrates how crucial tidal heating is to drive Io's active volcanism.

## III. SURFACE EXPRESSIONS OF VOLCANISM

Compared to other Solar System bodies, Io's colors are truly striking while its global topography is somewhat

**FIGURE 4** Detection of active volcanoes on Io by Galileo's Near-Infrared Mapping Spectrometer (NIMS). The image on the left is a Voyager global mosaic for comparison. The image on the right is a 5- $\mu\text{m}$  map by NIMS. The bright pixels represent hot materials from the active volcanic centers. The dark, roughly circular region on the lower right of the NIMS image is Bosphorus Regio, a cold region surrounded by a ring of hot spots. This NIMS image was obtained on June 29, 1996, and revealed three previously unknown active hot spots. Since then, NIMS has discovered over 20 other hot spots.

subdued. There are relatively few mountains and the surface is dominated by vast expanses of smooth volcanic plains. A major difference between the surface of Io and that of other bodies in the Solar System is that, to date, no impact craters have been found on Io, despite the relatively high flux of comets expected due to Jupiter's gravity and the fact that the surfaces of the other Galilean satellites all show the scars of impacts. The lack of craters on Io implies that the surface must be very young—probably at most a few million years old. Calculations using the expected rate of impacts on Io show that, in order to bury the craters, the resurfacing rate on Io must be at least 1 mm per year. If the resurfacing was uniform, this would mean that all of Io's surface would be buried to a depth of 1 km in only one million years.

Because of Io's high rate of volcanism, it is expected that its surface features must be almost entirely the result of volcanism and related plutonic and tectonic activity. The dominant features on Io's surface are volcanic constructs (such as calderas), mountains, and smooth plains. Plateaus and scarps are seen in some regions. The colors of the surface are mostly yellow, white, red, and black. A few isolated patches of greenish-yellow were recently discovered by P. Geissler from Galileo imaging data. Black materials that spot Io's surface are thought to represent recently erupted lavas. Many of these dark patches lie within and around depressions that appear similar to calderas on Earth (Fig. 5).

The most striking type of feature on Io's surface is volcanic centers. Although the currently available im-

ages from Voyager and Galileo do not have enough spatial resolution to show individual volcanic vents, many volcanic centers are seen dotted all over the surface. Over 350 of these have been identified from images, though many of these are not currently active. Their forms include caldera-like depressions, dark circles or ovals, and source areas of flows. About 40% are dark, which is thought to indicate that they were active more recently than the others, which appear as bright or brighter than their surroundings. M. Carr and colleagues have studied the distribution of these volcanic features on the surface and concluded that it appears to be uniform, except that the features are perhaps more sparse at high latitudes. The distribution suggests that volcanic activity has occurred everywhere on Io over the time represented by the present population of vent regions. This may imply that as activity in some areas declines, activity in other areas must be rekindled.

The calderas on Io range in diameter from about 20 to 200 km, are as deep as 2 km, and have steep walls and apparently flat floors. Calderas on Earth form by collapse of the surface above shallow magma chambers after the magma is rapidly withdrawn. It is likely that the calderas on Io are formed by the same process, but on Io they can be much larger in diameter than on Earth, while the Ionian volcanoes they are associated with are in general much more subdued in flank topography than terrestrial volcanoes. Some calderas on Io do not appear to be associated with a volcanic edifice at all and others are seen atop low shield-type volcanoes.

TABLE II Active Volcanic Centers on Io

Volcanic center	Location	Hot spot detected by	Plume detected?

<sup>a</sup> Active volcanic centers on Io detected by instruments aboard Galileo, Voyager, the Hubble Space Telescope (HST), instruments mounted on ground-based telescopes. Table modified from Lopes-Gautier et al. (1999). Additional data courtesy of A. McEwen, J. Spencer, J. Goguen, C. Dumas, and P. Geissler. Location marked with (?) are tentative identifications of surface features that are the sites of thermal emission. Detection marked with (?) are uncertain.

Given the direct measurements of very high temperature magmas on Io (discussed later), it is possible that the absence of large volcanic edifices could be due to very low viscosity lavas forming lava plains rather than building tall volcanoes.

An obstacle to the detailed study of the morphology of Io's volcanic features is the lack of high-resolution images. The highest resolution images available at the time of writing are at best 500 m per pixel. Lobate

features that are interpreted to be lava flows are seen associated with many of the dark markings on Io, but the lack of resolution and topographic information hinders attempts to use their morphology to obtain clues to magma composition, as has often been done using images of flows on other planets such as Mars. It is clear, however, that some of the flows on Io are tens of kilometers long. Comparison of Voyager and Galileo camera images by A. McEwen and colleagues shows that new

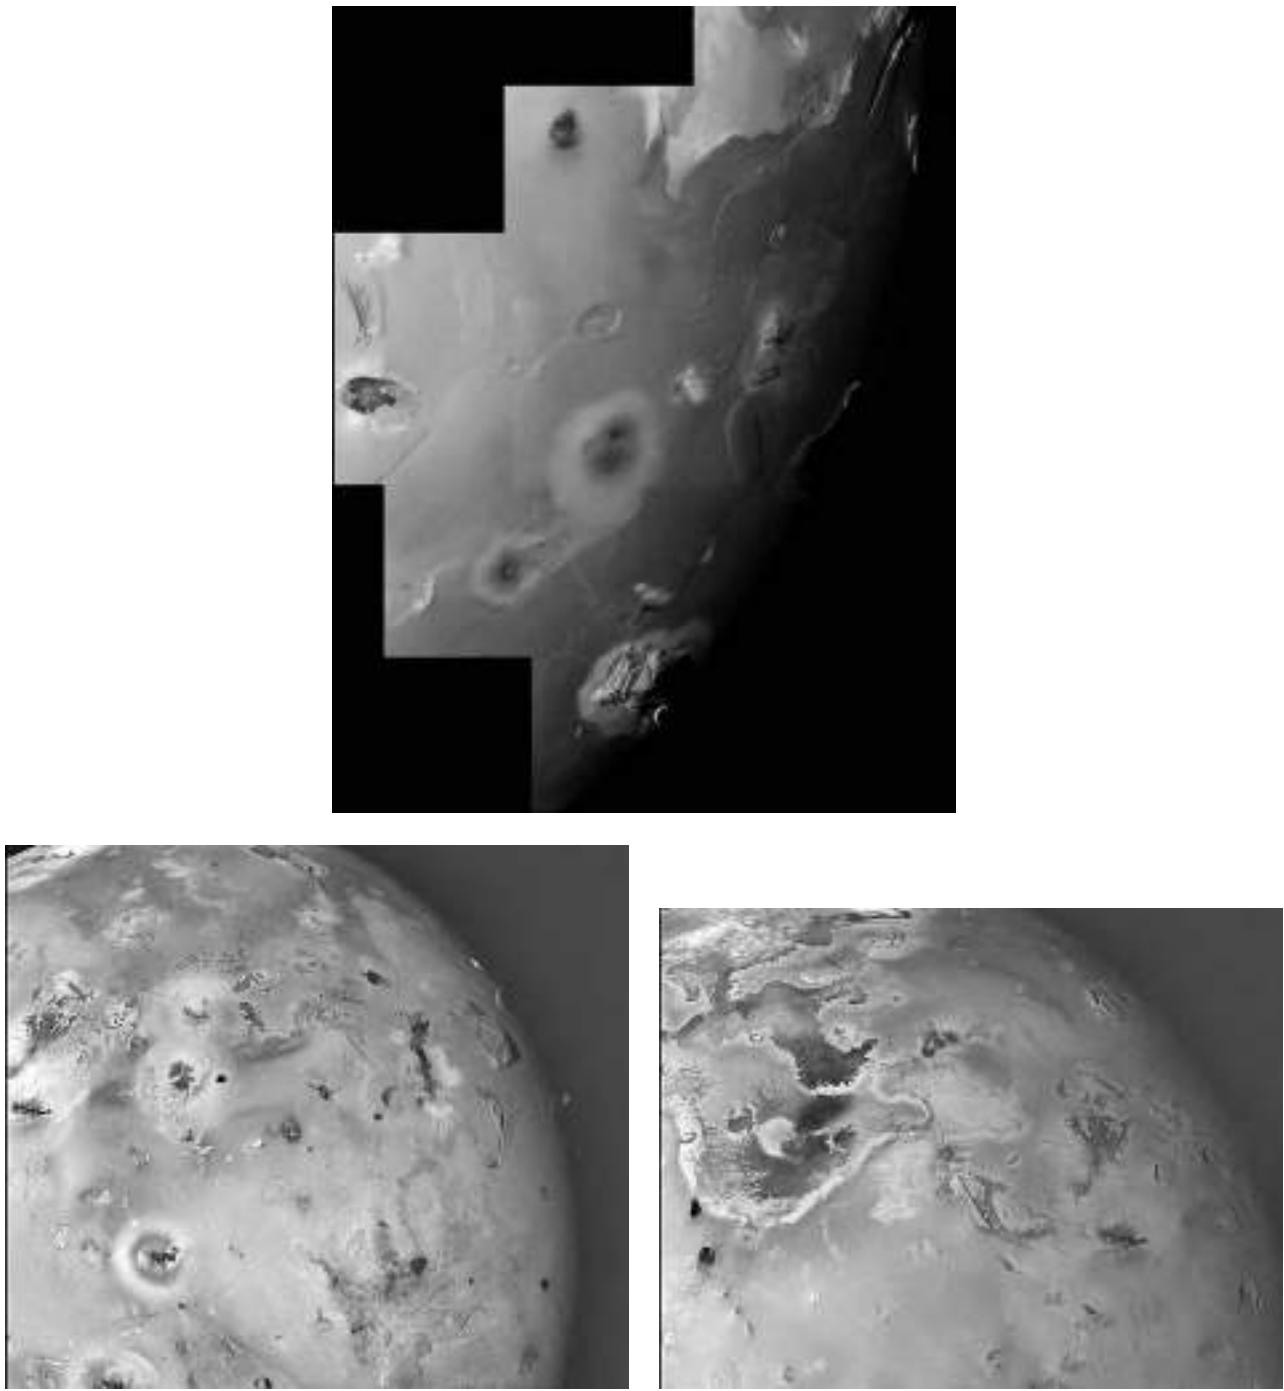

FIGURE 5 Images showing the varied landforms of Io. (a) Voyager 1 image showing the south polar region. Near the bottom of the picture is the 10-km-high Haemus Mons, one of Io's tallest mountains. The partly dark-filled caldera at the far left is Creidne Patera. Elsewhere, eroded volcanic plateaus and other volcanic calderas can be seen dotted on the smooth plains. (b) Topographic mapping image acquired by Galileo's SSI. The Prometheus volcano is prominent on the lower left. Note the bright annulus formed by plume fallout and the dark lava flow. To the right of Prometheus is Bosphorus Regio, a bright, roughly circular area surrounded by active volcanic centers, described as the "ring of fire." Numerous other dark calderas can be seen in this image. (c) Topographic mapping image acquired by Galileo's SSI. The prominent dark flows on the upper left are from the active volcanic centers of Lei-Kung Fluctus and Isum Patera.

flows up to 70 km long were emplaced in the years between these missions.

Mountains (Fig. 5) are also a major type of feature on Io, though they are scarce in comparison with mountains on Earth and do not form long chains and ranges. It is still debatable whether Io's mountains are a direct result of volcanic activity, though it is clear that they do not have the forms of volcanic features such as stratocones or shields. Their distribution on the surface appears uniform, and there is no correlation between their locations and those of hot spots and plumes. Mountains are generally isolated from one another and separated by vast expanses of plains. They can be up to 15 km high and their appearance is rugged, some being multi-tiered and perhaps disrupted by tectonic forces. The relationship between mountains and plains is still not well understood but, in most places, plains materials appear to be younger than mountains and to lap onto their bases. In one area, Euboea, a landslide of mountain material can be seen overlapping the plains.

Two possible explanations are likely for the origin of mountains. The simplest is that the mountains are indeed volcanic and that the youngest materials were deposited on top of the adjacent plains. The alternative hypothesis is that the mountains are exposures of an old subcrust and that the sides of some of the mountains have failed and the debris flowed over the surrounding plains.

Most of Io's surface is covered by volcanic plains that appear smooth in relief but are striking in their different colors and albedo patterns. The plains are thought to be formed by overlapping flows and deposits from volcanic plumes, such as SO<sub>2</sub> frost and sulfur. Although the flows have mostly sharp edges, other deposits surrounding vents and flows appear diffuse. One of the most intriguing features of the plains is the low, irregular escarpments seen in some areas, which imply that the plains are layered (Fig. 5). Many of the escarpments have a jagged outline, suggesting they may have been formed by erosion. A series of mesas in the south polar regions are particularly striking and appear erosional in nature. These features may have been formed from the explosive eruption of SO<sub>2</sub> from a subterranean reservoir or, alternatively, they may have been carved into the plains by fast-moving, low-viscosity lavas.

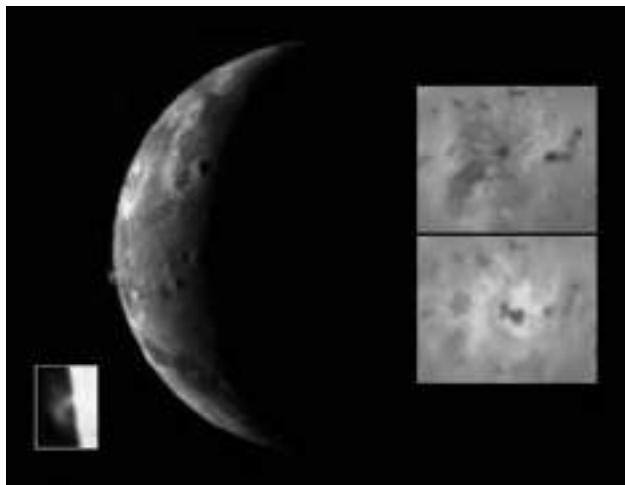

No evidence of global-scale tectonism has yet been found on Io. Scarps are seen to cut across the plains, and some of them appear to be tectonic in origin, given their linearity and tendency to occur in parallel groups. However, other scarps are irregular in plan view and appear to be erosional in origin. Alignments of hot spots occur in some areas, but there is no evidence that these

are tectonic in origin. Tectonic studies of Io have so far been handicapped by the small number of tectonic-like features that can be seen in the currently available images. It is possible that many previously unseen tectonic features will be revealed when high-resolution images are acquired during Galileo's close fly-bys of Io.

#### IV. SURFACE CHANGES, COLORS, AND COMPOSITION

Comparison between Voyager and Galileo images taken nearly two decades apart showed many areas of surface changes, but not as many as might have been expected given Io's high rate of volcanism. Surprisingly, hot spots where vigorous activity is known to have occurred, such as Loki, showed little surface change, presumably because the activity is mostly confined to the interior of the caldera. One of the most striking cases of surface change happened on Ra Patera, a region that so far has been identified only as an active plume site and not yet as a hot spot, though this could be due to poor spatial resolution of the thermal data over this region. Voyager images showed Ra to have a dark caldera surrounded by narrow flows. The flows showed a sequence of colors along their lengths that was consistent with the interpretation of Carl Sagan that Io's surface was covered by different sulfur allotropes, with the supposedly cooler materials further away from the vent. However, this interpretation of composition based on color was criticized on a variety of grounds, including the fact that the exact colors of sulfur can be drastically altered by even small amounts of other materials. Ra Patera became even more of a puzzle when observations from the Hubble Space Telescope showed that a significant brightening occurred in this region between 1994 and 1995. When images of Ra were returned after Galileo's first orbit (Fig. 6), they showed that the flows had been covered over by new deposits and that a plume was now erupting from Ra.

The intriguing question of what causes the vivid colors of Io's surface, including the colors of the flows that are now gone, remains unanswered, though Galileo results have brought new insights. The global distribution of the different color deposits gives some clues to their origin. Galileo images show that almost one-third of Io's surface is covered by red and orange materials, particularly at latitudes higher than 30° north and south. At lower latitudes, patches of red materials appear to be associated with hot spots and plumes. Red materials are

**FIGURE 6** The Ra Patera volcano showed dramatic changes in the 18 years between the Voyager and Galileo spacecraft observations of Io. The larger image was taken by the Galileo camera (SSI) on June 28, 1996, and shows a plume about 100 km high over the Ra Patera volcano. The two insets are comparisons of Voyager (top) and Galileo (bottom) views of the volcano. The Voyager image shows a dark caldera near the center of the image surrounded by long, narrow flows. The flows cannot be seen in the lower image, taken by Galileo. They were covered over by a bright deposit that extends over an area of about 40,000 km<sup>2</sup>. For a color image, see <http://photojournal.jpl.nasa.gov/cgi-bin/PIAGenCatalogPage.pl?PIA00293>.

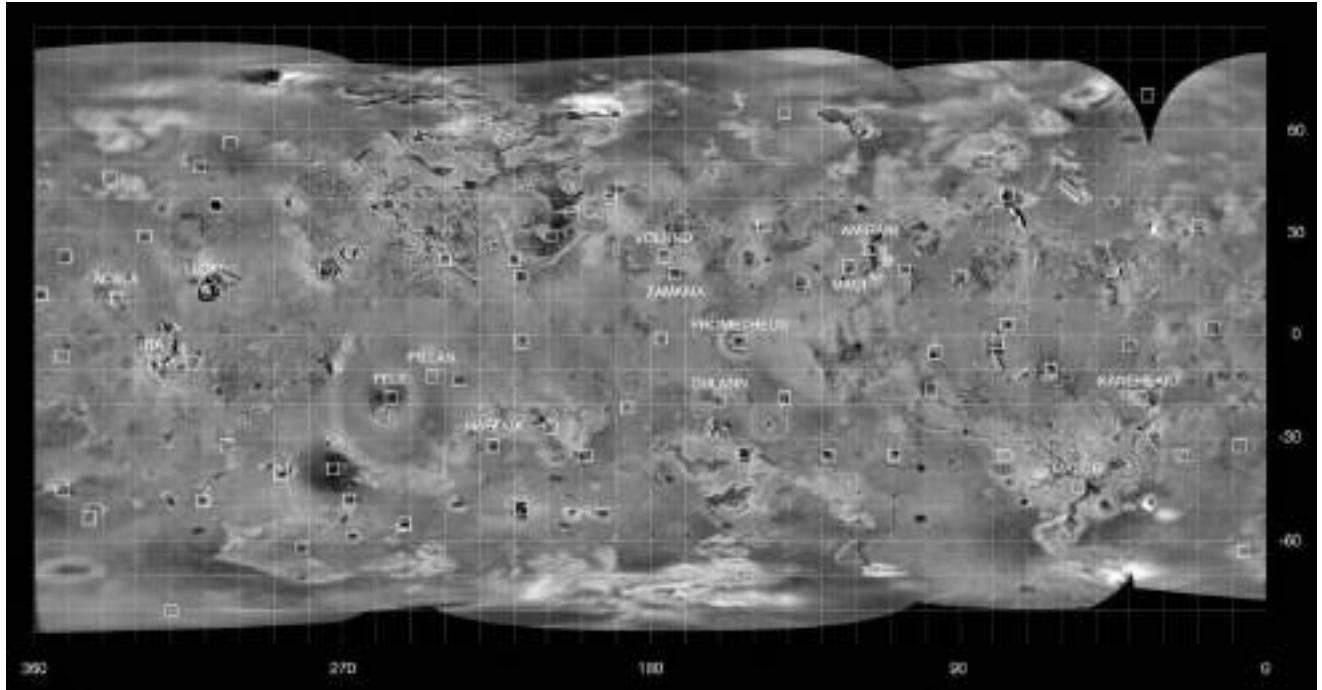

thought to be ephemeral, lasting perhaps a few years, and to be a sign of recent volcanic activity. It is likely that they represent pyroclastic deposits, perhaps fallout from plumes. The origin of the red deposits in the polar regions is probably different, even though the composition may be the same, since there is a clear scarcity of plumes at high latitudes. The red deposits may last longer in the polar regions because of lower surface temperatures.

Very dark deposits also appear to be associated with hot spots. They occur in isolated patches, both as diffuse deposits that are probably pyroclastic in nature and as continuous units confined to caldera interiors. Most dark calderas are found within 60° of the equator. The vast expanses of equatorial plains between individual hot spots are dominated by yellow, white, and gray materials that are generally anticorrelated with the hot spots. The most striking example of the anticorrelation is the “ring of fire” of hot spots (Figs. 4 and 7) surrounding the white, cold region of Bosphorus Regio. (The term is descriptive of the alignment of hot spots and does not imply a tectonic control as is the case for the ring of fire on Earth.)

What are the different compositions of these differently colored materials? Sulfur and sulfur compounds are the most viable compositional candidates for the variegated colors of Io, though silicate materials are thought to be exposed in places. So far, only SO<sub>2</sub> has been definitely identified on Io by its absorption features in the near-infrared. Recent studies by R. Carlson using data from the NIMS experiment on Galileo showed that most of Io’s surface is covered by a thin mantle of fine-grained SO<sub>2</sub> frost (probable grain sizes of 30–100 μm in diameter) and that the white and gray materials represent areas covered by moderate to coarse grained SO<sub>2</sub> frost (grain sizes of 250–500 μm in diameter) beneath smaller particles. Because NIMS detects SO<sub>2</sub> in both white and yellow regions, it is possible that the yellow unit may be in places a dilute mixture of sulfur and SO<sub>2</sub>, or perhaps a thin veneer of ordinary orthohombic sulfur (S<sub>8</sub>) that is colored at visible wavelengths but transparent in the infrared.

The most prominent red deposit on Io is the large ring surrounding the hot spot Pele. The existence of both red and black diffuse materials in the ring suggests that the two could be related in composition and sulfur is the most likely candidate. Red sulfur has considerably higher viscosity than the higher temperature (black) sulfur allotropes. Black is seen nearer the vent of Pele, while red is seen further away in the ring, which would be consistent with more viscous magmas being ejected more energetically, and falling further away, than fluid magmas with similar densities and volatile contents. However, it is possible that the black materials may be pyroclastic silicates rather than sulfur. Some of the very dark materials that are associated with calderas and active hot spots show an apparent spectral absorption feature at 0.9 μm, seen in the Galileo imaging data and interpreted by P. Geissler and colleagues as being due to orthopyroxene. Although further results from Galileo are needed to confirm the presence of this spectral feature and to provide a unique mineral identification, the presence on Io of orthopyroxene, a magnesium-rich silicate mineral common in terrestrial mafic and ultramafic rocks, seems likely.

Perhaps the most intriguing materials on Io’s surface are the greenish-yellow deposits seen in a few isolated spots. Unlike other terrains on Io, these areas show a negative near-infrared spectral slope, strongly suggesting that a nonsulfur component is present. These green materials could be made up of sulfur contaminated by iron, as suggested by J. Kargel and colleagues; however, the fact that an active hot spot is seen coinciding with one of these areas supports the alternative explanation of silicates such as olivine or clinopyroxene.

**FIGURE 7** Global distribution of active volcanic centers on Io are marked by squares in this Simple Cylindrical global mosaic of Galileo images. The named features are the sites of active plumes. The bright, roughly circular area to the west of Prometheus and Culann and to the south of Amirani/Maui is Bosphorus Regio, which is surrounded by active volcanic centers. (Modified from McEwen *et al.*, 1999.)

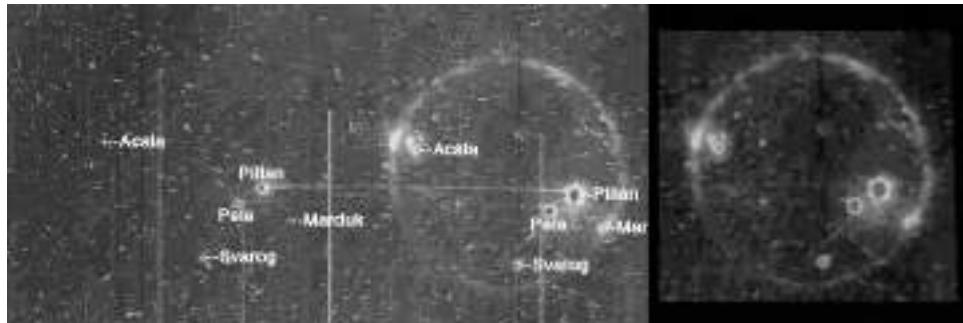

The poor spatial resolution of the observations of Io available so far and the thin coating of  $\text{SO}_2$  that seems to be prevalent on much of the surface have made it difficult to identify the compositions of the different deposits on Io. One of the most important goals of the close fly-bys of Io by Galileo is to reveal the true nature of Io's differently colored deposits.

areas, perhaps cooling lava flows. Between the Voyager observations in 1979 and the Galileo observations that started in 1996, several of Io's hot spots were detected by ground-based telescopes. Temperature measurements using infrared detectors mounted on telescopes showed higher temperatures than had been measured by IRIS—such as 900 K reported by T. Johnson and colleagues in 1988 and 1225 and 1500 K reported by G. Veeder and colleagues in 1991. These measurements are consistent with silicate magmas but not with sulfur volcanism. Sulfur boils vigorously on Io's surface at about 500 K and, although sulfur compounds such as sulfur polysulfides could be several hundred degrees hotter, temperatures as high as 1000 K strongly suggest silicate magmas.

Observations by Galileo's instruments have shown that the temperatures are indeed consistent with silicate rather than sulfur volcanism. However, the greatest surprise was the detection of extremely high temperature volcanism on Io. The best studied example is the activity of the hot spot Pillan in 1997. Galileo's NIMS and SSI instruments observed this hot spot within a few minutes of one another and their combined results, reported by A. McEwen and colleagues in 1998, provided unambiguous evidence of temperatures exceeding 1500 K, and

#### V. HOT SPOT TEMPERATURES AND COMPOSITION OF MAGMA

Shortly after the Voyager mission, the major controversy about Io's volcanism concerned the nature of the volcanism: sulfur or silicates? Io's surface colors were initially interpreted as sulfur deposits. The temperatures of the hot spots measured by the Voyager IRIS instrument were relatively low—mostly around 400 K—and could be consistent with either molten sulfur or silicates. IRIS was not capable of detecting small areas at higher temperatures; hence it was “seeing” only the cooler

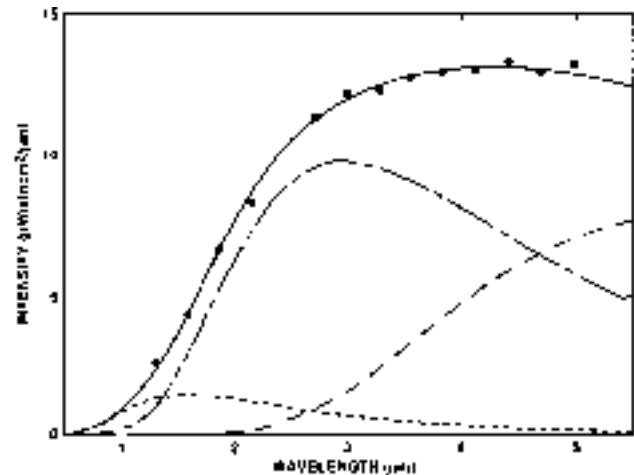

**FIGURE 8** Galileo camera (SSI) images showing Io in eclipse. The camera detects thermal emission from active hot spots by imaging Io when the disk is being eclipsed by Jupiter and is in darkness. The major hot spots are marked, including Pillan. The left-hand image was acquired using the camera's 1- $\mu\text{m}$  filter, while the right-hand image is the clear filter exposure. The resolution of the image is 14.6 km/pixel, but the hot spots appear "smeared" over an area about 9 pixels in diameter. Modeling of the data indicates that the areas of the hot spots are smaller than the pixels. The right-hand image shows diffuse glows on Io's limb and the plume over the hot spot Marduk. The glow is due to electronic excitation of gases. The small bright pixels and clusters of pixels seen all over the images are due to noise from radiation, the bright vertical lines are image blemishes, and the horizontal line between the images is due to exposure during motion of the spacecraft's scan platform. For a color image, see <http://photojournal.jpl.nasa.gov/cgi-bin/PIAGenCatalogPage.pl?PIA01635>.

possibly as high as 2000 K (Figs. 8 and 9). This implies magma liquidus temperatures of at least 1700 K, because lavas are expected to cool rapidly once they reach Io's surface. There is evidence that about 10 other hot spots on Io erupt lavas with temperatures hotter than about 1600 K. These temperatures are higher than any seen on lavas erupting on Earth now and in recent times. It is possible that high-temperature lavas are typical for Io but, given the distant observations of Io by Galileo, these temperatures can only be detected during particularly vigorous episodes, when large quantities of hot magma come up to the surface. The temperatures detected by the low spatial resolution observations of NIMS are mostly in the range of 400–1000 K, although hotter components can be inferred from the spectral data in some cases.

The most likely explanation for the very high temperatures of Io's lavas is that they are ultramafic (magnesium rich) in composition. This explanation is supported by the discovery of the 0.9- $\mu\text{m}$  spectral absorption feature discussed above, which is interpreted as magnesium-rich orthopyroxene. Ultramafic lavas have very rarely been erupted on Earth since the Proterozoic, about 1.8 billion years ago. Therefore, studying Io's current volcanism may lead to a better understanding of the emplacement of ultramafic lavas on the ancient Earth.

It is important to note that although the temperatures of Io's lavas indicate ultramafic compositions, at present there are no direct measurements to confirm this interpretation. The most critical question about Io's volca-

**FIGURE 9** Temperature fits to a spectrum of the hot spot Pillan taken by Galileo's Near-Infrared Mapping Spectrometer (NIMS). The spectrum (represented by the solid circles) was taken a few minutes apart from the images in Fig. 7, when Io was in darkness due to an eclipse by Jupiter. All the energy in the spectrum is due to thermal emission, as there is no component due to reflected sunlight. Three blackbody curves were fitted to the spectrum. the long-dash curve represents an area of 544  $\text{km}^2$  at a temperature of 475 K. The long dash-short dash curve represents an area of 17.6  $\text{km}^2$  at a temperature of 975 K, and the short-dash curve represents an area of 0.11  $\text{km}^2$  at a temperature of 1825 K. The smooth solid curve represents the sum of these three temperature-area components and it fits closely the original spectrum. (Modified from McEwen et al., 1998.)

nism—what is the composition of the erupting magma and crust—remains open.

---

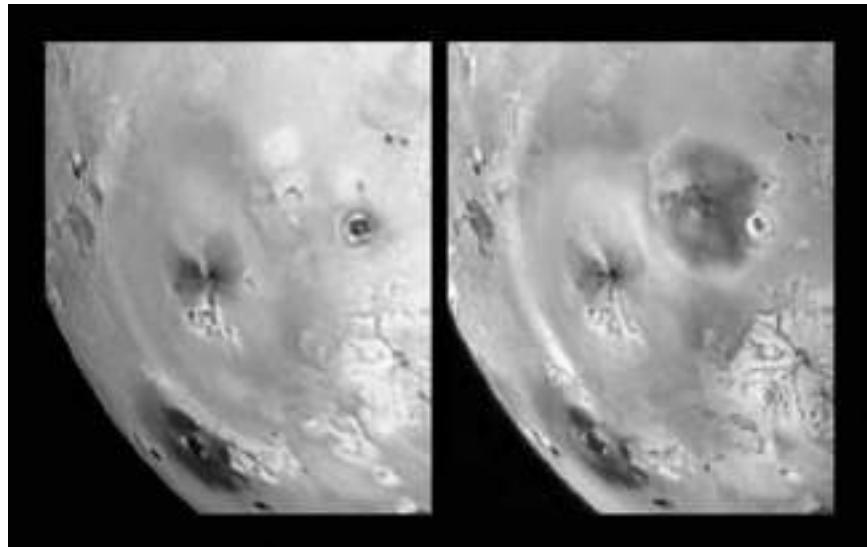

## VI. TEMPORAL VARIABILITY OF VOLCANIC ACTIVITY

Io is a dynamic body—the volcanic plumes turn on and off, the outpourings of magma vary in temperature and extent, and sometimes large-scale changes are seen to occur in a matter of months, completely changing the appearance of a region. Variations in the volcanic activity have been detected since the fly-bys of Voyager 1 and 2, as changes were apparent in the four months between the two spacecraft approaches to Io. However, the most dramatic change so far observed on Io's surface happened sometime between spring and fall of 1997. An image taken by the Galileo SSI camera during Galileo's 10th orbit revealed an enormous "black eye" surrounding the hot spot Pillan (Fig. 10). The diameter of the deposit is about 400 km and it covers an area about as large as the state of Arizona. It is likely that the dark deposit is pyroclastic in nature, and probably consists of silicates.

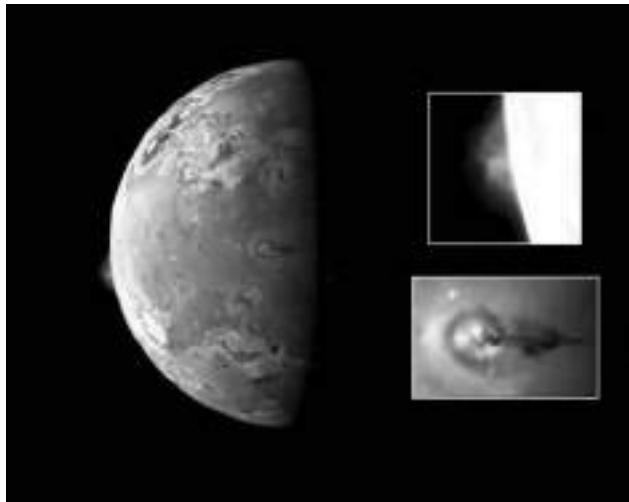

Pillan is a hot spot discovered by the NIMS instrument during Galileo's second orbit and seen by NIMS to be a persistently bright, active hot spot since that

time. Back in 1979, the Voyager cameras had shown Pillan to be a simple caldera located on the edge of the Pele plume fallout deposit. No hot spot or surface changes were found there between the two Voyager fly-bys. Pillan was not apparent as a hot spot in the observation of Io in eclipse taken by Galileo's camera in June 1996 and the caldera appeared unchanged since the Voyager days. In September of 1996, NIMS detected a hot spot at Pillan and camera images showed that the floor of the caldera had become dark—but the floor had become bright again by Galileo's third orbit in November 1996 and in subsequent orbits until April of 1997. The NIMS instrument continued to detect a bright, persistently active hot spot at the caldera. Observations by J. Spencer and colleagues using the Hubble Space Telescope on July 5, 1997, detected an active plume over Pillan, about 150 km high, and around the same time a plume was also detected by Galileo's camera (Fig. 11). When the Galileo camera imaged the Pillan region again in September 1997, it showed the remarkable dark deposit. Also shown in the September image are subtle changes to the Pele plume deposits, which may indicate that the two plumes were active at the same time and interacted with one another.

The surface change observed by the camera coincided with the high-temperature eruption discussed above, which has been so far the most impressive of these eruptions observed on Io. Since then, the eruption at Pillan has continued and it has been observed by both the

**FIGURE 10** Remarkable surface changes on the volcano Pillan Patera observed by Galileo's SSI camera. The image on the left was taken on April 4, 1997, and shows Pillan as a simple caldera on the edge of the red Pele plume fallout deposit. The image on the right, taken on September 19, 1997, shows a circular, dark deposit about 400 km in diameter surrounding the caldera. For a color image, see <http://photojournal.jpl.nasa.gov/cgi-bin/PIAGenCatalogPage.pl?PIA00293>.

**FIGURE 11** Two of Io's volcanic plumes are seen on this image taken by Galileo's camera (SSI) on June 28, 1997. One plume is seen against the bright limb in the larger image and also in the upper inset. This plume rises 120 km above the caldera of Pillan Patera volcano and it was also detected by the Hubble Space Telescope. The second plume in the larger image is seen near the terminator (boundary between day and night) and is being erupted by the Prometheus volcano to a height of about 75 km. The lower inset shows the shadow of this plume extending to the right of the volcano. The vent is near the center of the bright and dark rings. Prometheus was seen by the two Voyager spacecrafts to have an active plume and it is possible that the volcano has been continuously active since 1979. For a color image, see [http://photojournal.jpl.nasa.gov/cgi-bin/PIA\\_GenCatalogPage.pl?PIA00703](http://photojournal.jpl.nasa.gov/cgi-bin/PIA_GenCatalogPage.pl?PIA00703).

camera and NIMS. However, it has decreased in temperature and brightness, implying that activity is declining. Pillan continues to be observed by Galileo's instruments and the waning of its activity may provide clues to the dynamics of all of Io's eruptions.

Impressive as the Pillan eruption was, it is by no means the most energetic that Io can produce. The Loki volcano undergoes major variations in thermal emission, as shown by telescopic observations in the years since Voyager. The most dramatic changes in thermal emission are called "outbursts" and are defined as events having high fluxes and temperatures, and short lifetimes, that cause the total flux from Io at 5  $\mu\text{m}$  to at least double in intensity—one could say that a single outburst "lights up" the whole satellite. Outbursts are relatively rare. J. Spencer and N. Schneider calculated that outbursts occur only about 3% of the time; hence the probability of observing one, either from ground-based telescopes or from a spacecraft, is low.

Outbursts are interpreted as silicate eruptions having

a very high eruption rate. The best studied outbursts so far occurred in January 1990 and was observed from a telescope in Hawaii by D. Blaney and colleagues. The outburst is thought to have occurred at the hot spot Loki and it is the only one of these events so far that was observed to significantly cool in a few hours. In the simplest model of the event, Blaney and colleagues assumed that the flux reflected a single temperature and a circular hot spot, which would imply a temperature drop from 1225 to 555 K and a radius increase from 5.4 to 22 km in 2.6 h. This would correspond to a lava flow front speed of a few meters per second.

Io's hot spots commonly vary in brightness in a scale far smaller than that of outbursts. Loki is a common site for brightenings, which typically switch on in less than a month and last for several months before fading. These brightenings have been interpreted as changes in silicate eruption rates, with the fastest rates being considerably greater than those of the Columbia River Basalts. More subtle variations in intensity of hot spots are being studied by the Galileo NIMS instrument. The NIMS monitoring of Io's hot spots has detected variations in hot spot intensity but also shown that, despite variations, the activity of many of the hot spots is extremely persistent, while activity at others appears more sporadic. The combination of Galileo NIMS and SSI data over a period of 2 years showed that 30 of Io's hot spots are active for periods exceeding 1 year. These are classified as "persistent" hot spots, while others, observed active for periods of 3 months or less, are classified as "sporadic," though they might also represent persistent activity at low levels that are rarely detected by Galileo's instruments. Many of the persistent hot spots, such as Loki and Pele, were seen to be active during the Voyager fly-bys and from telescopic observations in the years in between Voyager and Galileo. It is likely that these hot spots remain active for decades and they are likely to represent the major pathways of magma from Io's interior to the surface.

The behavior of persistent-type hot spots can give us a window into the mechanisms involved in the transfer of magma from Io's interior to the surface. It is known that long-lived eruptions on Earth can last for decades. Current examples include the 1983 to present eruption of Pu'u O'o in Hawaii and the 1968 to present eruption of Arenal in Costa Rica. Much longer timescales of activity are known on Earth, up to the 2500 years of nearly continuous activity at Stromboli. "Steady-state" volcanism on Earth occurs when the magma eruption rate is balanced by the magma supply rate and it is likely that this balance is occurring on Io. H. Sigurdsson and R. MacDonald have pointed out that, on Earth, mea-

surements of the magma eruption rate can be used to estimate the minimum magma supply rate. So far, it has been difficult to estimate eruption rates for Io's hot spots because the volume of erupted magma is not known. Observations of Io at close range will give us the opportunity to measure flow sizes and to estimate flow thicknesses, which can then be used to estimate the rate of supply of magma to the surface.

---

## VII. GLOBAL DISTRIBUTION OF VOLCANISM

Detections of hot spots from Voyager, Galileo, and ground-based measurements and observations by J. Gouen and colleagues using the Hubble Space Telescope show that Io's surface is dotted with volcanic activity (Fig. 7). The distribution of hot spots is, to first order, uniform. However, detailed examination of the distribution reveals more significant departures from uniformity. Eclipse images obtained by Galileo's camera showed a field of bright vents near the sub-Jovian point (latitude and longitude 0 on Io) and a glow on the anti-Jovian point (latitude 0, longitude 180) that may be caused by a similar field of bright vents. It is unclear if these are hot spots, because enhanced thermal emission has not been confirmed at these sites and they could be gas vents that, in eclipse, are seen to glow. Another possible departure from uniformity is the hot spot concentration around Bosphorus Regio, as mentioned earlier.

Hot spots are not all the same, as they differ in terms of persistency of activity and energy of thermal emission. Io's most energetic hot spot, Loki, accounts for approximately 25% of Io's heat flow from hot spots. It is significant that the persistent hot spots are concentrated at lower latitudes. Monitoring of Io's active plumes has shown that plumes also occur mainly near the equatorial regions and not at high latitudes. The implication of these findings is that, although volcanic activity occurs all over Io, the bulk of the activity that manifests itself as hot spots and that can be mapped with the currently available instruments is concentrated at lower latitudes rather than nearer the poles. This has important implications for how tidal energy is being dissipated in the interior of Io.

Two basic models have been proposed by M. Segatz and colleagues and M. Ross and colleagues to explain how tidal energy is dissipated in and heats up the interior of Io. Both models assume that convection is the main

mode of heat transfer within Io, but differ on where the tidal heating predominantly occurs. If heating occurs mainly in an asthenosphere about 100 km thick, convection should occur globally, with centers of upwelling and downwelling separated by a few hundred kilometers. In the alternative model, tidal heating occurs in the deep mantle and the result is larger scale convection, with a relatively small number of mantle plumes spaced widely apart. The deep mantle model predicts greater heat dissipation toward the poles, while the asthenosphere model predicts greater heat dissipation near the equatorial regions. Although we expect that there are many yet undetected hot spots and "geothermal" regions on Io where heat from the interior is being dissipated and that the hot spots detected so far do not account for all of the heat dissipation, it is also reasonable to assume that the distribution of hot spots detected so far will reflect the dominant form of transfer of heat from the interior to the surface. The fact that the more persistent hot spots, the active plumes, and the most energetic hot spots such as Pele, Pillan, and Loki occur within 30° of the equator supports the asthenosphere tidal dissipation model rather than the deep mantle model. Although the distribution of hot spots cannot prove either model, it provides important observational constraints that any proposed models for Io's internal heating have to address.

---

## VIII. VOLCANIC PLUMES, ATMOSPHERE, AND TORUS

The most spectacular volcanic features on Io are the active plumes that can rise hundreds of kilometers above the surface (Fig. 11). Nine eruption plumes were detected by Voyager 1; eight of these were still active 4 months later when Voyager 2 flew by Io. Galileo has detected 10 active plumes (as of the end of 1998), 4 of which appear to be erupting from the same areas as those detected during Voyager. A total of 15 plumes from different volcanic centers have been observed so far. However, surface changes around other areas known or thought to be active volcanic centers indicate that other plumes may have been active recently. As discussed above, the distribution of active plumes on Io is not uniform, as most plumes are seen within 30° of the equator. All plumes, except for the one observed at Ra Patera, are seen to coincide in location with hot spots. It is possible that there is also a hot spot at Ra, but it

has not yet been detected, perhaps because of relatively low temperatures or small spatial extent.

Io's plumes differ in some characteristics. The plumes erupting from the Prometheus and Pele volcanoes are good examples of two different types. The Prometheus plume is lower in height (reaching 50–150 km above the surface) and seems to be very long-lived. It was active during the Voyager encounters and remains active during the Galileo mission; however, the source of the plume migrated about 70 km during the 17 years between spacecraft encounters—or else these are different plumes erupting from the same general region. The Pele plume is significantly fainter than the Prometheus plume at visible wavelengths, reaches higher altitudes—up to 460 km above the surface—and may not be as long-lasting. For example, the plume was not detected 4 months later when Voyager 2 flew by Io.

The fallout deposits from these two types of plumes are also distinct. The Prometheus plume is associated with a bright, white annulus that is probably SO<sub>2</sub> frost, while the deposits from the Pele plume are bright red. Results from Galileo NIMS show that SO<sub>2</sub> is notably absent from the Pele deposits. These differences could imply that sulfur rather than SO<sub>2</sub> is driving the eruptions of the Pele plume, though SO<sub>2</sub> gas has been detected over Pele.

SO<sub>2</sub> not only is common over the surface of Io but also is the major component of Io's tenuous atmosphere. SO<sub>2</sub> and sulfur are probably the volatiles that drive explosive volcanism on Io, as H<sub>2</sub>O and CO<sub>2</sub> (the dominant volatiles driving explosive volcanism on Earth) appear to be highly depleted on Io. So far, no definite H<sub>2</sub>O or carbonate absorption features have been detected in Io's spectrum, though some results suggest that H<sub>2</sub>S may be present on Io.

Early studies of plume emplacement, such as that by R. Strom and N. Schneider, proposed that some of the symmetric “umbrella-like” plume shapes, such as Prometheus, could be explained by models using ballistic trajectories for the particle fallout. Other plumes appeared less simple, perhaps reflecting more complex vent shapes or pressure conditions. Indeed, it is known that the dynamics of Io's plumes are very complex, particularly because models of plume emplacement have to take into account the very low atmospheric pressure on Io (about 10<sup>-9</sup> bar). S. Kieffer's landmark work in 1982 on the dynamics of Io's plumes discussed possible thermodynamic conditions for the formation of the plumes, which, by comparison with terrestrial conditions, ranged from unusually cold to unusually warm. These conditions correspond to various initial temperatures

in the reservoir and to various mixtures of SO<sub>2</sub> and sulfur.

The coldest scenario modeled by Kieffer has liquid SO<sub>2</sub> in a reservoir at temperatures below the liquidus temperature of sulfur (393 K). In this model, the liquid SO<sub>2</sub> in a shallow crustal reservoir begins ascending due to buoyancy and starts “boiling” as it approaches the surface. As it erupts, a plume of vapor and ice condensate forms as the fluid emerges into the cold, low-pressure atmosphere of Io. At slightly higher initial temperatures, the SO<sub>2</sub> boils in the reservoir and also as it ascends toward the surface. Both these scenarios produce a change in the SO<sub>2</sub> from liquid to vapor to ice. In a different scenario, SO<sub>2</sub> vapor coexists with sulfur in a reservoir that has an initial temperature equal to the liquidus temperature of sulfur. In higher temperature scenarios (such as if the reservoir is close to a body of silicate magma), either SO<sub>2</sub> or sulfur exists in a superheated vapor state. The resulting plumes from these “hot” reservoirs consist mostly of gas. Because they may be difficult to detect from images, they have been called “stealth plumes” (discussed below).

Modeling Io's plumes involves not only the thermodynamic considerations, as described above, but also the fluid dynamics of the plume emplacement. Recent work by Kieffer involves numerical simulations varying initial conditions such as temperature, the mass fraction of gas versus particles, and initial pressure. One particularly interesting early result is that pyroclastic flows may form on Io. Previous studies assumed that pyroclastic flows would not form on Io because of the very tenuous atmosphere. However, Kieffer's simulations have shown that plumes that are rich in volatiles can create their own local atmospheric conditions, in which fountain collapse to form pyroclastic flows becomes possible. The activity from Io's plumes feeds its tenuous atmosphere. The low pressure of Io's atmosphere is equivalent to good laboratory vacuums on Earth, although, as Kieffer's work has demonstrated, the local atmosphere near volcanic vents can be higher. The principal constituent of Io's atmosphere is SO<sub>2</sub>, but SO has been detected and other species, such as O<sub>2</sub>, have been suggested. A major question is, where is the SO<sub>2</sub>—and hence the atmosphere—coming from? There are two possible sources for the SO<sub>2</sub> in the atmosphere, and probably both sources are important. The first is from evaporation of the SO<sub>2</sub> frost deposits on Io's surface, but recent studies, including observations of Io at millimeter wavelengths by E. Lellouch and colleagues, show that this mechanism has a minor role. The bulk of the atmospheric SO<sub>2</sub> is thought to be supplied by Io's volcanic activity. Observa-

tions in the ultraviolet wavelengths using the Hubble Space Telescope have shown that Io's atmosphere is patchy, very thin, and tenuous over most of the planet but that the density increases at some locations, such as Pele, where  $\text{SO}_2$  is being supplied by the volcanoes. Therefore, Io's volcanic activity plays a major role in supplying Io's atmosphere, though some contribution from  $\text{SO}_2$  frost deposits is also expected.

The observations of Io's atmosphere at millimeter wavelengths posed a new question about Io: explaining the amount of  $\text{SO}_2$  gas detected would require about 30–50 large plumes to be erupting at one time. Since Voyager had only detected nine, the question of "missing plumes" arose. Spacecraft observations detect plumes because sunlight is scattered by the small particles of  $\text{SO}_2$  within the plumes. Torrence Johnson and colleagues proposed the existence of stealth plumes, that is, plumes composed almost entirely of gas, which would be hard to detect, but that Kieffer's modeling work suggested to be possible. These plumes are thought to occur when a hot, molten silicate intrusion encounters a reservoir of liquid  $\text{SO}_2$  buried at depths of at least 1.5 km. The high temperature and pressure at the subsurface ( $>1400$  K,  $>40$  bars) result in an eruption that is geyser-like, in which particles do not form through condensation. The existence of stealth plumes has been supported by Galileo observations, including those from the camera. The plume over the hot spot Acala is not seen in sunlight, presumably because of lack of particles in the plume, but it can be seen in observations of Io in eclipse, in which the gas appears to glow.

What happens to the gases erupted by the plumes? It turns out that only a relatively minor amount of atmospheric gas is lost to space. The temperatures of the frost deposits on Io's surface are sufficiently low (around 100–110 K) that cold-trapping of  $\text{SO}_2$  by condensation is a very important process. However, some material does escape Io, forming a corona and neutral clouds near Io and the Io torus further away. The corona refers to the region within Io's gravitational pull, where bound and escaping atoms and molecules populate a low-density shell. The neutral clouds of sodium, oxygen, and sulfur extend from the corona to distances of many times the radius of Jupiter. The Io torus is a doughnut-shaped trail along Io's orbital path, made up almost exclusively of various charged states of sulfur and oxygen, thought to be derived from the breakup of volcanic  $\text{SO}_2$  and  $\text{S}_2$ . The ionized particles are held within the torus by Jupiter's magnetic field, in a similar way to the mechanism that holds charged particles in the Van Allen radiation belts around the Earth.

The most easily observed of the neutral clouds is the sodium cloud. The cloud is populated by sodium atoms escaping Io at about  $2.6 \text{ km s}^{-1}$ . The existence of this cloud places an important constraint on the composition of Io: no sodium has yet been detected on Io's surface or atmosphere, but since the atoms are escaping Io, sodium must be present. Neutral clouds of oxygen and sulfur are also seen, but they are faint compared to the sodium cloud and these species have been detected on Io's surface and atmosphere. Where the sodium is coming from remains one of the most puzzling questions about Io.

## IX. FUTURE STUDIES

At the time of writing, Galileo is still monitoring Io's volcanoes and the highest resolution observations have not yet been made. The close fly-bys of Io are expected to provide a wealth of totally new information about this intriguing volcanic world. Our current plans are to have three fly-bys, in October 1999, December 1999, and February 2000. These fly-bys will bring Galileo within about 500 km of Io's surface, the first time near the equator, the second over the south pole, and the third over the northern hemisphere. The equatorial pass will provide the opportunity to measure the high magma temperatures of Pele and Pillan from close range. Our goal is to measure temperatures with both the NIMS instrument and the SSI camera, to try to constrain what the maximum lava temperature is. The polar pass will be important to determine if Io has its own self-sustained magnetic field. Galileo images are expected to reveal details of the surface and of the volcanic flows that, together with the spectral data from NIMS, can reveal the composition of Io's lavas, their temperatures, and emplacement mechanisms. Measurements of Io's heat flow by NIMS and by the Photopolarimeter Radiometer (PRR), an instrument that can observe at longer wavelengths and therefore detect lower temperatures than NIMS, will provide tighter measurements on Io's total heat flow. Other areas to be investigated using the close-range observations are the dynamics of plumes, the composition and origin of the mountains, and the composition of the polar volatiles.

If the fly-bys are successful, the observations returned to Earth will not doubt provide the answers to many of the outstanding questions. However, much more could still be learned from future missions, from observations

from Earth, and from Earth's orbit. Galileo will only be able to observe a very small part of the surface at high resolution and Io is a dynamic, constantly changing world. Even after Galileo's fly-bys are completed, much will remain for future missions to explore.

## GLOSSARY

- arachnoids** Annular structural patterns consisting of concentric or circular pattern of fractures or ridges with radial arrays of fractures or ridges extending outward for several radii and interior flows and small shield volcanoes. The radial fractures frequently merge outward with the linear patterns of the fracture belts on which arachnoids are arranged. The term "arachnoid" derives from this arrangement, like spiders along "webs" of linear fracture belts. The radial patterns are more strongly developed; otherwise arachnoids are similar to coronae.
- canali** A planetary physiographic term for long sinuous channels, most of which on Venus are thought to be lava channels although the fluid from which they formed is not known.
- chasma (pl., chasmata)** A planetary physiographic term for a deep, linear valley with steep sides.

**colles** A planetary physiographic term for a cluster of small hills or volcanoes.

**corona (pl., coronae)** Dominantly circular or elliptical structures consisting of an annulus of concentric ridges or fractures, an interior that may be topographically positive, a peripheral moat or trough, and, frequently, numerous volcanic centers and tectonic landforms in the interior. Coronae may be associated with mantle plumes or hot spots; related volcanism, in the form of large and small volcanoes, is frequently present within the corona or on its margins.

**farrum (pl. farræ)** A planetary physiographic term for a type of volcano (all of which are less than 100 km in diameter) with a steep perimeter slope and relatively low angle flanks; also referred to as "pancake" domes.

**flow field** An area covered by numerous individual lava flows, usually digitate, either fan-shaped or uniformly directed patterns down regional slopes and covering large areas.

**fluctus (pl. flucti)** A planetary physiographic term for a large lava flow field.

**fluted dome (also, "modified dome")** A type of intermediate size-range volcano characterized by steep margins, flat or broadly concave top or small summit crater, and, usually radiating, ridges or scalloped margins.

**intermediate volcano** On Venus, centers of volcanic accumulation between 20 and 100 km in diameter are consid-

ered “intermediate” compared to small shields and cones (which are <20 km) and the more prominent large volcanoes that are generally several hundred kilometers in diameter. This usage was originally defined from the mapping of the northern one-quarter of Venus by the Russian Venera 15/16 radar-mapping mission.

**large volcano** On Venus, centers of volcanic accumulation characterized by radially dispersed lava flows and diameters larger than 100 km, frequently associated with concentric or circular central features and radial fracture patterns and centered on a region of positive topography as indicated either by radial lava flows, by topography inferred from radar characteristics of slopes, or by altimetric radar observations.

**magmatic center** Refers to any center of deformation interpreted to be fundamentally magmatic in origin and in which any eruptive morphologies are subsidiary to larger scale concentrated structural deformation.

**patera (pl., paterae)** A planetary physiographic term for an irregular depression. The term is frequently applied to calderas but, as used on Venus, may include some arachnoids, coronae, and some large volcanoes.

**SAR (synthetic aperture radar)** A type of radar that illuminate a surface with radar energy in directions at right angles to the antenna (spacecraft) motion to build up “images” of the surface.

**shield fields** Localized concentrations of small (less than 20 km), dominantly shield-shaped volcanoes. The individual morphology of each small shield in Magellan data is variable but commonly consists of a low and conical to domelike edifice frequently surmounted by a pit.

**small shield** Small shield volcano; a characteristic morphology of most of the smaller volcanoes on Venus. Sometimes used loosely to refer to any small volcano on Venus, although many small volcanoes include other morphologies, such as steep-sided domes and steep cones.

**small volcano** On Venus, any volcano less than 20 km in diameter. Includes shield, cones, and domes.

**steep-sided dome** A circular, small to intermediate size range volcano on Venus characterized by flat, domical, or distinctly steep margins; broad, flat-topped examples with steep margins are also referred to as “pancake domes.”

**radial fracture center** A magmatic center in which a pattern of fractures radiates from a common center; annular or circular fractures may be present but are subordinate. They are interpreted to be the surface expression of radiating, shallow dikes, possibly analogous to giant radiating dike swarms that are known to occur on Earth.

**tessera (pl., tesserae)** Complexly fractured, and frequently elevated, terrain characterized by a mosaic-like pattern of pervasive orthogonal fractures, ridges, and troughs. Tesserae are identified as the oldest preserved surfaces

on Venus; include most of the large, continent-like elevated areas that constitute ~15% of the surface of Venus; and are frequently embayed or covered by later volcanic plains and individual volcanic centers.

**tholus (pl., tholi)** A planetary physiographic term usually referring to an upper size range of intermediate volcano in which the flanks appear steep relative to most volcanoes on Venus.

## I. DEFINITION AND SIGNIFICANCE OF VENUS VOLCANISM

**I**N TERMS OF the absolute number of volcanoes on its surface, Venus is second only to Earth. It exceeds Earth and Mars combined in terms of the absolute number of well-preserved and pristine volcanic landforms. This abundance of volcanoes is a reflection of the Earth-like size of Venus. The magnitude and longevity of the geologic activity and volcanism on any planet are related to the planetary size and density, unless there are unusual circumstances. (For example, the strong tidal forces that act on Io, a satellite of Jupiter, maintain active volcanism there even though Io is similar in size to the Moon.) Venus is only ~330 km smaller in diameter than Earth and is similar in density. Venus is therefore the most Earth-like of all the planets in terms of its bulk composition and potential chemistry of its magmas. The geological complexity and young surface ages of both Venus and Earth may be attributed to their more dynamic thermal evolution relative to smaller terrestrial planets, their warmer and more mobile interiors, and corresponding surface deformation (tectonism) and copious production of mantle melts (volcanism) over extended periods of geological time.

The style of volcanism on Venus differs from that on Earth, however. This fact was unknown prior to 1983 when the Russian Venera 15/16 radar-mapping mission mapped the northern quarter of Venus and the early nineties when the U.S. Magellan synthetic aperture radar mission mapped Venus globally at even higher resolutions. Early results from planetary mission data showed that the presence and type of global volcanism on most planets are sensitive to the dominant mode in which internal heat is transferred to the surface. Heat transfer and volcanism on Earth are dominated by plate tectonics in which broad convection, upwelling of mantle at spreading ridges, and sinking of cold plates at subduction zones liberates much of the heat from the interior. In the process, volcanism is generated at the

plate boundaries. Other planets appear not to be dominated by plate tectonics, but by a style of volcanism characteristic of the intraplate hot spots on Earth. In this style, referred to as “hot spot tectonics,” heat is released in isolated volcanoes distributed over the surface and by normal conduction through the lithosphere rather than large-scale convection and sinking of cold slabs of lithosphere.

The great size and complexity of volcanic and magmatic centers on Venus provides insights into the processes of large magmatic provinces. They are records of the subtle and little appreciated details of the character, magnitude, and timing of deformation arising from regional scales of magma emplacement and the corresponding details of surface eruptions. It is likely that many of the characteristics of large magmatic provinces on Venus also occur on Earth but are not recognized because of the unanticipated large scale of influences on surrounding terrains and because they are not well preserved or easily identifiable. These may not be available for study on Earth because they are continually erased by erosion almost literally as fast as they form.

Another advantage of studying volcanic phenomena on other planets is that it forces volcanologists to consider a range of processes and mechanism not readily apparent on Earth. This results in further insight into volcanic processes and directions of investigation not otherwise anticipated from studies on Earth alone. For example, radial fractures and/or concentric fractures are typical of almost all magmatic and volcanic centers on Venus. Similar deformation may occur on Earth but is generally poorly preserved or erased during the lifetime of the volcanic activity. Given the curatorial preservation of volcanic landforms in the dry, CO<sub>2</sub> atmosphere and the great abundance of examples, Venus offers an opportunity to better understand the details of surface deformation associated with shallow magma bodies. An excellent example of this is the interpretation that radial fracture centers may represent radial dike swarms. On Earth, the only recognized examples of radial dike swarms are deeply eroded; any connection with surface deformation that they may have had is no longer available for study. Even the suggestion that radial fracture patterns may be dike swarms, by terrestrial volcanology standards prior to the Magellan mission, might have been viewed as folly, particularly given that they extend over thousands of kilometers. Yet the case can be made on the basis of Venus data that, in the absence of erosion, shallowly emplaced dikes may have a significant surface expression and that dikes may propagate horizontally over extreme distances from large and shallow magmatic sources.

### A. Basic Venus Data

Despite the large-scale similarity to Earth, surface conditions on Venus differ greatly from those on Earth. This has potential influences on the eruption styles and morphology of volcanism as well as fundamental geologic processes. If Venus is a volcanological paradise and a tectonic nightmare, it is also an environmental infernal region that belies the harmony, peace, and beauty that the planet’s name implies. The atmospheric surface pressure is nearly 100 times that of Earth (or equivalent to pressures at about 1-km depth in the sea), and surface temperatures are hot enough to melt lead (700 K) and hot enough to potentially increase long-term rates of geological strain in areas of high, mountainous relief. The atmosphere consists mostly of carbon dioxide (~97%), capped with clouds (from 45- to 60-km altitude above the surface) consisting not of water vapor but instead sulfuric acid droplets. These clouds are thick and unbroken and perpetually obscure the surface from Earth or orbital spacecraft observation at optical wavelengths. From the surface one would see not a uniformly blue sky, as on Earth, but a glowing yellowish-white sky. (The Russian scientist Alexander Basilevsky has described being on the surface as probably like “being inside a giant fluorescent light bulb.”) It is believed that these non-Earth-like characteristics are a consequence of a “runaway greenhouse effect,” a condition first recognized from study of Venus and now frequently used to describe potential environmental problems associated with industrial additions to the atmosphere of Earth.

Venus differs from Earth in several other large-scale characteristics. It is the only major planet that does not have a satellite. Its rotation is retrograde, and a single day is  $243.0185 \pm 0.0001$  Earth-days long. Also unlike Earth, if a magnetic field exists, it is below current detection limits. An extremely weak or nonexistent magnetic field may be a consequence of slow rotation on the circulation necessary to excite a magnetic dynamo in the core, or it could result from fundamental differences in the core composition or size.

Although many of these basic facts were known prior to the Magellan mission, little was actually known about the geological characteristics of the surface or the presence, number, or morphology of its volcanoes. Despite its proximity and overall similarity in dimension to Earth, Venus was the last planet in the inner solar system to be explored geologically. Not only did the dense, opaque atmosphere, extreme pressures, and high surface temperature prevent observation of the surface from a distance, but the extreme surface environment rendered it technologically challenging to design surface landers

that could survive long enough to take meaningful measurements with surface instruments. Assessment of the geologic details of volcanism on Venus required the development of Earth-based radar-observing techniques and, later, synthetic aperture radar (SAR) technology on orbiting spacecraft. The latter had to await the funding, construction, transport, and multiyear operation in Venus orbit of a modern spacecraft with radar-imaging capabilities. Ironically, with radar, the surface of Venus is now more completely and uniformly mapped, and at higher resolution, than the seafloor of Earth.

Prior to the availability of high-resolution radar surface images, several lines of evidence suggested that volcanoes might be common on Venus. First, because of the size similarity between Venus and Earth and the overall similarity to Earth in density characteristics and position in the solar system, similar elemental abundances and internal heat sources seemed likely. This implied that the two planets were likely to have had an essentially similar thermal history involving long-lived interior melting, magma production, and surface volcanism. Second, Earth-based radar images of the surface of Venus, and later global altimetric maps, indicated that numerous circular features and symmetric mountains were associated with large-scale valleys bearing tectonic riftlike characteristics of length, width, depth, and distribution. Third, telescopic observation with spectroscopic methods in the late seventies had shown an anomalous short-time scale global change in the sulfur content and related compositions of the atmosphere. The most likely interpretation was that a large volcanic eruption had injected volcanic dust and sulfur-rich gases into the upper atmosphere, as frequently happens with large explosive eruptions on Earth (e.g., the Mount Pinatubo eruption in the Philippines, 1991). Another possibly transient and localized variation in atmospheric composition was detected by one of the atmospheric entry probes of the Pioneer Venus mission in the late seventies and interpreted as being potentially the result of a similar large eruption. Both events require extremely energetic eruptions, which are relatively rare on Earth, but must be particularly rare on Venus given that the high atmospheric pressure is likely to greatly suppress explosive volcanism for all but the most volatile-enriched cases. These early observations of atmosphere-related changes associated with eruptions suggested that not only was currently active volcanism possible, but that the physical products of volcanism were likely to be common on the surface of Venus as well.

Observations from the Magellan radar-mapping mission show that volcanism on Venus is morphologically diverse and appears to represent a wide range of scales

and potential rates of magmatic, tectonic, and mantle convective processes. The great range in scales of volcanic centers and associated lava flows on Venus implies that central volcanism and volcanic effusion on Venus are associated with a large range of volume scales of magma transport, storage, and emplacement in the lithosphere. These may be evidence for variable scales of associated mantle convection and melting processes.

## B. Previous Observation and Knowledge

In the following we set forth some of the basic observations on which our current understanding of Venus is based. This discussion is not intended to be an exhaustive review, for which there are several volumes listed in the bibliography.

Prior to the first spacecraft fly-bys, passive observations of the thermal microwave emission from Venus using radio telescopes suggested that the surface temperatures were in excess of several hundred kelvin. Later U.S. (including Mariner 2, in 1962, the first interplanetary mission) and Soviet fly-bys, atmospheric entry probes, Soviet Venera and Vega landers, and Vega balloon mission observations confirmed these conditions. However, very little was known about the actual regional surface characteristics of Venus, including the presence or morphology of volcanic centers. Almost nothing was known about the geologic characteristics prior to the early development of interplanetary spacecraft and modern Earth-based radar observations, chiefly from the Goldstone and Arecibo radio telescopes. Radar technology and spacecraft technology paced each other in resolution, with alternately Earth-based and spacecraft-based observations bearing the highest resolution information.

The first global view was obtained at relatively low resolutions (on the order of 100 km) during the Pioneer Venus mission beginning in 1978. The Pioneer Venus mission obtained a global map of altimetry and global thermal emissivity characteristics at low resolution. The Soviet interplanetary space program repeatedly placed landers on Venus (Venera 8, 9, 10, 13, and 14 and Vegas 1 and 2). The missions were able to characterize the surface at lander scales with optical images and chemical analyses, proving that at least those areas observed by landers are fundamentally basaltic surfaces. They also directly measured and confirmed the previous estimates of high surface temperature (700 K), high atmospheric pressures (9 MPa, or 90 atm), and a water-free, dominantly carbon dioxide atmosphere. Optical images taken by the Venera landers are unrevealing as regards the

origin of the surface materials. Generally, they showed moderately flat terrain characterized by local soil patches between flat “outcrops” of dark, more consolidated material. The chemical compositions of most of the surface materials are similar tholeiites. One site (Venera 8) suggested the possibility of more evolved, alkali-rich (e.g., trachytic) compositions. Another site (Venera 13) measured compositions essentially similar to alkali basalts. In contrast, Vega 1 identified a much more mafic composition comparable to gabbroic materials and Vega 2 measured a sulfur-enriched surface composition.

Synthetic aperture radar (SAR) images from the Russian Venera 15/16 spacecraft of the northern 25% of the surface of Venus initially demonstrated the morphologic diversity of volcanic centers on Venus, including large volcanoes characterized by patterns of flows radiating for tens to hundreds of kilometers, circular structural patterns up to several hundred kilometers across with associated volcanism (coronae), patterns of lava flow fields, extensive low-lying regions of lava plains, and low-relief domical edifices, many less than several kilometers in diameter that are interpreted to represent globally abundant small shield volcanoes. The division of volcanic centers into “large” ( $>100$  km), “intermediate” (20–100 km), and “small” ( $<20$  km) was based on the Venera 15/16 results and is still in use.

SAR images, radar altimetry, and radiometry data from the Magellan spacecraft were acquired beginning in late 1990 and continued through several global mapping cycles through late 1992. During each cycle Venus rotated once beneath the orbital plane of the spacecraft every 243 days. The spacecraft was in a near-polar orbit, allowing it to image the surface in near-longitudinal strips. Image data were acquired at resolutions of 300 m. For Magellan, each strip was 20 km wide and 17,000 km long. The results of many orbital passes were mosaicked to form broader images, ultimately covering 97% of the surface. Most of the imaged areas are now available on CD-ROM as F-MAPs, that is, full-resolution image mosaics of broad areas of the surface in which the stripes are rarely visible because they have been digitally processed and blended. For a general account of this mission, its results, and our current knowledge about Venus, the reader should refer to the reference works by Bougner *et al.* (1997), Cattermole (1994), Cooper (1993), and the special Magellan issue of the *Journal of Geophysical Research* listed in the bibliography.

In interpreting Magellan images, it is important to note that, because these are not optical images, they have some unique characteristics. SAR is a type of radar that illuminates a surface with radar energy in directions at right angles to the antenna (spacecraft) motion to build up “images” of the surface.

Magellan also acquired altimetric data. These may either be viewed as separate profile tracks across features of interest or combined spatially in map view as color-coded, contoured, or shaded relief maps. There are additional data products, including maps of radar emissivity, radar reflectivity, and radar roughness, but the products described above are the primary ones that are likely to be encountered most frequently.

## II. VOLCANIC LANDFORMS

Initial surveys and analysis of Venera 15/16 and Magellan data identified numerous morphologically varied volcanic centers and edifices from small shields less than 1 km in diameter to volcanic edifices greater than 1000 km in diameter and widespread plains-type volcanism with associated lava flows from those less than several kilometers long to vast flow fields, lava floods, and lava channels in excess of 1000 km long. The great abundance of youthful volcanic features and the observed relatively low global crater abundance over the surface imply that global rates of resurfacing due to volcanism on Venus over late solar system history have been high relative to the smaller terrestrial planets.

Several specific types of volcanic center identified from Magellan data include (1) effusive edifices such as small shield volcanoes, low to steep-sided intermediate volcanoes of differing morphology similar to, but much larger than, terrestrial volcanic domes, and large volcanic edifices of low relief and complex structure; (2) centers identified by structural characteristics and relatively minor effusive characteristics; and (3) negative topographic expressions such as calderas and complex topographic annular features such as coronae and arachnoids. Many of these structurally defined annular features are generally thought to represent local formation of large and deep magma reservoirs or diapiric upwellings and evidence for shallow to deep, dikelike magma intrusions such as stellate fracture patterns. The structural and volcanic characteristics of coronae, and related features such as arachnoids, are consistent with origins related to hot spots or underlying mantle plumes, although nothing similar is preserved on Earth.

### A. Distribution of Volcanic Centers

We have identified and cataloged 1738 volcanic centers, magmatic centers, coronae, and related features (Table I) larger than 20 km (as well as significant lava flow

TABLE I. Classification, Location, Dimensions, and Existing Names of All Volcanic Centers on Venus Larger Than 20 km in Diameter

Latitude (deg)	Longitude (deg)	Diameter (km)	Name	Latitude (deg)	Longitude (deg)	Diameter (km)	Name
<b>Large volcanoes</b>

*Notes:* This is an abridged version of the complete catalog which also includes detailed comments for most of the features listed, reference MVC number, and other information about relevant CI-MIDRs and F-MIDRs.

*Feature terminology.* The feature designations used here are informal. Some terms imply a geologic origin and other terms are nongenetic. The level of geological detail available from Magellan image data are such that many of the centers may be assigned with reasonable certainty to a broad class of relatively well-known geologic phenomena, such as volcanoes or calderas, and the need for generally nongenetic terminology is diminished.

Several nongenetic terms for many large-scale features originated during the analysis of Venera 15/16 image data because the resolution was such that the geologic origin of many large-scale structures, such as coronae or arachnoids, was indeterminate. Similar informal terms were used early in the Magellan mission for many types of newly identified morphological features. An attempt was made with some preliminary terms used by the Magellan

---

team to use Latin derivative terms, as was done successfully with tesserae earlier. Informal usage of Latin in addition to informal and colloquial terms in general impeded this approach and resulted in errors. These and other problems are of the type that are sorted out with usage, but should be noted and avoided. Currently the term "corona" seems to be accepted, "arachnoid" is not favored but may have been in use long enough to continue. We find that "arachnoids" are distinguishable as a class of feature in the broad category under corona. Simple terms that readily characterize a feature are most convenient, and as a rule non-whimsical terms are more appropriate.

For reasons having to do with the direction of detailed research following Magellan, several lists of specific types of volcanic centers were generated by different investigators. Some of these lists include centers smaller than 20 km. Some of these list were focused on a particular type, they are more inclusive, and contain features that we have assigned, on the basis of examining all magmatic centers, to other categories.

1. *MVC number.* Many features are not formally named; we have assigned a Magellan Volcanic Feature Catalog number to each feature to assist in identification. The MVC number is an abbreviated description of the latitude, longitude, and volcanic feature type for each entry.

2. *Locations/catalog accuracy.* The data in this catalog were compiled initially by L. Crumpler and J. Aubele, jointly verifying each identification, classification, and numerical entry and acting as a check of the other's observations. In addition to providing a continual check of individual accuracy, the initial tandem survey controlled excessive "drifts" in identification and interpretation criteria that often occur in efforts of this type requiring observations over an extended period by a single individual. The Magellan Volcanic Feature Catalog is assembled with extreme attention to consistency.

Each feature location and classification was subsequently checked and corrected by three people and every effort was thus made during compilation to check and recheck the accuracy of identifications, locations, dimensions, and tabulation. As with any carefully assembled, large geophysical data set of this size and complexity, a certain low percentage (generally  $\leq 5\%$ ) of transcription and related "mechanical" errors may occur [for example, see discussion of Pacific intraplate seismicity map in Lay (1991) *EOS*, **72**, 468, or Wysession et al., (1991)]. Users might be alert for the few obvious errors. Errors identified and corrected during the subsequent review process included latitudinal errors resulting from inversion of north or south (e.g.,  $15^\circ$  instead of  $-15^\circ$ ), corresponding misinterpolation from latitudinal scale label points (e.g.,  $-20^\circ$  misread as  $20^\circ$  and a feature  $2^\circ$  north of that identified as being at  $22^\circ$  instead of  $-18^\circ$ ), multiplicative longitudinal shifts (e.g.,  $290^\circ$  instead of  $190^\circ$ , or  $180^\circ$  instead of  $190^\circ$ ), incorrect MVC numbers, and typographical errors in feature descriptions. Remaining instances of these types of errors should be few, but these examples are offered as keys for recovering the data from the most likely occurrences of listing errors.

3. *Diameter.* Most features are roughly equant in plan shape, but the minimum and maximum dimensions for elongate features are included where appropriate. Dimensions listed for lava channels and flow fields are lengths. The diameters of large volcanoes are measured to the distal edges of the radial lava flows of median length. Diameters of coronae and arachnoids represent the mean diameter of the most prominent concentric ring. The diameter of radial fracture centers or stellate patterns is the diameter defined by using the median fracture length; fractures that are continuations of longer rift or fracture belt trends were not considered in arriving at the value for the median length.

4. *Feature names and feature type classification.* Names assigned to individual features included in the catalog are those approved by the International Astronomical Union. Great effort has been taken to correlate these names with our list as of the time of this writing. In some cases the coordinates listed in the IAU list for a feature may differ from those judged from Magellan data as representing the center of a particular volcanic feature. The IAU names have been assigned in many cases to terrain features apparent in pre-Magellan data sets and do not always correspond to geologic features visible in the Magellan data. IAU names for which no corresponding volcanic feature is identified have not been included. Where the coordinates of our list and the IAU list differ significantly, the corresponding feature name is listed with a query ("?") symbol. Official IAU physiographic terms such as *farrum* and *fluctus* frequently refer to a variety of volcanologically defined features. Many volcanologically defined features have locations close to the IAU feature location, so it is difficult to determine which feature has been named on the basis of coordinates alone. Names and formal terms within the IAU list are constantly evolving and new names have been added subsequent to compilation of the list. Many IAU feature names have been redefined (*mons* to *tholus*, *corona* to *patera*, etc.) with further study subsequent to initial inclusion in this list. Identification of feature types is here based largely on volcanic criteria and infrequently corresponds to a single IAU physiographic term. For example, "*patera*" often includes arachnoids, calderas, and large volcanoes. Similarly, some IAU physiographically defined "*coronae*" are the same as our calderas or even radial fracture centers. A prominent example of this problem is MVC 19/80LV, which is named Kunlid Corona, yet it is a large volcano with a 100-km summit caldera. And many names submitted as a result of this catalog and included tentatively have not been used in IAU nomenclature decisions. The interested student is encouraged to refer to the most recent IAU nomenclature list if there is any question.

Several lists that identified just one individual type of volcanic feature have been generated and these have often been used in constructing IAU lists. Also, due to variations in assumed defining characteristics and differences in interpretation, many individual features may have been assigned to different feature types in other surveys of individual feature types. For example, some lists are concerned with identification of corona give precedence to structural characteristics, whereas in this listing the presence or absence of distinct radial lava flows is used to first identify whether a volcanic center is present. Our list is based on complete examination of all volcanic centers and was thus able to assign individual features to different categories on the basis of a broad overview of the characteristics of all types. Thus each category in this list tends to be more exclusionary than many lists of individual feature types. Because it includes all categories, this catalog represents a balanced identification of all volcanic centers based on fixed and well-thought-out criteria.

5. *Comments.* Comments have been kept to the minimum necessary in order to note any salient characteristics or to describe relationships with other features.

*Abbreviations.* The following abbreviations are used throughout the catalog: MVC = Magellan Volcano Catalog; AR = Arachnoid; IV/SSD = Steep-Sided Dome ("pancake"); CO = Corona; LC = Lava Channel; FF = Festoon Flow (unusual flows); LF = Lava Flow, Lava Field; IV = Intermediate Volcano; LV = Large Volcano; IV/FD = Fluted Dome (or modified dome); RFC = Radial Fracture Center; IV/RP = Radially Patterned volcano; SF = small Shield volcano Field

---

fields and channels) on Venus. Spatial concentrations as well as morphologic groupings are common. The latter include four broad morphologic categories: volcanoes, volcanic fields, magmatic centers (intrusive), and lava fields and plains. Beta-Atla-Themis Regiones, an area of nearly hemispheric concentration of volcanic and magmatic centers several times the global average number density, is a region dominated by relatively higher surface elevation and numerous riftlike patterns of fractures and deep linear chasmata (Fig. 1, see also color insert). Several large volcanic rises consisting of exceptionally large volcanic complexes and many smaller concentrations of volcanic centers appear to be associated with large rifts, rift intersections, and complex global-scale patterns of extension. Because features believed to be representative of mantle upwelling, such as coronae, are common in these clusters, large concentrations of volcanic centers and rifts like these might represent global mantle anomalies resulting from patterns of convection and regional mantle upwelling. In all of these associations, linear arrangements of volcanic centers are not common. The overall distribution of volcanic centers and coronae on Venus is thus more analogous to the distribution of hot spots related to mantle plumes on Earth than volcanism associated with plate boundaries.

*Note on the Magellan Volcano Catalog.* The following section defines and describes the principal identified volcanic features on Venus and shows some examples of each of the basic types. The text reviews some of their associations, interpreted origins, and remaining questions about their characteristics and origins.

The level of geological details available from Magellan image data is such that many of the centers may be assigned with reasonable certainty to a broad class of relatively well-known geologic phenomena, such as volcanoes or calderas, and the need for generally nongenetic terminology is reduced. Detailed division of feature types is generally more nongenetic. Several nongenetic terms for many large-scale features originated during the analysis of Venera 15/16 image data because the resolution was such that the geologic origin of many large-scale structures, such as coronae or arachnoids, was indeterminate. Similar informal terms were used early in the Magellan mission for many types of newly identified morphological features. An attempt was made with some preliminary terms used by the Magellan team to use Latin derivative terms, as was done successfully with tesserae earlier. Informal usage of Latin in addition to informal and colloquial terms in general impeded this approach and resulted in errors. These

and other problems are of the type that are sorted out with usage, but should be noted and avoided. Currently, the term "corona" seems to be accepted; "arachnoid" is not favored by many researchers but may have been in use long enough to continue. We find that "arachnoids" are distinguishable as a subclass of corona.

For reasons having to do with the direction of detailed research following the completion of the Magellan mission, several lists of specific types of volcanic centers were generated by different investigators (Table II). Some of these lists include centers smaller than 20 km. Others are focused on a particular type, are more inclusive, and contain features that we have assigned, on the basis of examining all volcanic and magmatic centers, to other categories. Many of the thematic papers listed in the bibliography contain additional listings of volcanic features. For these and other reasons discussed below, the reader is referred to these lists for alternative interpretations and dimensional measurements.

## B. Volcanoes

The following landforms are classed as volcanoes and are defined as centers of activity dominantly characterized by patterns of radial or circular extruded material extending over 360° from the central vent. This is to distinguish them from the broad class of features referred to as "magmatic centers" in which structural characters are the sole or dominant expression of the center of activity and to distinguish them from areas of extensive volcanism, principally lava flow fields, in which the volcanic materials do not constitute a well-defined edifice.

### 1. Large Volcanoes

These are volcanic centers (diameters  $\geq 100$  km) characterized by radially dispersed lava flows, frequently associated with concentric or circular central features and radial fracture patterns and centered on a region of positive topography as indicated either by radial lava flows, by topography inferred from radar characteristics of slopes, or by altimetric radar observations. The lateral dimensions are measured to the average distal end of the associated digitate lava flows that compose the circular part of the edifice; unusual flow fields that run out from a central volcano over great distances in one direction are not specifically included in the dimensional estimate given in Table I. Although large in lateral dimension, most large volcanoes on Venus are actually relatively low in relief, averaging approximately 1.5 km high. Although volcanoes of equivalent diameter occur on Mars, the volumes of large volcanoes on Venus are actually much less because their relief is an order of magnitude lower. Very large volcanoes (exceeding several thousand kilometers in diameter) may be further referred to as "volcanic rises" to allow for the possibility that some or much of the observed topography may be nonconstructional (uplift, "swell," etc.).

A total of 168 large volcanoes have been identified and occur preferentially in intermediate to higher elevations, particularly in broad rises and at the junctions of extensive rifts, chasmata, and belts of fractures. They are morphologically diverse, implying variable levels of volcanological complexity and evolution. Because the radial pattern of lava flows is diagnostic of a volcanic center, in our classification the presence of radially dispersed lava flows is accorded priority over concentric structures. For this reason, some features identified by other researchers as coronae, including those in discussions of Venera 15/16 results, are here considered large volcanoes.

Several fundamental morphological types of large volcano have been identified based on caldera sizes, associated fracture patterns, subsidiary intermediate and small volcanoes on their summits and flanks, and relationships with other identified types of magmatic features. The simplest examples are characterized by a relatively simple radial array of lava flows. An example is Chloris Mons (Fig. 2). Chloris Mons illustrates several of the characteristics typical of the less complex volcanoes. The distal ends of the flows are commonly radar bright and are interpreted to be relatively rough and blockier. Scattered about the summit are small volcanoes, many with steep-sided morphology and central pits, yielding an overall morphology analogous to many terrestrial shield volcanoes such as Etna or Mauna Kea in which subsidiary cones are built around the summits. The summit region is relatively radar dark compared with the lower flanks and topographic summit. Origin of the darker terrains around the summit is unknown; potential causes include lower radar reflectivity due to ash, unusually smoother lava flows, or altitude-dependent chemical phases. The circular shape of the dark area together with faint concentric bands that may be underlying fractures

suggests that the dark region may lie within a former caldera-like summit depression, in which case the dark characteristic reflects the accumulation of relatively radar-absorbent dust and ash in low-lying and flat regions near the summit. Superimposed and buried within the pattern of flows and domes are arcuate and radial fractures, suggesting that the volcanic center is in some way associated with radial deformation, either being responsible for the pattern or located on it by virtue of the intersection of preexisting fractures. The occurrence of volcanic centers at loci of global and regional patterns of fractures and rifts is a common characteristic of magmatic centers on Venus.

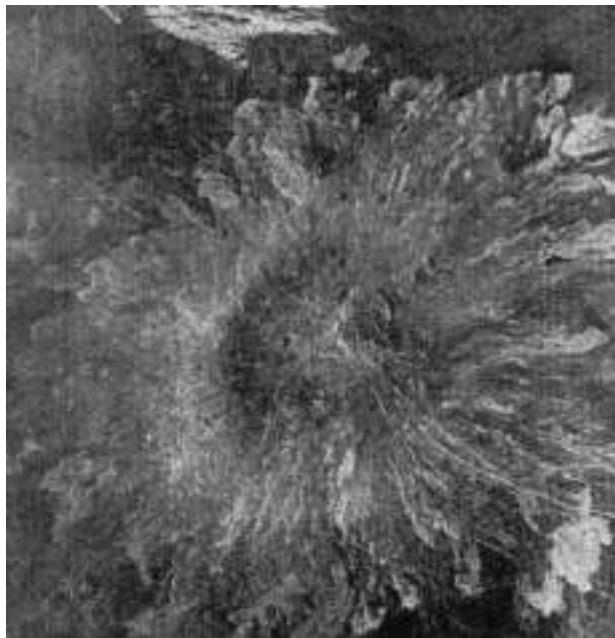

Other large volcanoes may be characterized by complex summit landforms, including strong radial fracture patterns, annular structures similar to coronae, and even multiple and large domical summits. Although the nature of domical volcanoes on Venus is not clear (see discussion of steep-sided intermediate volcanoes below) the presence of such features on the summits of many large volcanoes may be viewed as representing secular evolution of the eruptions during the history of the individual large volcano analogous to late-stage silicic volcanism or late-stage, volatile-rich, pyroclastic-dominated activity in evolved terrestrial volcanoes. Together these characteristics hint at the presence of underlying reservoirs that undergo some type of evolution with time.

## 2. *Intermediate Volcanoes*

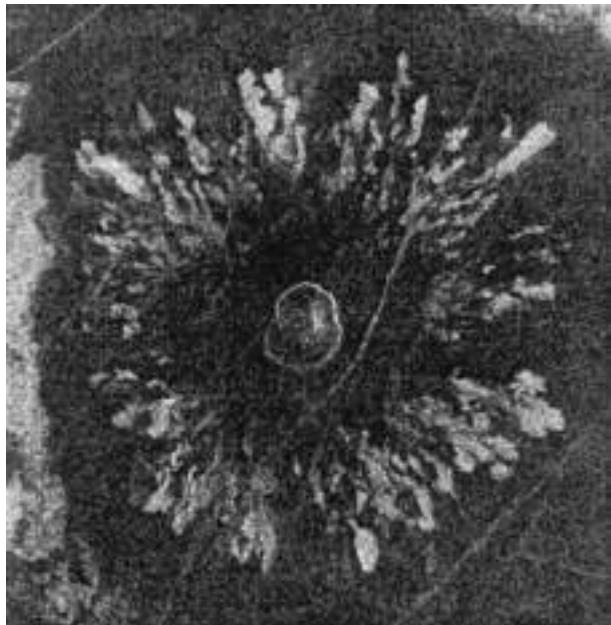

Volcanic centers between 20 and 100 km in diameter are considered “intermediate” between the diameter of small volcanoes and the more prominent large volcanoes that are generally several hundred kilometers in diameter. The term was originally defined from Venera 15/16 radar data.

Several informally named morphologic types of intermediate volcanoes have been identified and include “radially patterned volcanoes,” “steep-sided domes,” “scalloped domes,” “modified domes,” or “fluted domes.” A total of 289 intermediate volcanoes are recognized. Intermediate volcanoes are notably concentrated in the Beta–Atla–Themis areas. Fluted domes and steep-sided domes frequently occur together and also occur in association with coronae. Otherwise undistinguished volcanoes in this size range are listed here simply as “intermediate volcanoes” and are analogous to simple large simple large shield volcanoes.

“Radially patterned volcanoes” (Fig. 3) are characterized by multiple radial digitate lava flows of strikingly uniform length. The radial lava flows are typically radar

**FIGURE 2** Chloris Mons, 300-km-diameter large volcano with numerous digitate bright and dark lava flows, radiating fractures, and several small volcanoes with steep-sided dome morphology near the summit. Like most large volcanoes on Venus, Chloris Mons is a shield volcano. The origin of the concentric bright and dark areas near the summit is unknown. Radar illumination is from the left in both images.

**FIGURE 3** A simple intermediate volcano (MVC-9.5/201 IV/RF, courtesy of NASA) 20 km in diameter with radial bright and dark lava flows and a summit caldera. Radar illumination is from the left.

bright at their termini, suggesting increased roughness and blockiness at the distal ends. Also similar to large volcanoes, the summits are frequently relatively dark either as a result of the smoothness of near-vent lava surfaces or due to some radar-dark mantle, such as ash.

“Steep-sided domes” are among the more interesting and enigmatic intermediate volcanoes on Venus. They are also morphologically diverse, including domes that are relatively convex (Fig. 4), domes that are relatively flat on their summits and bounded by steep flanks, or domes that are “pancake-like,” broad and flat, very circular, and steep along their perimeter. Others are simple inverted-bowl shapes or shield-shaped edifices. They frequently occur in clusters, or appear to be overlapping. In detail, many steep-sided domes on Venus have small summit pits and complexly patterned fractures on their surfaces. The circular form typical of steep-sided volcanoes appears to be the result of radial growth of a single extrusive mass, analogous to silicic domes on Earth. However, in size (typically 20–40 km and up to 80 km) and in terms of their remarkable circularity, they are unlike the relatively small domes associated with silicic volcanism on Earth.

Several origins have been proposed for steep-sided domes. One possibility is that the domes represent evolved magmas. A flat, pancake-like dome occurs near the Venera 8 landing site, where the surface materials

were found to have anomalously high K, U, and Th typical of more alkalic rock compositions such as trachyte. Some steep-sided domes are associated with coronae, particularly along their characteristic ring fractures, implying an origin possibly related to petrologic evolution of large magma bodies responsible for coronae. Others occur on complexly fractured and elevated regions of tessera, suggesting melting or incorporation of preexisting thick crustal rocks into shallow reservoirs and subsequent evolution of more evolved compositions. Another model suggests that the magmas need not be silicic but could be intermediate or even basaltic due to unusual properties of viscosity resulting from excessively high volatile concentration. In the extreme pressures of the atmosphere of Venus, sufficient volatiles could result in a bubble-rich froth but disruption and bursting of bubbles typical of pyroclastic eruptions and ash flows may be impeded. Bubble-rich silicate “foams” occur in isolated instances in lava flows on Earth under certain conditions although not in the cubic kilometers required for formation of the typical steep-sided dome observed on Venus. Large-volume ash-flow eruptions on Earth may be an analogy in terms of volume. The result on

**FIGURE 4** A typical steep-sided dome with a convex profile. The particular example (MVC-26/80 IV/SSD, courtesy of NASA) is 40 km in diameter. It is located on a set of annular fractures defining the margins of a corona. The common occurrence of steep-sided domes in association with coronae is further evidence for the presence of shallow magma reservoirs in association with coronae. Radar illumination is from the left.

Venus might be a bubble-charged fluid or voluminous foam. Regardless of the mechanism, the widespread occurrence of steep-sided domes over a large range of scales implies that it is a common process on Venus.

Whereas many steep-sided domes are circular, some have apparently collapsed partially, resulting in a distinctly modified appearance in which deep scallops mar the flanks. In some, the collapsed material has flowed out to form a knobby terrain at the foot of the collapsed flank. Given that the steepest part of the flanks of many steep-sided domes approaches 30°, collapse of the margins in some is understandable. The origin of such gravitational instabilities may not be entirely spontaneous. There are several examples of steep-sided domes that predate nearby impact craters, yet their flanks are relatively undisturbed. The timing of the collapses with respect to the emplacement of the domes cannot be determined, so it is possible that such instabilities are part of the emplacement process rather than a degradation of older domes.

Another common morphology of steep-sided domical edifices on Venus is “fluted domes,” characterized by relatively flat upper surfaces, frequently with a central depression or pit, and relatively steep margins with radial buttress-like ridges or flutes. There are tremendous variations in this basic theme: some examples are similar to many steep-sided domes with the exception of their unusually ridged margins (Fig. 5), and others have odd morphologies with deep central depressions, high-standing margins, and regularly arrayed radial ridges.

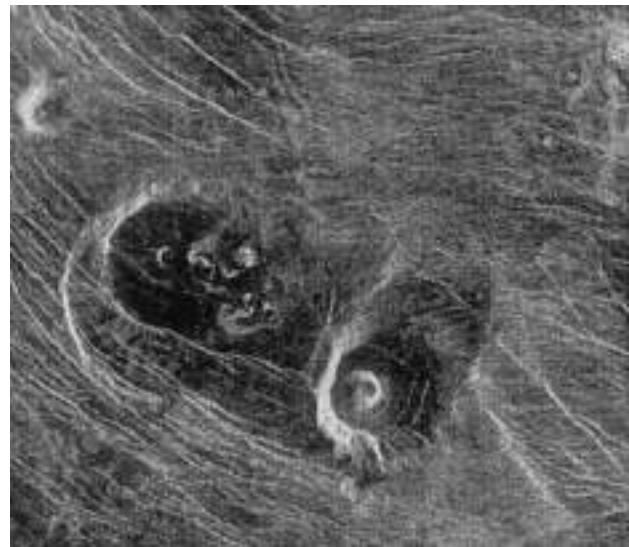

Considering the similarity of some fluted domes with modified steep-sided domes, one possible interpretation of fluted domes is that they are steep-sided domes in which the outer flanks have collapsed around the entire perimeter, leaving behind distinctly scalloped heads of collapse areas cradled between high-standing chutes. This interpretation is consistent with the “bubble foam” model of steep-sided dome formation in that an edifice built from such materials may be structurally weak. The similarity to some “starfish” seamounts bearing radiating ridgelike rift zones has also been noted. Although they are morphologically similar to some terrestrial tuff rings, their extremely large dimensions (up to 60 km) and close association and morphological similarity with steep-sided domes suggest nonexplosive origins.

### **3. Small Volcanoes and Fields of Small Shield Volcanoes (Colles)**

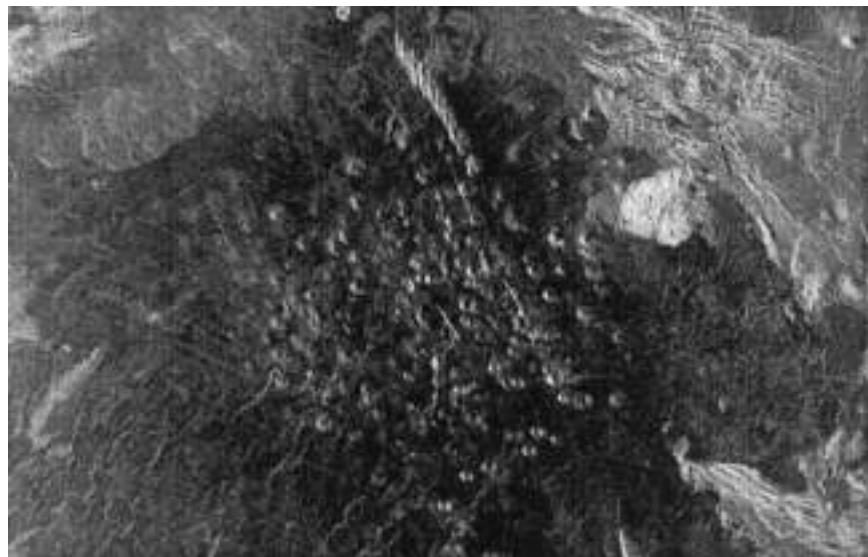

Small (<20-km diameter) volcanoes are the most abundant volcanoes on Venus and number in the hundreds of thousands, if not millions. Their abundance is so great

that they defy identification and tabulation individually. Small volcanoes exhibit almost all of the same characteristics seen in intermediate and large volcanoes, including steep-sided domes, modified and scalloped domes, radial-patterned volcanoes, and, the most abundant morphology, simple low shield volcanoes. Their closest terrestrial analogy in terms of abundance is the small volcanoes that occur on the seafloor of Earth. On Venus, they occur in plains as well as on the flanks of large volcanoes, in rift settings, and within corona and are abundant in the two large regions near Beta Regio and east of Tellus Regio in the Akkruba Colles region.

The most salient characteristic of small volcanoes is their tendency to cluster in fields (Fig. 6). Localized concentrations of small, shield-shaped volcanoes are considered to be “fields” in the sense used in terrestrial volcanology. There are 647 identified fields of small volcanoes, or “shield fields,” each consisting of several tens to several hundreds of vents and ranging from several tens to several hundreds of kilometers in diameter, measured across the areal extent of the fields. As with terrestrial volcanic fields, shield fields clearly represent a concentration of numerous small volcanic vents over a localized source supplying magmas at rates insufficient to build a single edifice. The common occurrence of shield fields within the interior of many coronae and

**FIGURE 5** MVC-13.5/252 FD (on right) is a 25-km-diameter fluted dome. A deep central crater on the summit has an inverted conical profile. The morphology of the other domes in this image is transitional between typical steep-sided domes and fluted domes. Pancake-like steep-sided dome at left (MVC-13.5/251.5 SSD, courtesy of NASA) is 35 km in diameter. Radar illumination is from the left.

**FIGURE 6** A typical small volcano field or “shield field” (MVC-52/302.5 SF, 150 km in diameter, courtesy of NASA) with associated radar dark lava flows that inundate the surrounding plains. Some of the small volcanoes are steep-sided domes, whereas others are shield shaped. Individual volcanoes are several kilometers across. Radar illumination is from the left.

arachnoids is consistent with the interpretation that such large-scale annular structures (see discussion later below) represent relatively localized mantle melting or shallow bodies of magma. It is useful to speculate that annular deformation patterns may characterize fields and large volcanic provinces on Earth but are not as a rule recognized because of the dimensions (several hundred kilometers) and continual erosion that acts to erase any such subtle structural characteristic nearly as fast as it is generated.

In addition to their occurrence as discrete fields, many small shield volcanoes occur with nearly uniform spacing over vast areas, resulting in what are known as “shield plains.” There is no terrestrial precedent that may be used as an analog in understanding the origin and emplacement of shield plains except perhaps oceanic seamounts. When examined in detail, shield plains on Venus are found to be among the oldest plains preserved, stratigraphically overlaying (younger than) tessera. Thus they appear to represent small volcano production that occurred over broad regions early in the preserved history of Venus. There is no evidence for structural control on the location or alignment of small volcanoes within shield plains. This implies that their emplacement was remarkably isotropic for a process that was widespread and dependent on lithosphere properties for access to the surface. Considering the abundant evidence for structural control of vent locations in most volcanoes on Venus together with their great age, the emplace-

ment and significance of shield plains are among the more intriguing volcanologic mysteries on Venus.

#### 4. Calderas (*Often, Patera*)

A typical caldera is circular to elongate in shape, surrounded by an annulus of closely spaced fractures along the topographic rim, a floor from 1 to 3 km below the surrounding terrain, and evidence for associated surface volcanism (Fig. 7). Calderas frequently develop at the site of extensive prior eruptions. They are characterized mainly by concentric patterns of enveloping fractures and other geologic characteristics indicative of a depression formed through collapse of the surface. A total of 97 calderas are identified and are most abundant in the size range 60–80 km, with depths up to several kilometers. In many cases the floor is dark and appears to be flooded or partially covered with later flows. Some calderas are the loci of intensely fractured concentric patterns bearing very little evidence of subsequent surface eruptions. This suggests that most of the room for collapse may have been accommodated by lateral intrusions along the typically strong regional patterns of riftlike fractures.

Radial flows may be distinguished in some cases, some of which appear truncated by the central depression. Such examples are identified as calderas in our listing instead of volcanoes in deference to the greater morphologic expression of the collapse feature over any con-

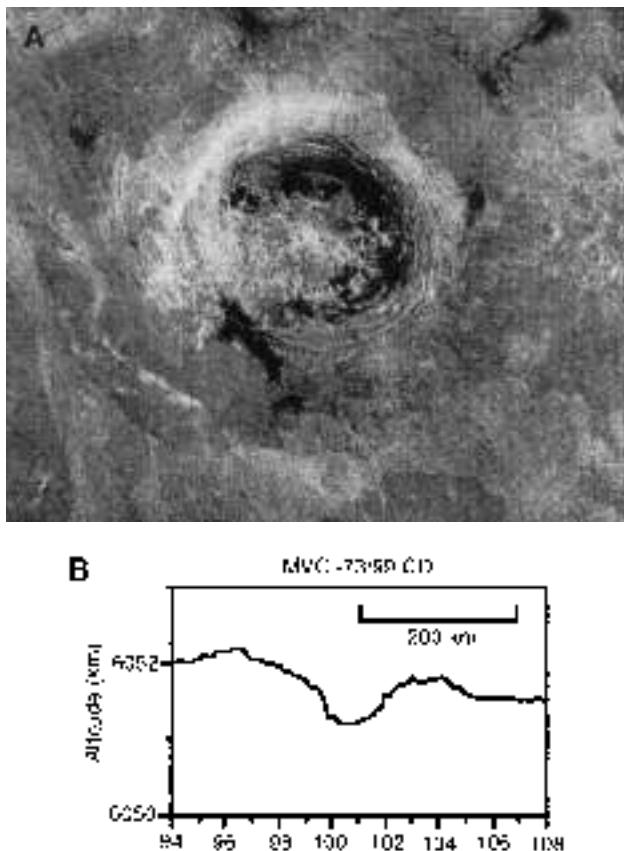

FIGURE 7 (A) A circular caldera (MVC-73/99 CD, 175 km in diameter, courtesy of NASA) encircled with numerous ring fractures. Radar illumination is from the right. A complex array of small volcanoes and radar-bright lava flows contrasts sharply with the radar-dark floor. Note that surrounding plains lavas have partially inundated the ring fractures, suggesting that a slight raised rim occurs where the fractures are preserved. (B) Magellan radar altimetry profile indicates that the floor lies 1 km below the surrounding terrain. This caldera has been identified as a corona (Mykh-Iml Corona) in some other studies, illustrating the confusion in terminology and IAU naming. Shield fields occur to the east (MVC-73/104 SF) and north (MVC-71.5/99 SF).

structural feature. It is useful to note that “caldera” is more interpretive than are the terms “arachnoid” and “corona,” which are similar in some respects, including their dimension and some structural characteristics. The use of the term caldera for a volcanic feature on Venus implies that the feature so-named is comparable in apparent geologic mechanism of formation to calderas as defined on Earth and on the other solid terrestrial planets. Calderas on Venus are defined, as they are on Earth, as a large volcanic collapse depression that is circular, or approximately circular, in plan shape, the diameter

of which is many times greater than any included vents. There are only a few features recognized as calderas above 100 km in diameter, and the sudden onset of features identified as arachnoids and coronae above that diameter suggests that calderas, arachnoids, and coronae may be related. Annular deformation processes associated with the underlying magma body may be associated with the caldera formation process (or its volcano-tectonic equivalent) at its extreme upper scale. In addition to annular patterns of strain, regional strain patterns associated with emplacement of radiating dike-like bodies could be a component of the overall structure.

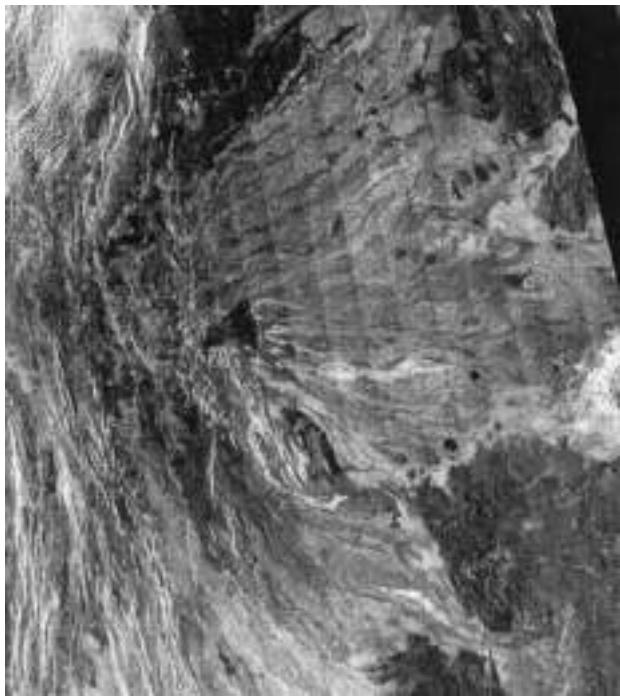

### C. Lava Flows and Channels

#### 1. Plains Lavas

Most of the surface of Venus consists of relatively low elevation, flat, and featureless plains. They are generally radar dark as a result of their smoothness. From the way these plains embay structures and surround local relief features, it is clear that most of the surface is a result of extensive flooding with widespread lava flows. In most of the images reproduced here, the darker areas are examples of these types of flooded surfaces. Many of these were emplaced at or near the same time, early in the observable geologic record of Venus. The hypothesis that Venus was globally and nearly completely resurfaced during a short geologic time interval arises from the pervasiveness and similarity in stratigraphic position of many of these plains (in addition to the low number of recognized impact craters on the plains).

#### 2. Lava Flow Fields (*Fluctii*)

These are distinguished from the lava plains described above by numerous digitate flows notable for their great lengths ( $10^2$ – $10^3$  km long) and unusually large area. Many of these consist of flows thousands of kilometers in uniform directions, indicative of the relatively uniform regional slopes. Several specific informal subtypes of lava flow are noted. Lava floods (also formally, “fluctus”) consist of radar-bright and radar-dark lava flow fields, generally digitate in plan and exceeding several hundred kilometers in length, that have flowed in one direction from an apparent source area. The source areas for these floods are often associated with intense bands or belts of linear fractures and riftlike chasma. Some sources have numerous small volcanoes (Fig. 8), and others are the site of calderas. Nearly one-half of all coronae are predated by areally extensive lava flow fields. This asso-

**FIGURE 8** Turgman Fluctus (MVC 56/218 LF, courtesy of NASA), a typical large lava flow field consisting of digitate radar-bright and radar-dark flows fanning out from a common point. Many flow fields like this one have sources located on ridge belts. Note the small volcanoes located near the source area. Radar illumination is from the left. Image width, 400 km.

ciation is consistent with the current model for coronae formation as the surface expressions of mantle plumes. Voluminous melting and lava eruption might be anticipated as a result of pressure-release melting as the plume arrives in the shallow mantle.

### 3. Unusual Lava Flows

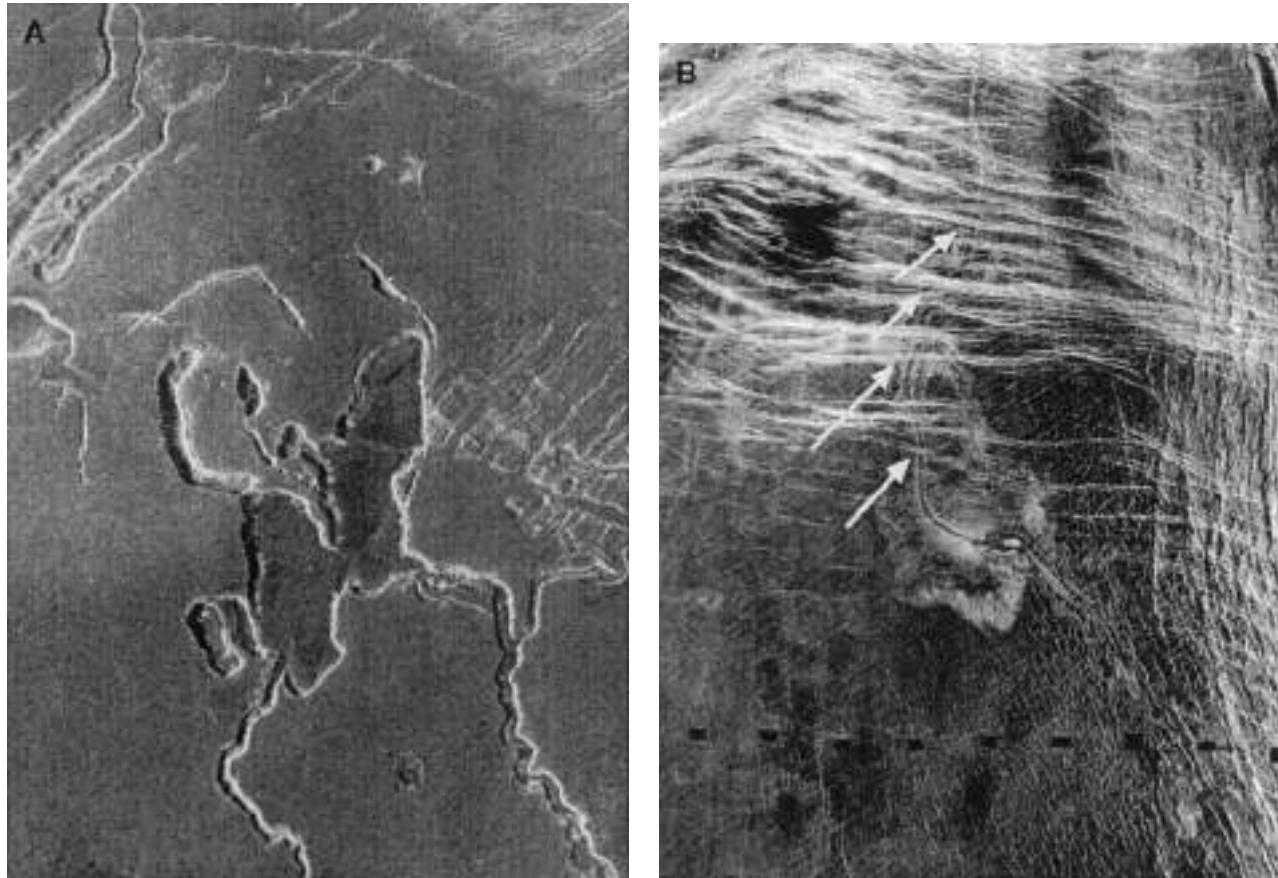

Flows with transverse ridges, troughs, and other fluid banding characteristics include radar-bright flows that show organized patterns of internal streamlines analogous to the ridges and flow bands typical of viscous terrestrial lava flow. Several large, lobate, festooned, and thick lava flows occur at isolated points on Venus. The simplest interpretation based on their resemblance to viscous and silicic lavas on Earth is that they are unusually silicic in composition compared to most large flow fields. However, as is the case for steep-sided domes, more mafic composition lavas with unusual viscosity characteristics arising from bubble-rich eruptions are also possible.

### 4. Lava Channels (*Canali*)

These are linear to sinuous parallel-sided valleys that are from 0.5 to 1.5 km wide and up to 10 km wide, may extend for  $10^2$ – $10^3$  km in length, and occur frequently within areas of lava plains or plains associated with larger volcanic centers (Fig. 9A). Several morphologically distinct types of channels have been identified. “Simple” channels are isolated, narrow channels that frequently meander across plains. “Complex” channels may be characterized by multiple channels, frequently with an anastomosing, braided, and even distributary morphology. “Compound” channels exhibit characteristics of both simple and complex channels in combination, and “integrated” channels are analogous to branching valleys such as those associated with sapping processes on Mars and Earth.

The longest channel is over 6800 km long, the record holder for any single channel in the solar system. (The length of the Nile River is 6497 km.) Formation of a lava channel of this length defies our current understanding of likely emplacement processes. The great length and occurrence within extensive plains imply extremely fluid materials with viscosities as low as 0.1 Pa s (comparable to the viscosity of water). Viscosity for basaltic lava flows ranges from 1 to 100 Pa s. Potential lava-forming fluids with a viscosity of 0.1 Pa s include ultramafic compositions such as komatiites, high-Ti lunar-type basalts, carbonatites, and sulfur flows. The great width of most channels, particularly the longer examples, implies that they are not simply collapsed lava tubes. Because our current understanding of Venus excludes the possibility of significant amounts of water now or in the past, the fluid must be related to the emplacement of the volcanic plains lavas. The most likely scenario at present is that the dense atmosphere of Venus resulted in rapid cooling of lavas to form discontinuous, platelike crusts riding on the fluid filling the channels, thus enabling one of the likely silicate compositions to remain molten over great distances with relatively little cooling. Carbonatites and sulfur flows are attractive alternatives, especially due to the abundance of sources for carbon and sulfur on Venus. Current estimates suggest that although these materials have melting points below that of the surface temperature of Venus, thus enabling them to act essentially as water does on Earth, neither material appears to be stable in the surface environment, making them unlikely to survive as fluids long enough to form channels of the observed length.

One final characteristic of channels that makes them of interest beyond their volcanologic significance is that they record changes in elevation subsequent to their

**FIGURE 9** (A) Lava channels (MVC-12/90 LC) emerging from an irregular collapsed region. Radar illumination is from the left. Image width, 100 km. (B) Part of an extensive plains lava channel (MVC-35/251.5 LC), this channel has been crossed by subsequent ridges (arrows) during deformation of the plains. Radar illumination is from the left. Image width, 300 km. (Photos courtesy of NASA.)

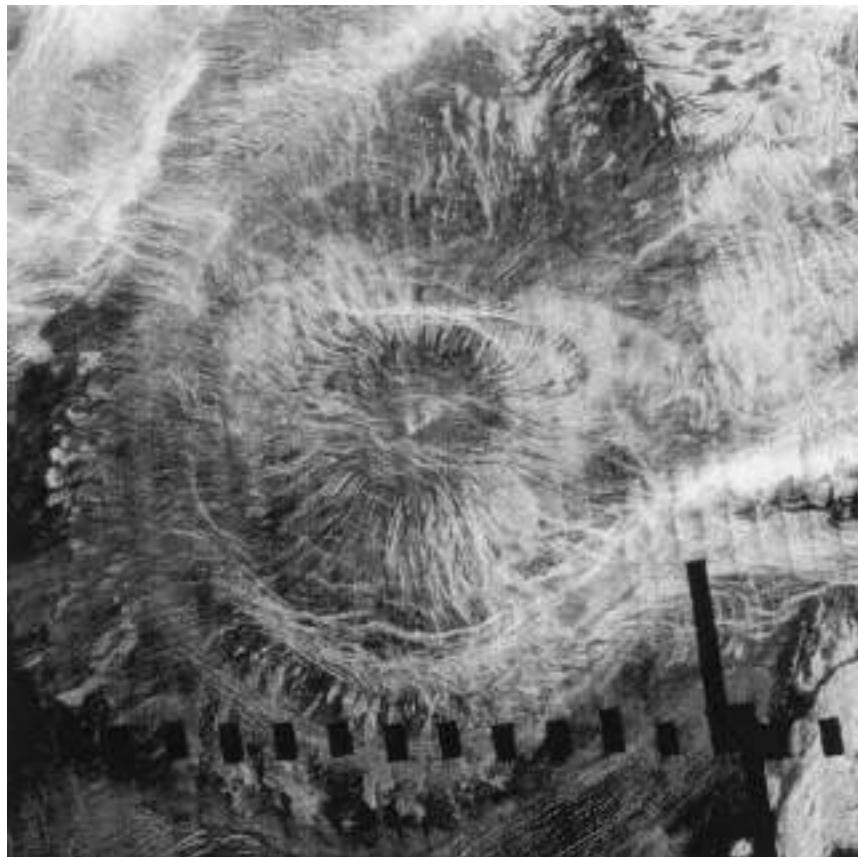

emplacement. Using Magellan altimetry data, significant undulations in the regional relief can be detected along the length of many channels such that locally the gradient of the channel floors is reversed in places from that which must have existed during their emplacement. These influences are particularly apparent where sinuous ridges that occur throughout the plains areas of Venus, similar to wrinkle ridges on the Moon, intercept channels (Fig. 9B). These changes in elevation imply that, on a geologic timescale, the surface of the plains has swelled and rolled like great seas in slow motion, thus preserving the fundamental motion of a planetary surface in response to mantle convection and tectonic strains over geologic time.

#### D. Magmatic Structures

Many features on Venus are characterized more by surface deformation associated with subsurface magmatism

on a large scale. In these features, volcanic edifices and lava flows may be relatively minor or subsidiary to the structures indicative of deformation. These include the broad class of features known as coronae, including subclass arachnoids, and radial fracture centers. The magmatism may be deep-seated reservoirs, or in the examples that are over several hundreds to 1000 km in diameter, the process of formation may be more allied to dynamic topography associated with regional uplift from upwelling mantle plumes. The close association of surface volcanism in many of these or the apparent evolution to or from large volcanoes and other landforms such as radial fracture centers (Fig. 10) further implies a close association with large magma bodies.

The term cauldron, which is applied to volcanic subsidence-related features on Earth regardless of size, shape, depth of erosion, or association with surface volcanism, may be appropriate for larger caldera-like structures such as arachnoids and coronae, particularly since surface volcanism in those features is frequently limited or

**FIGURE 10** Large magmatic centers bearing the characteristics of large volcanoes, coronae, and radial fracture centers such as this example (MVC-14/164 LV; Miralaidji Corona, 600-km diameter, courtesy of NASA) are relatively common on Venus. Note the radial lava flows exterior to the annulus, indicating the original occurrence of a central edifice. Examples such as this imply that all of the large magmatic centers may have fundamentally similar origins, the differences in structure relating to differences in degree of growth, evolution, and modification of the reservoirs. Radar illumination is from the left.

absent. However, since most volcanic terms on Earth are laden with empirical and model-based interpretation, in planetary cases, where the origin of a feature is often not apparent or identifiable with any features on Earth, as is the case with arachnoids and coronae, a distinctive terminology is probably appropriate.

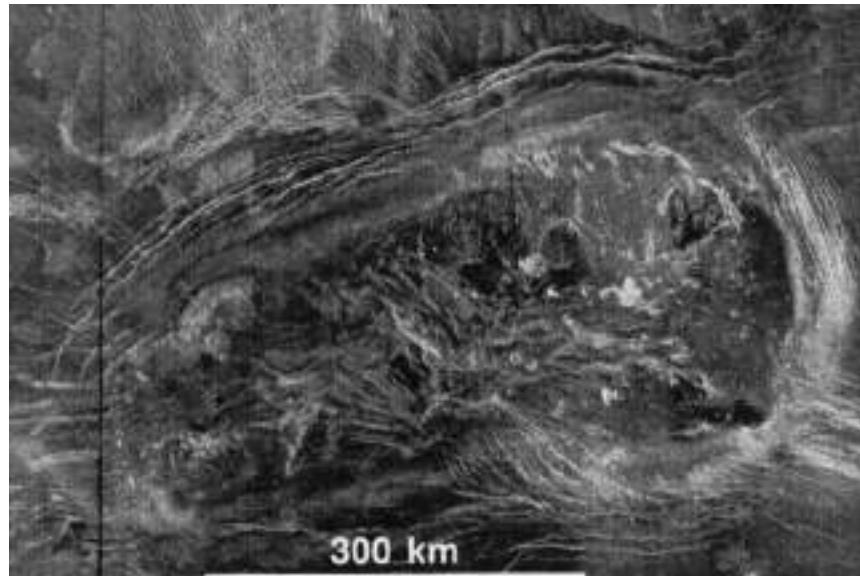

### 1. Coronae

These features, first identified on Venus from Earth-based radar data, are dominantly circular to elongate annular structures consisting of an annulus of ridges or fractures, an interior that is either topographically positive or negative, a peripheral moat or trough, and, frequently, numerous volcanic and tectonic landforms in the interior (Fig. 11). There are 208 coronae identified in the catalog on the basis of the criteria stated here. Coronae decrease in frequency with size from 200 to  $\sim$ 1000 km following an inverse exponential re-

lationship and are commonly between 200 and 250 km in diameter.

Topographically, coronae exhibit a variety of forms, including domical profiles, plateaus, plateaus with central depressions, and rimmed depressions. Coronae are included in the volcanological catalog because of the common association of related smaller volcanic centers and the apparent transitional relation of coronae to features of extrusive, constructional, or composite volcanological origin such as large volcanoes and calderas. Because of their great size and associated volcanism, they have been widely interpreted as associated with mantle plumes or hot spots, their topography resulting from a combination of uplift of the surface over mantle plumes and subsequent gravitational relaxation.

Coronae are one of the most extensively studied features of Venus and several models for the origin of coronae have been proposed. Since they are not simple depressions, but consist of annular ridges or concentric

**FIGURE 11** Demeter Corona (MVC-54.5/295 CO, 650 × 350 km, courtesy of NASA) is a typical corona and is defined as much by the annular structure as by associated volcanism. The widespread distribution of volcanic vents within the interior implies a locally diffuse, if regionally localized, underlying melt source. Radar illumination is from the left.

fractures with elevated interiors, the process must be related to both uplift and collapse, either concurrently, in sequence, or in cycles. One scenario suggests that coronae start out as radial fracture centers developed during arrival of a mantle “blob” beneath the lithosphere that bulges the surface and induces extensive radial arrays of fractures. Subsequent flattening of the blob against the lithospheric lid and continued uplift result in a plateau-like uplift and continued fracturing and associated volcanism. Subsequent relaxation of the uplift results in annular patterns of strain in the surface characteristic of “mature” coronae.

Because coronae, arachnoids, and large volcanoes may represent localized areas of mantle upwelling, a map of the distribution of coronae and related magmatic features suggests that mantle upwelling has been widespread but particularly concentrated in the hemisphere between Atla, Beta, and Themis Regiones. Coronae and volcanism in this area tend to occur in association with extensive networks of riftlike chasma, suggesting that, if they are the results of mantle plumes, the concentration of rifting may be closely allied with the processes of an upwelling mantle.

## 2. Arachnoids

These are structures characterized by a combination of radial fracture patterns or ridges extending outward for

several radii and a concentric or circular pattern of fractures or ridges. In many cases they include a few interior flows and small shield volcanoes within the interior (Fig. 12A). The radial fractures frequently merge outward with the linear patterns of the fracture belts on which arachnoids are arranged. The term “arachnoid” derives from this arrangement, like spiders along “webs” of linear fracture belts (Fig. 12B). The distinction between arachnoids and coronae is based on the relative abundance of radial versus concentric fractures/ridges, respectively. There also appear to be differences in average size. In general, arachnoid-like circular structures tend to be less than 200 km in diameter.

There are 265 identified arachnoids; thus they are second in abundance after shield fields. The relative dearth of other extrusive volcanic features associated with arachnoids may imply that magmatism associated with arachnoids is largely intrusive and that the radial ridges are compressional features related to subsidence-related deformation. The regional distribution of arachnoids is similar to that of coronae although somewhat more allied with regional rifts and fracture belts. In most other characteristics, arachnoids are similar to coronae and are likely to be a variation on the process of coronae formation in the presence of strong regional tensile stress fields associated with rifts and linear fracture belts. The radial fractures may be similar in origin to the radial fracture patterns described below.

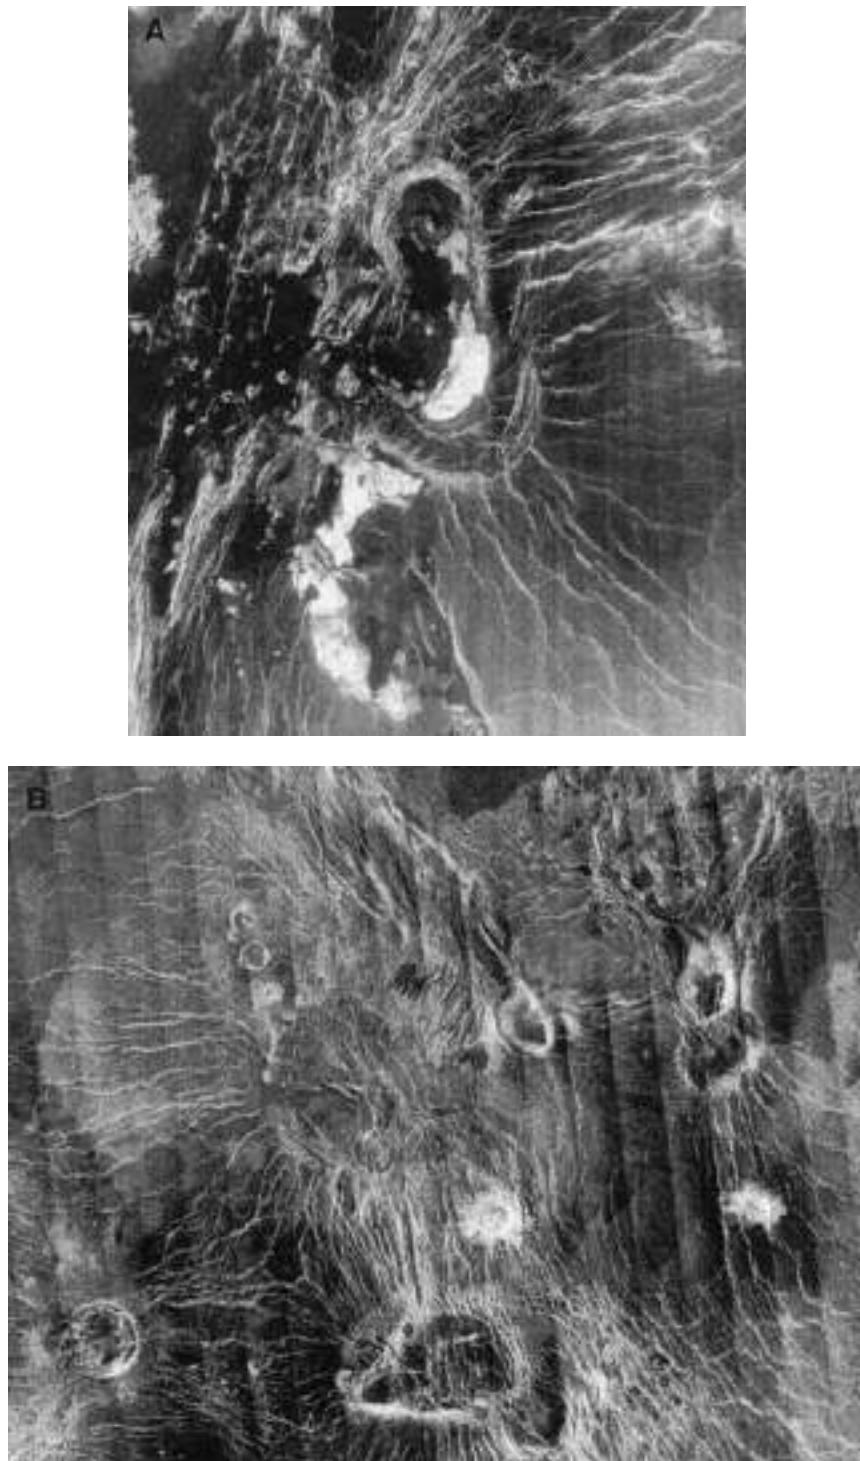

FIGURE 12 (A) Razia Patera (MVC-46/198 AR), a  $200 \times 100$  km diameter arachnoid surrounded by a complex of radiating ridges and whose floor is covered with lava flows. Razia Patera is part of a local concentration of volcanic centers that includes several small shield volcanoes, small calderas, and radar-bright lava flows. Radar illumination is from the left. (B) Regional cluster of arachnoids of various sizes centered about a circular 100-km-diameter arachnoid (MVC-5.5/169 AR). Arachnoids resemble small coronae connected in a web of surrounding fractures. Radar illumination is from the left. (Photos courtesy of NASA.)

### 3. Radial (or Stellate) Fracture Centers

Prominent radial fracture patterns consist of a plexus of graben radiating from a common point (Fig. 13), resulting in a stellate pattern that frequently crosses preexisting structures and surrounding plains; concentric structure is absent. The stellate pattern is frequently centered on a broad domical topographic high (generally  $>100$  km in diameter), in the center of radial flow patterns, in the interior region of large volcanoes, or within arachnoid-like and corona-like concentric structures. Radial fracture centers occur frequently in association with both large volcanoes and coronae, are clearly superimposed on large volcanoes and coronae in some examples, and predate large volcanoes and coronae in other examples. There are 64 significant radial fracture centers identified ranging from 50 to 300 km in diameter, occurring along the flanks of several rises and situated frequently in chains and at the centers of large volcanoes. As many as 160 radial fracture centers may be identified if those visible on more prominent features, such as coronae, arachnoids, and volcanoes (see Table II), are included.

Two different modes of emplacement have been proposed for radial fracture centers: (1) tensile fracturing

associated with domical uplift, probably over shallow magma bodies, and (2) tensile deformation resulting from shallow subsurface dike emplacement. Although both mechanisms are probably influential in the development of radial fracture patterns, domical topography does not characterize all examples of radial fracture centers. Even if the topography has relaxed in such cases, the annular pattern of deformation predicted to occur upon relaxation (see discussion of coronae evolution above) is not present in all cases. In addition, many radial fracture patterns extend for distances much greater than any associated domical rise in the topography. As a result, not all radial fracture centers may be attributed to strain associated with uplift. The recognition that tensile fractures accompany shallow emplacement of dikes on Earth, the similarity to giant radial dike swarms, and the frequent association with clear centers of volcanic activity all suggest that radial fracture centers may be analogous to radial dike swarms. Radial fracture patterns in many cases may be the precursor for more evolved large magmatic centers such as coronae, arachnoids, calderas, and large volcanoes. In this model, they represent the initial events of deformation and magma emplacement upon arrival of upwelling mantle plumes be-

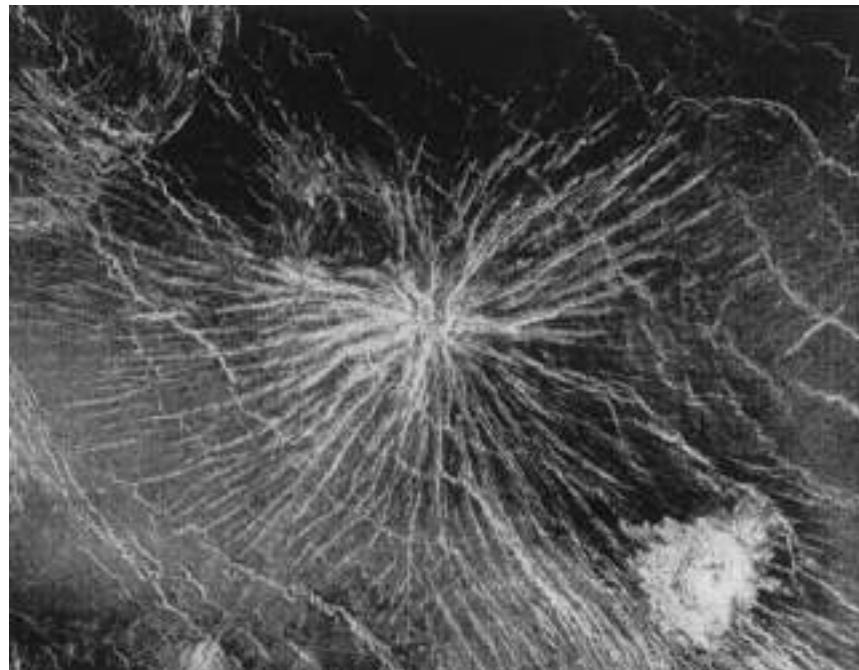

FIGURE 13 A simple radial fracture center (MVC-34/21.5 RFC, courtesy of NASA) located within ridged plains. This example illustrates the confusion between physiographic and volcanic terminology: although it is unlike any corona, it has been identified as a corona by the IAU and named Lilinau Corona. Note impact crater in lower right. Radar illumination is from the left. Image width, 230 km.

neath the lithosphere or initial emplacement of large bodies of magma within the lithosphere, lateral injection of radiating dikes in the shallow subsurface, and corresponding development of graben in the overburden.

---

### III. FACTORS INFLUENCING VOLCANIC ERUPTIONS AND VOLCANIC LANDFORMS ON VENUS

Important questions and goals in the study of Venus include determining how the differences in surface and interior conditions are linked to the observed diversity and complexity of volcanoes. The influence of the extreme temperature and atmospheric pressure and density on magma eruption and emplacement both within the crust and lithosphere and on the surface are likely to be significant.

As yet unaddressed questions associated with the problem of large-scale magma transport and emplacement under the distinctly different conditions of Venus might reveal substantial insights into a variety of basic volcanological phenomena as well as enhance our understanding of the origin of the diverse styles of volcanism on Venus. For example, what governs whether a center of volcanism develops from magma effusions into a single large volcanic shield, a cluster of small shield volcanoes characterized by effusive flows, or a radial fracture center, a corona, or a caldera characterized by very little effusion and a large unerupted magma reservoir? Past study of volcanism and volcanic rocks on the terrestrial planets and recent studies of magma transport-related processes on Earth suggest that the three most important factors in development of individual volcanic centers on Venus are likely to be (1) magma composition, (2) environmental influences, and (3) magma ascent characteristics, specifically emplacement and replenishment rates.

#### A. Influence of Chemical Composition

Chemical composition is an important influence on the viscosity and volatiles abundances typical of erupted silicate melt. On Venus the question arises as to whether all the observed volcanic landforms are the results of silicate melts. As discussed above, the possibility of exotic compositions such as carbonatites and sulfur flows has been considered in order to account for the apparent

extreme fluidity of lava channel-forming materials. The high abundance of sulfur (several percent) in the surface soil analyses of Vega 2 lander implies that sulfur may be important in the surface chemistry. Observed chemical compositions of silicate materials from Venera landers imply whole-rock compositions comparable to tholeiitic basalts, subalkaline basalts, and some evolved compositions with high alkalis.

#### B. Influence of Extreme Surface Temperature and Pressure

The surface temperature (700 K) and pressure (9.2 MPa) at the mean surface elevation of Venus differ substantially from the environment in which most of the characteristics of volcanism on Earth have been studied and corresponding differences in eruption characteristics and behavior of melts and volatiles on Venus are to be expected. Basically, the influences are thermal effects and pressure effects, although the ways in which these influence volcanism are subtle.

##### 1. *Influence of Surface Conditions on Eruptions*

The influence of surface conditions on eruptions is primarily a result of the extreme pressure rather than temperature. Although the surface temperature is 700 K, this is far below the solidus of common silicate melts. Given the close chemical similarity between measured Venus surface compositions and terrestrial tholeiitic basalts, melt temperatures similar to those on Earth (1700 K) are likely for most volcanic eruptions. Even melt temperatures for rhyolitic eruptions (1200–1300 K) are far above the surface temperature. Calculations of the rate of cooling of a typical basaltic lava flow erupted onto the surface of Venus show that the temperature at the surface of the flow will be fractionally lower compared to that on Earth soon after eruption. This counter-intuitive result merely reflects the enhanced convection in the dense CO<sub>2</sub> atmosphere. The cooling efficiency is such that it may be compared with a subaqueous eruption. In the longer term, the surface temperature of a lava flow will be greater on Venus as it cools to the higher ambient temperature, thus sustaining the length of time slightly over which the flow must cool before complete solidification. A predicted result is that lava crusts will develop more quickly on Venus than Earth, thereby enhancing the early formation of lava tubes.

The atmospheric density is therefore the primary influence. In fact, the pressure on the surface of Venus is equivalent to the pressures at 1 km in Earth's oceans, with many of the same predicted consequences. A significant influence of the high pressure is the suppression of gas exsolution, with important consequences for vesiculation of lava flows and pyroclastic disruption of erupting magmas at volcanic vents. For any magma bearing volatiles in concentration comparable to those on Earth (<2%), pyroclastic eruptions will be unlikely to occur. As a result, large pyroclastic eruptions and corresponding composite volcanoes and ash flows are unlikely to occur unless volatile contents of eruptions on Venus significantly exceed that common on Earth. Early observations of large increases in sulfur content of the upper atmosphere, originally ascribed to a large Plinian-type eruption process, suggest the possibility of significant volatiles. The occurrence of radar-dark areas around the summits of some large volcanoes, attributed to extensive ash deposits, may be an additional clue to the high volatile abundance. Either the erupting magmas may be significantly enhanced in volatiles by some poorly understood process or the interpretation of these phenomena as pyroclastic deposits and eruptions is in error. Similarly, vesiculation of lava flows should be suppressed. However, as discussed in the above section on steep-sided domes, volatile abundances in the normal high range of erupting magma may favor extensive vesiculation, if not disruption, of lavas, leading to extremely frothy basaltic eruptions. One consequence might be that an eruption that on Earth would result in an ash-flow eruption might on Venus result in a massive frothy outpouring. The resulting landform might resemble a giant viscous dome.

## *2. Influence of Surface Conditions on Magma Ascent Characteristics*

The high ambient temperature of the lithosphere is likely to influence the thermal efficiency during magma transport so that magma in dikes and plutonic bodies is expected to experience less cooling during ascent. As a result, smaller and slower magma bodies are able to reach the surface than on Earth. This might in part explain the greater variety and distribution of volcanic centers on Venus relative to Earth: special conditions such as lithospheric plate boundaries are not necessary for magmas to make their way to the surface. The greater abundance of shield fields on Venus than that seen on the other terrestrial planets may be another consequence of the thermal efficiency on Venus of ascending magmas. Fields of volcanoes develop from ascent of individual

bodies of magma directly from a local melting source instead of from the large, shallow reservoirs that are necessary for development of large magmatic centers. This is consistent with calculations of the magma replenishment rates necessary for shallow reservoirs (discussed further in the next section).

Magma ascent may be governed by the presence of variable magma buoyancy with respect to the country rock, a possible factor contributing to fundamental differences in volcanic style on Venus and on other planets. Here again the extreme atmospheric pressure may be a stronger influence on magma ascent. Because the crust and lithosphere of Venus are probably largely volcanic, the density in the shallow levels will be influenced by the density of erupted rocks. Given the extreme suppression of vesiculation and the greater abundance of lavas over pyroclastic materials, the density of typical crustal rocks will be greater than on Earth. One predicted consequence is the effect that this will exert on the development of neutral buoyancy during magma ascent. On Earth, it is found that magma tends to ascend buoyantly within the lithosphere until the density of the melt approaches the density of the country rocks, at which point the magma stalls. Further arrivals of magma will continue to stall at the same level, resulting in the eventual development of shallow reservoirs from which other effects must take over in order for the magma to continue its ascent. The condition of neutral buoyancy may not occur in many cases on Venus, primarily at the lower elevations where atmospheric pressure is greatest, vesiculation is suppressed, and the corresponding crustal density is high. As a result, in areas of lower elevation, direct ascent and eruption of magmas may occur with very little reservoir development. At higher elevations, where atmospheric pressure is lower, shallow reservoirs might be able to form and large magmatic centers characterized by shallow reservoirs might be more common. Many large centers of volcanism on Venus do occur in intermediate and upper elevations. Currently, the full range of influences on shallow reservoir formation and the fundamental significance of neutral buoyancy as the primary cause of reservoir formation have not been explored sufficiently to enable us to say whether the density structure is the principal cause of this distribution.

## **C. Influence of Ascent and Emplacement Rates on Eruptions**

Differences in volcanologic characteristics of surface features may arise from influences other than variations

in chemical composition or direct environmental effects. Part of the diversity of volcanic morphology observed on Venus may reflect the diversity of rates of magma emplacement in contrast to the smaller terrestrial planets. Numerical evaluation of the thermal conditions necessary to establish and maintain an active magma reservoir shows that the two important characteristics necessary for reservoir development under given conditions of magma temperature and ambient crustal rock type are (1) the presence of a level or zone within the crust where the magma is in a state of neutral buoyancy and (2) a rate of magma emplacement great enough that new magma arrives more quickly than the previously emplaced magma solidifies (in other words, the net thermal flux into the magma emplacement zone is positive).

Volcanological studies on Earth over the past decade suggest that many of the salient characteristics and variations in morphology of volcanic centers may depend on the rate of magma production, replenishment, and extrusion within individual magmatic systems and volcanic centers. Although the geochemical character of magmas, surface environment of eruption, and buoyancy considerations may be important in controlling the style of eruptions in individual volcanic centers, the total rate of magma eruption, emplacement, and replenishment (the *magma rate regime*) might exert an equal or greater influence on the presence of shallow magma reservoirs, long-lived volcanic centers, and the overall morphology of the volcanic center as a whole. Reservoirs capable of supplying central volcanic edifices, volcanic complexes, or long-lived centers of intrusive or extrusive activity on Earth frequently occur only for a very narrow range of magma transport rates and storage conditions. These conditions are sensitive to lithospheric structure and thermal gradient. As a result, the presence of magma reservoirs (for example, coronae and calderas) on any planet implies specific magma transfer rates from the mantle and timescales over which magma is stored in the crust. Assessment of these rate-related influences and the rates as recorded in the characteristics of volcanic centers will be one of the few means of determining rates of geologic processes, melt productivity, and heat transfer associated with mantle plumes on Venus. The large-scale effect of tectonic environment (hot spot instead of plate boundary) may also influence the rates of magma emplacement globally and net rates of resurfacing. Volume rates associated with volcanism on Venus are estimated to be similar to or lower than that associated with hot spots on Earth ( $0.1\text{--}1 \text{ km}^3/\text{a}$ ), more than one to two orders of magnitude lower than volume rates of volcanism associated with plate tectonics.

The largest and shallowest magma reservoirs and most voluminous eruptions on Earth are associated frequently with moderate rates of magma emplacement in midcrustal levels, with corresponding development of large magma reservoirs. This rate is approximately equivalent to the rate of magma intrusion and eruption at the Hawaiian hot spot averaged over the past 70 million years. Rates of emplacement lower or higher than this moderate rate tend not to yield well-developed, isolated, long-lived magma reservoirs that evolve chemically and structurally in association with single volcanic edifices. Rates of emplacement lower than this value on Earth frequently result in numerous short-lived volcanic centers and are characteristic of “fields” of small volcanoes. Rates greater than the moderate-rate regime frequently result in massive flow fields, incompletely developed volcanic centers and magma reservoirs, and relatively minor associated amounts of evolved magma compositions. Neutral buoyancy is necessary but is not a sufficient condition for development of complex dike patterns and long-lived magma reservoirs, and variations in reservoir depth appear insufficient to account for all of the disparate morphologies seen in volcanic centers on Venus.

Results of simple calculations of the influence of replenishment rates on Earth are consistent with observed rates of magma replenishment typically associated with reservoir development ( $\leq 10^{-3} \text{ km}^3/\text{a}$ ). Similar calculations for Venus imply that magma reservoirs are likely to form at volume rates of magma transfer at least a factor of two less than on Earth ( $\leq 5 \times 10^{-4} \text{ km}^3/\text{a}$ ). This means that magma replenishment rates typical of many fields of small volcanoes on Earth are capable of generating central volcanic centers and magma reservoirs on Venus. Additional details of the process may be significant, including the geometry of the magma emplacement and whether the reservoir is tabular or cylindrical. Rates of magma transport and corresponding style of volcanic centers may also be modulated to a limited extent by magma composition.

---

#### IV. FUTURE DIRECTIONS

The list of unanswered questions about volcanism on Venus is as long as the list of volcanoes. No single discussion may cover them all. What follows are just some questions that have been raised during the course of the above discussion.

The great abundance of shield fields over other landforms is a distinctive characteristic of Venus. On Earth, fields of small volcanoes are diagnostic of long-lived magma supply at rates too low to sustain a shallow magma reservoir. If the shield fields on Venus originate by a similar process, the larger abundance of shield fields is understandable given that, in any normally distributed population of magmatic events (magma replenishment rates), the smaller events will be more common than larger ones. For Venus, we estimate that rates  $\leq 5 \times 10^{-4} \text{ km}^3/\text{a}$  are necessary to ensure that a shallow magma reservoir does not form. This is about half the rate necessary on Earth. This is a useful hypothesis, and Venus would seem to be an excellent place to test it. But given the near impossibility of determining ages on Venus, how can we test this concept?

It remains to be determined why the large volcanoes of Venus are characterized by extremely low relief. The case can be made that the primary influence on the lateral dimensions of lava flows is volume flux, which, in combination with the extremely low relief of the general surface of Venus, will result in extremely long flows and corresponding shield volcanoes of great width and not much height. If volume flux is a significant influence, why are the lava flows characteristically erupted at high rates from shallow reservoirs on Venus? What characteristics of magma ascent and eruption are likely to be influenced by the lithosphere and tectonic conditions unique to Venus?

In the absence of erosion on Venus, the complete range of processes that operate in the course of evolution of large magmatic provinces are perfectly preserved. Recognizing the existence of some of the large-scale structural phenomena associated with large magmatic provinces based on study of Venus examples, it may be useful to reexamine terrestrial volcanic provinces for similar features. Ultimately, it would be useful to know if large-scale patterns of deformation such as those associated with coronae, arachnoids, and radial fracture centers occur on Earth.

A significant result of early Magellan data analysis was the recognition that much of the surface, particularly vast areas of low-lying plains formed by lava floods, is old (several hundred million years) by Earth standards (although young when compared with the other smaller terrestrial planets). Initial studies, and studies since that time, suggested that a global resurfacing event occurred on Venus. The timing of this event is not known, but based on estimates from the global population of impact craters, it could be either as late as 300 million years ago or up to 1600 million years ago. Geologic mapping and stratigraphic studies imply that most of the volcanic

centers have developed since the global resurfacing event. Volcanism appears to have been volumetrically low in the intervening time, accounting for a few tenths of a cubic kilometer per year, or considerably less than the rates for Earth over the same time interval (essentially Phanerozoic). If so, the globally averaged style of volcanism on Venus, particularly the volumetric rate of eruptions, has differed greatly from that associated with plate tectonics on Earth. Current models for how this process might work imply that Venus undergoes a cyclical style in which large outbursts of volcanism occur globally, perhaps every few hundred million years, and that rates of volcanism are relatively low in the times in between these outbursts. It has also been suggested that, whereas plate tectonics does not now characterize the surface, it is possible that during or immediately prior to these global volcanic events, global tectonism is somewhat more akin to plate tectonics. This concept is supported somewhat by the presence of large areas of extremely deformed and elevated terrain known as tessera, which are also among the oldest identified surfaces, somewhat like continents on Earth, although covering less than 15% of the surface. In this model, once the global event runs its course, the planetary style of tectonism reverts back to a simple hot spot style characterized by low rates of volcanism erupted from several large hot spot swells. The process is repeated later when the heat builds up in the interior, large-scale melting takes place, and mobile tectonics and extensive volcanism occur once again. This style is completely unlike any recognized activity of Earth. It remains to be seen what consequences this might have for the fundamental characteristics of its volcanoes.

Although the global tectonic style of Venus currently differs greatly from that of Earth, it is useful to consider the possibility that either Earth-like styles of global tectonic occurred on Venus in the past or Venus-like tectonics have occurred on Earth during some previous phase of its history. The extreme nonuniformitarian style of Venus, characterized by massive outbursts of volcanism and tectonism followed by great periods of relatively low activity, is also a departure from our previous assumptions about the way in which planetary-scale mechanisms of evolution occur. It is therefore of equal benefit to consider ways in which Earth's tectonic cycle may have undergone significant changes in rates. Most of what we consider to be typical Earth geology spans only the Phanerozoic. Similarly, most of what is preserved on Venus spans approximately the same time interval, even though it is of an altogether different character. Both planets could well have presented different volcanic styles prior to 1 billion years ago for the

simple reason that the long-term evolution of a planet may depart radically over short intervals of time from that characterizing processes that act over long periods of time. In other words, uniformitarianism may still be an appropriate concept, but may be strongly dependent on the length of time over which one samples the geologic record.

## GLOSSARY

- Amazonian** The youngest of the geologic epochs on Mars identified through geologic mapping of superposition relations, and the areal density of impact craters.
- caldera** An irregular collapse feature formed over the evacuated magma chamber within a volcano.
- central volcano** Emplacement of volcanic materials from a centralized source vent rather than along a distributed line of vents.
- composite volcano** A volcano consisting of intermixed effusive lava flows and pyroclastic materials. Flank slopes are typically  $>10^\circ$ , or more than twice as steep as the flanks of a shield volcano.

**Fossae** Descriptor applied to an aligned series of fractures in a planetary surface.

**Hesperian** The intermediate geologic epoch on Mars identified through geologic mapping of superposition relations, and the areal density of impact craters.

**Icelandite** Volcanic rock with silica content comparable to an andesite, but which did not form as a result of subduction or orogenic processes.

**Mons** Descriptor applied to a large isolated mountain on a planetary surface.

**Noachian** The oldest of the geologic epochs on Mars identified through geologic mapping of superposition relations, and the areal density of impact craters.

**Patera** Descriptor applied to an irregular or complex crater with scalloped edges, surrounded by shallow flank slopes.

**pseudocrater** A “rootless vent” created by the interaction of lava with groundwater or wet sediments beneath the flow.

**shield volcano** A broad volcanic construct consisting of multitudes of lava flows. Flank slopes are typically  $\sim 5^\circ$ , or less than half as steep as the flanks on a composite volcano.

**SNC meteorites** A group of meteorites thought to originate on Mars, due to a relatively young age and trapped gases very like the atmosphere of Mars. The acronym is derived from the names of the three meteorites that define the major subdivisions identified within the group: S, Shergotty; N, Nakhla; C, Chassigny.

**Tholus Descriptor** applied to an isolated domical small mountain or hill, usually with slopes much steeper than that of a patera.

**volcanic plains** Planar mappable units interpreted to consist of volcanic materials, usually with individual flow margins resolvable within the unit.

**yardang** A rounded erosional landform produced by wind-driven sand. Some yardang fields on Mars are interpreted to be formed in wind-eroded pyroclastic deposits.

## I. INTRODUCTION

The advent of spacecraft exploration revealed that Mars possesses some of the most dramatic volcanic features found anywhere in the solar system. How did a planet half the size of the Earth generate volcanoes like Olympus Mons, which is several times larger than the largest volcanoes on Earth? This question is just one example of the issues currently being investigated as part of the relatively recent scientific endeavor called “Comparative Planetology.” This article will summarize the basic information presently known about volcanism on Mars. The reader can then compare the Martian volcanoes to the numerous volcanoes studied in great detail here on the Earth as well as to volcanoes observed on other planetary bodies.

Two generalizations can be made before we investigate the Martian volcanoes in greater detail. Volcanoes on Mars appear to be broadly similar in overall morphology (although different in scale) to volcanic features on Earth, so there is no direct evidence for Martian eruptive processes that are somehow significantly different from the volcanic styles and processes known on Earth. This inference strengthens our confidence in using the basic approach of attempting to understand the Martian volcanoes in terms of traditional volcanology. Next, the Martian volcanoes occur on terrains of various relative ages (discussed below), so that volcanism represents a dominant geologic process throughout much of Martian history. This is in contrast to volcanism on the smaller body of Earth’s Moon, where volcanic activity was confined to roughly the first third of lunar history (see “Volcanism on the Moon”). Comparative planetology thus supports the concept that volcanism is the primary mechanism for a planetary body getting rid of its internal heat, where smaller bodies tend to lose their internal heat more rapidly than larger bodies (Jupiter’s moon Io appears to contradict this trend because this object, the size of Earth’s Moon, is the most volcanically active

body in the solar system, but this activity is powered by unique gravitational tidal forces within the Jovian system; see “Volcanism on Io”). Next we review some important background information before examining the types of volcanic features present on Mars.

---

## II. BACKGROUND

The first direct evidence of the importance of volcanism on Mars came during the Mariner 9 orbital mission. A massive global dust storm obscured the entire Martian surface when Mariner 9 arrived at Mars on November 14, 1971, but as the weeks passed, the dust slowly began to settle. The first surface features at equatorial latitudes to become visible through the dust pall were four dark “spots” in the region of the planet that telescopic observers called Tharsis. Gradually these spots were revealed to each be topped by a complex crater assemblage, the first clue that four huge volcanoes were present in the Tharsis area. By chance, the three previous fly-by Mariner missions failed to image this area in detail sufficient to show these large volcanoes. Mariner 9 continued to map the entire Martian surface until October 12, 1972, revealing that Tharsis was not alone in containing impressive volcanic constructs. The Mariner 9 view of Mars was updated significantly with the improved resolution of the cameras on the two Viking Orbiter spacecraft that operated at Mars from June 19, 1976, to August 17, 1980. The ~55,000 Viking Orbiter images led to refined interpretations for many Martian features, but they did not significantly alter the first global perspective of Mars revealed by the Mariner 9 images.

The distribution of volcanoes on Mars is not uniform; there are four regions where central volcanoes are concentrated (Fig. 1). Twenty-three volcanic constructs have been given names (Table I) by the International Astronomical Union, the only organization that can officially designate names for planetary features. The largest concentration of Martian volcanoes occurs in the Tharsis region, where the volcanoes are distributed on and around a 4000-km-diameter bulge in the Martian crust, centered on the equator at 110°W longitude. This bulge has lifted the crust to an elevation ~10 km above the Martian datum, twice as high as the highest portions of the cratered highlands that dominate the southern hemisphere of Mars (shaded portion of Fig. 1). The “Tharsis Bulge” is surmounted by three volcanoes collectively called the Tharsis Montes (5, 6, and 16 in Fig. 1), aligned along a N40E trend that includes addi-

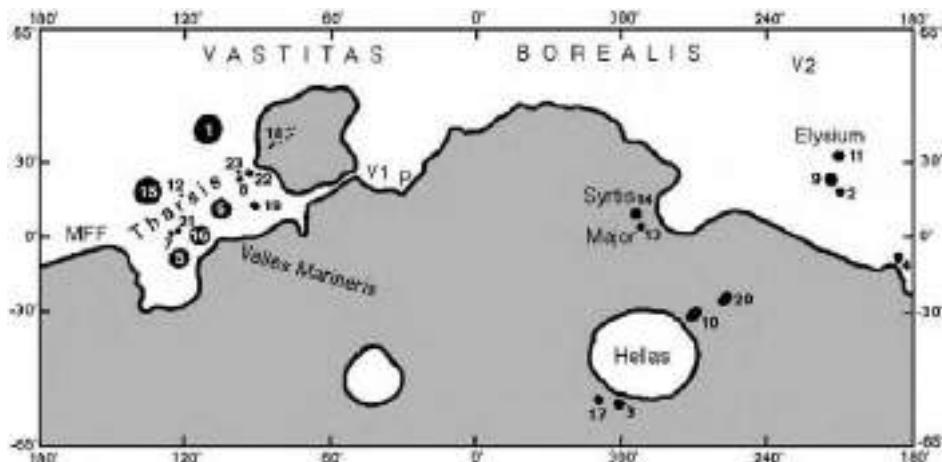

FIGURE 1 Location map for named central volcanoes on Mars. The black areas indicate various volcanic centers, with numbers keyed to Table I. The shaded area represents densely cratered materials typical of the highlands that dominate the southern hemisphere. Letters indicate landing sites (V1, Viking 1; V2, Viking 2, P, Mars Pathfinder) and the Medusae Fossae Formation (MFF). Mercator projection.

tional volcanic centers northeast of the Tharsis Montes. The Tharsis Montes and nearby Olympus Mons (15 in Fig. 1) are the four tallest features on Mars, the summit calderas of which were first imaged by Mariner 9 above the dusty lower atmosphere. Outside of the Tharsis area, Martian central volcanoes are confined to the Elysium, Syrtis Major, and Hellas regions (Fig. 1), all named for broad bright or dark surface markings visible with Earth-based telescopes. In addition to the named central volcanoes, broad expanses of regional plains exist across Mars, many of which include compelling evidence that they were formed by the emplacement of numerous individual volcanic flows.

The Mariner 9 and Viking images showed the physiographic makeup of the entire surface of Mars. Through careful observation of the superposition and cross-cutting relationships of distinctive material units, a global geologic sequence has been developed. The areal density of impact craters present on the various material units allows the relative stratigraphy to be established even where units are not in contact with each other. The convention defined for three major divisions of Martian geologic history are the Noachian (oldest), Hesperian (intermediate age), and Amazonian (youngest) epochs, providing a broad temporal sequence in which we can discuss the various Martian volcanoes. Unfortunately, the absolute age of these Martian epochs is very unconstrained at present; various models of the impact flux on Mars allow the Amazonian period to be from millions to billions of years in age. Most planetary scientists likely would accept that Amazonian materials represent events

late in Martian history, but ages for documented samples collected from regionally expansive terrains are needed to constrain the precise time range covered by the cratering record on Mars. In spite of this uncertainty in absolute age, the geologic stratigraphy provides a robust framework in which the relative ages of various materials, including both central volcanoes and regional volcanic plains, can be evaluated.

Remote-sensing data provide information about Martian materials that is complementary to the photogeologic interpretation of spacecraft images. Reflected visual and infrared light provides compositional information by the wavelengths at which some of the light is selectively absorbed. Earth-based telescopic studies can not resolve individual volcanoes but reflectance spectra indicate that bright regions are covered with a dust that includes considerable oxidized iron whereas the dark regions are less dusty and may include pyroxene-bearing material such as mafic volcanic rock like basalt. Thermal infrared measurements by the Viking orbiters indicate that the Martian surface is coated with particulate materials, ranging from micron-sized dust covering practically all of surface in the bright regions to sand-sized particles mixed with larger unresolved blocks in the dark regions. Significantly, the Viking thermal measurements showed no "hot spots" attributable to internally generated heat anywhere on the planet. Radar signals transmitted from Earth and reflected from the Martian surface have shown that some individual volcanoes, such as the Tharsis Montes, display strong scattering behavior. The scattered radar signals indicate

TABLE I Named Volcanic Centers on Mars

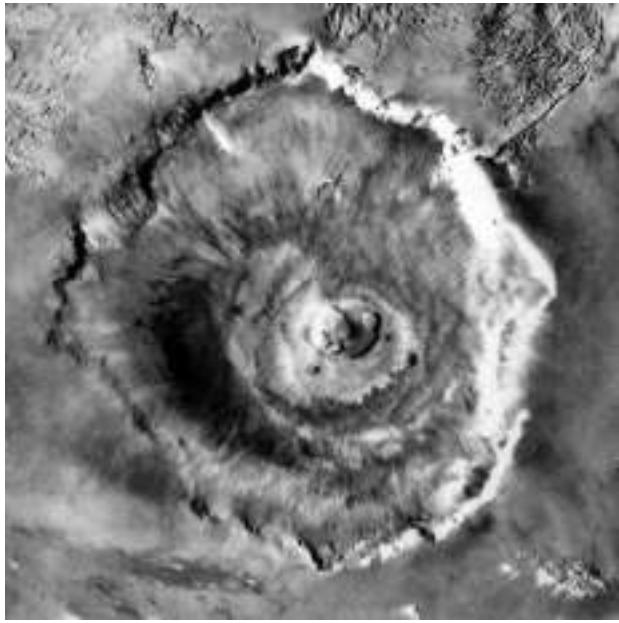

Number	Name	Center	Horizontal scale <sup>a</sup> (km)	Relief <sup>b</sup> (km)
1	Alba Patera	40°N, 109°W	450	~4
2	Albor Tholus	19°N, 210°W	160	~5
3	Amphitrites Patera	59°S, 299°W	130	<1
4	Apollinaris Patera	8°S, 186°W	180	~5
5	Arsia Mons	9°S, 120°W	350	~11
6	Ascreaeus Mons	11°N, 104°W	350	~17
7	Biblis Patera	2°N, 124°W	150	~4
8	Ceraunius Tholus	24°N, 97°W	150 × 100	~5
9	Elysium Mons	25°N, 214°W	300	~12
10	Hadriaca Patera	30°S, 266°W	180	<1
11	Hecates Tholus	32°N, 210°W	170	~6
12	Jovis Tholus	18°N, 117°W	60	~2
13	Meroe Patera	7°N, 291°W	50	<1
14	Nili Patera	9°N, 293°W	60	<1
15	Olympus Mons	28°N, 133°W	500	~25
16	Pavonis Mons	0°N, 113°W	350	~10
17	Peneus Patera	57°S, 307°W	120	<1
18	Tempe Fossae <sup>c</sup>	36°N, 86°W	3 × 1	≤1
19	Tharsis Tholus	13°N, 91°W	170 × 110	~6
20	Tyrrhena Patera	22°S, 253°W	180	~1
21	Ulysses Patera	3°N, 122°W	100	~2
22	Uranius Patera	26°N, 93°W	150	~1
23	Uranius Tholus	26°N, 98°W	60	~4

<sup>a</sup> Approximate horizontal dimension (maximum and minimum values for elongate features).<sup>b</sup> Estimated relief from summit to the surrounding terrain; from U.S.G.S. (1991).<sup>c</sup> Largest of several small features along Tempe Fossae (Fig. 4).

considerable surface roughness at the 10 cm to meter scale on the surface of the Tharsis Montes, something that may likely also apply to other volcanoes but which are too small to be clearly resolved with Earth-based radar. West of the Tharsis Montes, a region of several million square kilometers returns no radar signal back to Earth; this area has been nicknamed “Stealth” after its very low radar reflectance properties. Stealth could be a deposit sufficiently thick so that the radar signal is fully absorbed, such as through deposition of pyroclastic materials associated with the nearby volcanoes, or Stealth also might have unusual relief that efficiently scatters the radar signals away from the antennas on Earth.

### III. LARGE CENTRAL VOLCANOES

Olympus Mons and the three Tharsis Montes each have shapes typical of a basaltic shield volcano on Earth, but at non-Earth-like scales (Fig. 2). The flanks of the four mountains have maximum slopes of ~5°, with shallower summit and basal slopes, much like the shape of the subaerial portion of the Mauna Loa shield volcano. The great bulk of the Mauna Loa volcano, which with its subaqueous mass comprises the largest mountain on Earth, is still dwarfed by any one of these four mountains, but particularly by Olympus Mons with its 500-km diameter and 25-km vertical relief. The four Tharsis

**FIGURE 2** Olympus Mons, the largest central volcano on Mars (15 in Fig. 1 and Table I). Olympus Mons has shallow flank slopes typical of a shield volcano. The volcano has 25 km of relief from its summit to the plains surrounding the basal scarp, which is ~600 km in diameter and from 3 to 6 km in height. (Viking Orbiter image 646A28, courtesy of NASA.)

shield volcanoes are so large that their size is not fully appreciated without considering the curvature of the Red planet; an astronaut on the surface anywhere near these mountains could not see their summits because this would be beyond his (or her) local horizon!

The great size and height of the four large Tharsis volcanoes generated considerable discussion about their potential source regions. If buoyancy is assumed to be the sole driving force for a typical basaltic magma on Mars, the summits of the four large Montes volcanoes indicate their sources lie at depths >120 km, potentially implying a thick lithosphere in the Tharsis region. Interestingly, older Martian volcanoes generally display reduced relief (when compared to the Tharsis shields), so lithospheric thickness may have increased throughout Martian history. When combined with the lack of any obvious nearby plate tectonic features such as subduction arcs or transform faults, the great bulk of these mountains may result from mantle sources that released their magma at one location without the lithospheric movement we associate with plate tectonics on Earth. In this light, it is interesting that the volume of Olympus Mons is roughly comparable to the integrated volume of the Hawaiian-Emperor seamounts. The descriptor

“Mons” refers to a large isolated mountain, and all four Tharsis shield volcanoes clearly deserve this designation.

The lower flanks of the Tharsis Montes have been buried by plains-forming flows emanating from the volcanoes themselves or vents in between them. Only Olympus Mons is surrounded by an arcuate scarp nearly 600 km in diameter and with 3–6 km of vertical relief (Fig. 2). The origin of the basal scarp at Olympus Mons remains controversial, but several enormous fan-shaped deposits northwest of the volcano have been interpreted to be gravitationally driven landslides, perhaps aided by volatile lubrication along the detachment surface. High-resolution Viking images show multitudes of interwoven lava flows extending down the flanks of Olympus Mons and over the basal scarp, spilling onto the surrounding plains. Many of the individual flows have medial channels similar to channel-fed lava flows on terrestrial volcanoes. Thermal infrared data indicate that all four of the volcanoes are thoroughly coated with fine windblown dust, severely limiting any information about the volcanic rocks that can be learned from most remote-sensing techniques.

As noted earlier, all four shield volcanoes are surmounted by summit calderas. Olympus and Ascraeus Montes have complex calderas revealing multiple episodes of collapse whereas Arsia and Pavonis Montes have only a single collapse rim preserved at present. Geophysical modeling of fractures around the caldera on Olympus Mons verifies that these features are consistent with collapse into evacuated magma reservoirs within the shield construct. By analogy to terrestrial shield volcanoes, these intermediate magma chambers may have been periodically replenished from a larger magma source located beneath the volcanic pile.

A separate volcanic center with its own crustal bulge (but one considerably smaller than the Tharsis Bulge) is present in the Elysium region (11 in Fig. 1). Elysium Mons is the largest construct in the region, and it has some important distinctions from the four Tharsis shield volcanoes. Elysium Mons has considerably steeper flank slopes (up to 12°) than the Tharsis shields, surmounted with one major caldera (although the floor preserves subtle details that suggest repeated collapse prior to the last lava infilling). The shape of Elysium Mons is somewhat reminiscent of conical composite volcanoes typical of subduction margins such as the Andes or the Cascades, but there are no associated features (such as a nearby trench) to indicate that subduction is in any way responsible for this Martian volcano. Following Mariner 9, Elysium Mons was compared to the volcano Tibesti in Africa, where an intracontinental hot spot is a more likely analog than an active plate margin. While

there are some vocal supporters of possible subduction on Mars, the consensus impression since Mariner 9 has been the apparent dearth, if not total absence, of any classic plate tectonic features on Mars.

Alba Patera, north of the three Tharsis Montes (1 in Fig. 1), represents another important exception to the broad shield morphology. This volcano is only slightly smaller in horizontal dimension than Olympus Mons, but it lacks the dramatic relief present on the Tharsis shields and Elysium Mons (Table I). Early results from the Mars Orbital Laser Altimeter on the Mars Global Surveyor spacecraft indicate that this volcano has flank slopes  $\leq 1^\circ$ , much less than the already shallow  $5^\circ$  flanks of the shield volcanoes. Even more unique is a band of dense fractures that makes almost a complete ring around this shallow-sloped construct. Some researchers have compared this tectonic pattern to that which would surround a core of competent rock that is subjected to intense regional stress; such an interpretation would imply that Alba Patera was completely solidified well before the regional stress pattern was imposed. Crater densities indicate that Alba Patera has been exposed to the impacting bombardment longer than either the Tharsis shields or Elysium Mons, but some volcanic effusion may have postdated the stress that produced the distinctive arcuate band. Recently, it was proposed that Alba Patera may be a Martian example of a Venusian corona (see "Volcanism on Venus"); such an interpretation has profound implications for crustal thicknesses on Mars during an epoch when other comparable thin-lithosphere features are not readily apparent. As we shall see next, Alba Patera is not representative of the majority of features that have been given the name "patera."

#### IV. PATERAE AND THOLI

Alba Patera is the largest member of a class of volcanic construct on Mars that is quite distinct from the Mons-type volcanoes. The descriptor "Patera" refers to an irregular or complex crater with scalloped edges that is surrounded by shallow flank slopes. These features contrast greatly with impact craters or basins of comparable size, and a volcanic caldera is the consensus interpretation. Another distinctive class of volcanic construct, which is consistently smaller than the Mons type, has the descriptor "Tholus" applied to an isolated domical small mountain or hill, usually with slopes much steeper than those of a patera. Both Paterae and Tholi (other

than Alba Patera discussed above) are generally smaller than 200 km in diameter (Table II).

Paterae in the Tharsis region (7, 21, and 22 in Fig. 1) tend to have caldera diameters more than half as broad as the overall construct. This observation led some researchers to conclude that such paterae may be the summits of shield volcanoes whose lower flanks have been buried by more recent volcanic plains, which seems quite reasonable for the Tharsis region, where volcanic plains are abundant and likely quite thick. Tholi in the Tharsis region (8, 12, 19, and 23 in Fig. 1) tend to have slopes steeper than those of the shields but usually not as steep as Elysium Mons. Some volcanoes (e.g., Ceraunius Tholus) have sinuous channels carved into their flanks, implying significant effusive (and erosive) flow after the bulk of the construct formed (Fig. 3). A few researchers have interpreted the erosive channels on tholi and paterae flanks to be due to pyroclastic flows. The buried-

**FIGURE 3** Ceraunius Tholus, a volcanic dome with an elongate crater from an oblique impact at its northern base (8 in Fig. 1 and Table I). The volcano is noncircular, with dimensions 150  $\times$  100 km. At least one sinuous channel carved into the volcano was active after the oblique impact since a riverlike "delta" formed in the crater where its rim was breached by the lava channel. (Viking Orbiter image 516A24, courtesy of NASA.)

shield interpretation for paterae has difficulty accounting for the close proximity of both broad patera and steep tholus in the Tharsis region (8, 22, and 23 in Fig. 1), where the tholi volcanoes may indicate either effusive or compositional properties quite different from those of paterae volcanoes.

The Elysium region has paterae and tholi as well, although fewer than in the Tharsis region (2, 4, and 9 in Fig. 1). These volcanoes have both scoured flanks and, on Hecates Tholus, a portion of the summit area where very few impact craters are preserved. Both characteristics have been interpreted to result from pyroclastic activity: erosive pyroclastic flows to generate the flank scours and an inferred ash deposit following a plinian-style eruption at the summit of Hecates Tholus. Neither of these interpretations should be considered proof of pyroclastic activity, but they do suggest an increased possibility for a pyroclastic component associated with paterae- and tholi-style eruptions, as compared to Mons-style volcanoes.

## V. HIGHLAND PATERAE

Paterae located in the cratered highlands of Mars deserve special treatment because they appear to have several characteristics distinct from those of the small volcanoes in the Tharsis and Elysium regions. The highland paterae are concentrated in two regions: a linear trend of four volcanoes on the outer rim of the Hellas impact basin in the southern hemisphere (3, 10, 17, and 20 in Fig. 1), and two vents relatively recently identified within the classical dark region of Syrtis Major in the northern hemisphere (13 and 14 in Fig. 1). Both regions include evidence that suggests that pyroclastic materials comprise an important fraction of the products produced by these highland paterae, suggesting that volcanism in the highlands may have involved eruptions fundamentally different from those that produced the broad Mons volcanoes, the shallow paterae, or the steep tholi.

The four paterae on the rim of the Hellas basin are notable in that all possess very shallow flank slopes, likely much less than the shallow 1° flanks of Alba Patera. The Hellas volcanoes are more noteworthy for their intensely eroded appearance than for any obvious construct around the central vent (Fig. 4). The channels cut deeply into the flanks of the Hellas paterae have been interpreted to indicate removal of friable material concentrated around the central vent, possibly through either fluvial or volcanic processes, or both. The logical

**FIGURE 4** Tyrrhena Patera, one of the low-profile paterae in the southern highlands near the rim of the Hellas impact basin (20 in Fig. 1 and Table I). The radiating pattern of channels has eroded into material ~180 km in diameter, interpreted to be ash deposited around the volcanic vent. (Viking Orbiter image 87A14, courtesy of NASA.)

way to build up a broad low-profile deposit of friable materials around a volcanic vent is through deposition of pyroclastics. Currently, it is not clear if pyroclastic flows or falls are the dominant agent for emplacement of the ash, and both processes appear to be viable candidates. What is apparently rare at these volcanoes is a significant effusive lava flow component. The top of the friable deposit at each volcano appears to be more competent, forming a caprock between channels eroded into the deposit; this resistant zone may be case-hardened or indurated friable materials, or it may involve some effusive lava flows, but this is difficult to resolve with current data. All four Hellas volcanoes represent a substantially different style of eruption and emplacement than the other central volcanoes discussed above, suggestive that the magma involved may have somehow been different (increased volatile content?) from the effusive lavas that dominate the more recent Martian volcanoes.

Nili and Meroe Paterae were only recognized as being volcanic vents in the 1980s, long after Mariner 9 and the early Viking images established the presence and types of the other volcanic centers. Both paterae are

near the center of the Syrtis Major dark region that has been observed telescopically from Earth for several centuries. Remote-sensing data of the Syrtis Major region indicate the dark materials are significantly less oxidized than the bright dusty portions of the planet, with strong indications of a mafic chemistry that likely includes a pyroxene component. When the volcanic vents were identified, researchers proposed that the dark material in Syrtis Major may in fact be wind-transported mafic volcanic ash. Viking images in Syrtis Major reveal abundant dark dunelike features, supporting the concept that wind action is crucial to the story of this area. The action of the wind on the individual ash particles may help to remove an oxidation coating as the grains bounce into each other.

#### VI. SMALL CONSTRUCTS

Mars has numerous occurrences of small domes, some of which may have a volcanic origin. Unfortunately, these features are mostly small enough that Viking imaging data are not sufficient to provide definitive evidence for their origin. One of these features that is big enough to show some important physical characteristics is found in the Tempe region, within a zone of fractures called Tempe Fossae (Fig. 5). Here an oblong low mound is present around an elongated summit depression (between the arrows in Fig. 5). The depression follows the trend of the surrounding fractures, so that structural control likely played a role in determining where vented materials could reach the surface. The vast majority of these features are smaller than the Tempe example; typically, the individual domes are  $<1$  km in diameter and at most a few hundred meters in height. A popular interpretation of their origin is that of cinder cones, with the variation that some may be pseudocraters where a lava flow interacted with either a shallow water layer or wet sediments. There are literally thousands of these features in various places throughout the northern lowlands of Vastitas Borealis (Fig. 1), so that either a cinder cone or pseudocrater origin would imply abundant water–lava interaction across the northern plains. An alternative nonvolcanic interpretation is a periglacial feature such as a pingo (an ice-cored mound).

The final category of distinct volcanic landforms on Mars consists of about two dozen deeply dissected conical hills scattered throughout the highlands. These features typically are  $<30$  km in diameter and were only recognized as potentially of volcanic origin through

**FIGURE 5** Small volcano (between arrows) located along Tempe Fossae (18 in Fig. 1 and Table I). Solar illumination from the left indicates an elongate mound built up around a very elliptical depression, probably analogous to a Strombolian eruption along a linear vent. The feature is  $\sim 3$  km in length and likely  $<300$  m in vertical relief. (Viking Orbiter image 627A28, courtesy of NASA.)

careful study of the extensive Viking database. There are no names given to these features, nor is there any obvious pattern to their occurrence throughout the highlands. The dominant characteristic is deep scours present on all of their flanks, similar to the scoured exteriors of some paterae that are thought to have been subjected to pyroclastic flows. Assuming they are volcanic in origin, they appear to represent yet another distinct style of volcanic deposit confined to the old densely cratered highlands of Mars. The eroded domical hills cannot be dated by crater density due to their small areal extent, but their presence solely within the ancient materials of the cratered highlands leads most researchers to assume an old age for these features.

#### VII. VOLCANIC PLAINS

Volcanic plains comprise some of the most extensive geologic units on Mars outside of the cratered highlands. The plains tend to be quite featureless at moderate to

low resolution, but in high-resolution images, these plains display numerous lobate margins surrounding individual packages of material that appear to have been emplaced through flow of fluid materials (Fig. 6). The lobate margins are sufficiently thick (various measurements indicate lobe thicknesses of tens to hundreds of meters) that the flowing material is widely accepted to be lava rather than something like a water-rich debris flow. Volcanic plains surround both the Tharsis and Elysium volcanic centers, and a stacked sequence of such flows likely accounts for a significant part of the topographic bulges surrounding these centers. Volcanic plains also comprise regionally extensive units in locations that presently do not have visible volcanic constructs. In particular, the plains of the Lunae Planum area east of the Tharsis region and the Hesperia Planum plains northeast of the Hellas basin extend over many thousands of kilometers, and both of these plains have crater densities that indicate a Hesperian age that must be older than the volcanic plains around Tharsis and Elysium. Thus substantial outpourings of plains-forming lava flows, likely from vents that are themselves buried beneath the thick pile of flows, were significant events during both the Hesperian and Amazonian epochs.

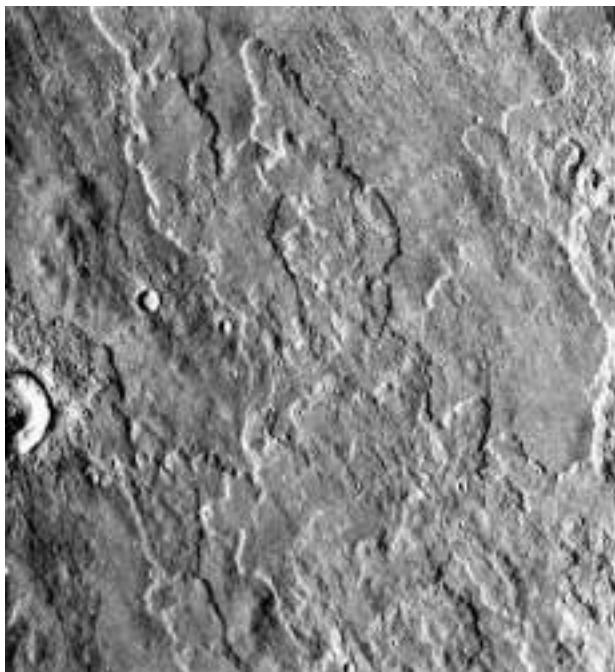

FIGURE 6 Lava flow margins on the Elysium plains near Hecates Tholus. Image width ~54 km, centered on 32.2°N, 213.5°W. (Viking Orbiter image 651A10, courtesy of NASA.)

The volcanic plains of Mars display flow features that can be divided into at least two broad categories: simple and complex. This distinction follows from an extension of George Walker's classification of terrestrial lava flows by the cooling units preserved in the volcanic sequence, with simple flows representing a single cooling unit of great extent (and probable large volume of effusion) and complex flows representing an intermixed sequence of discrete flow lobes that each comprise individual cooling units. Some plains units are nearly featureless in terms of detail visible in even the highest resolution orbital images, and many of these plains units may eventually turn out to be volcanic in origin, even though at present they are not readily placed within the simple or complex designation. Many of the volcanic plains that fill the floors of impact basins (like Hellas) or that lack clearly resolvable individual flows over wide areas are considered to be simple in the sense that the volcanic emplacement most likely was sufficiently rapid or prolonged to allow the plains to be considered as representing one major cooling unit. The younger volcanic plains around Tharsis and Elysium are primarily complex (as in Fig. 6), with numerous finger-like flow lobes traceable in some cases for many hundreds of kilometers. As orbital image resolution improves, as with the Mars Orbiter Camera on the Mars Global Surveyor spacecraft, some of the older volcanic plains likely may turn out to be made up of a series of complex flow lobes like the ones that surround Tharsis and Elysium.

Not surprisingly, some plains units are problematic in origin. These units tend either to be relatively featureless or to have such complicated surface exposures that their origin remains the subject of considerable controversy. The Medusae Fossae Formation southwest of the Tharsis region (MFF in Fig. 1) deserves a brief discussion here because although its origin remains controversial, one of the contending hypotheses is that this material is the result of massive pyroclastic eruptions. The Medusae Fossae Formation consists of several discrete layers of material that is very friable (eroded by the wind into huge fields of yardangs) but locally prominent caprock units help preserve the underlying materials. This observation has been compared to the welded and nonwelded zones present within many ignimbrite deposits on Earth. A significant problem with this hypothesis is that there is no indication of the possible source vent or vents, which is troubling if volcanic eruptions laid down ash that in places is over 2 km thick and that extends over several million square kilometers along the Martian equator, following the boundary between the southern cratered highlands and the northern lowland plains. The prospect of large ash-producing eruptions in

this part of the planet is strengthened by recent remote-sensing observations that an area west of Arsia Mons and east of the majority of the Medusae Fossae Formation displays the unique property that Earth-based radar signals are not reflected from this broad area. "Stealth" has been interpreted to be associated with pyroclastic eruptions from vents west of the Arsia Mons volcano, which lends some support to possible major ignimbrite eruptions in the area.

### VIII. COMPOSITIONAL CONSTRAINTS

Compositional information for Mars is available from three different sources: remote-sensing data (from either spacecraft instruments or Earth-based telescopes), on-site analyses by instruments on spacecraft that have returned data from three landing sites on Mars, and a special group of meteorites for which there is compelling evidence that these rocks were blasted from the surface of Mars and eventually fell to Earth. Each of these data sources has unique advantages and disadvantages as well as various limitations to the utility of the data. Here we will explore each data type for its implications for volcanic materials on Mars.

Remote-sensing studies of Mars began with telescopic measurements of various properties of the Martian surface and atmosphere, and since the 1960s these data have been augmented with higher spatial resolution data from a host of instruments on spacecraft that either flew by or orbited the planet. Earth-based instruments can achieve very high spectral resolution but only with relatively low spatial resolution on the planet (covering an area that may be hundreds of kilometers across). Spacecraft instruments tend to achieve substantially improved spatial resolution, but often this has come at the expense of spectral resolution. The ubiquitous Martian dust complicates this effort at any spatial resolution, masking significant portions of the surface within the instrument field of view and generally decreasing the contrast of the already subtle spectral features being sought. In spite of this handicap, remote-sensing data have shown that the dark regions of the planet have strong mafic affinities. Unfortunately, only the Syrtis Major volcanoes are present within a dark region, and the spectral information of other volcanic centers is effectively masked (at visual and thermal wavelengths) by the dust. Tens of microns of dust can strongly affect visual reflectance, and only 2 cm of dust can totally obscure even competent bedrock from thermal infrared observations.

The first concrete compositional information obtained for Martian materials came from an X-ray fluorescence instrument that was flown on both the Viking 1 and Viking 2 landers. In spite of the fact that the landers set down over 6000 km apart, the composition of the Martian fines at both sites was remarkably uniform (Table II), which in itself was a strong indication of the homogenizing influence of the regular global dust storms. Although repeated attempts were made to obtain a rock fragment with the Viking sample arm, no Martian rock was analyzed by the Viking instruments (centimeter-sized fragments all turned out to be indurated clods of dust). This situation changed dramatically in July of 1997 when the Mars Pathfinder mission successfully landed near the mouth of the Ares Vallis canyon and deployed the first mobile vehicle on Mars, the Sojourner rover. Sojourner had a spectrometer that the rover was able to place directly on several Martian rocks, as well as on the fine-grained materials between the rocks. The fines at the Pathfinder site were generally quite consistent with the fines observed at the Viking sites (Table II; note the differing sums for columns 2 and 3), but the rocks show distinct chemical differences from the fines ("Yogi" and "Barnacle Bill" in Table II). Images of the rocks at the Pathfinder site give a strong impression of being volcanic in origin, with ubiquitous pits that are likely vesicles. Assuming the rocks are volcanic, the compositions obtained from the Sojourner spectrometer imply they may be basaltic andesite. If the anomalously large sulfur content for the rocks is assumed to be contamination by dust on the rock surface, the measured silica contents become lower limits and at least some of the rocks may turn out to be andesites (e.g., "Barnacle Bill"), although recently the term Icelandite has been applied to these silica-enhanced rocks in an attempt to eliminate the subduction-related processes usually associated with the term andesite. Indeed, there is no evidence in or near the Pathfinder site for orogenic generation of andesite lavas, but fractional crystallization within isolated pockets of basaltic or basaltic andesite magmas could have generated some Icelandite-like rocks. The Pathfinder results are undergoing further refinement in association with the instrument calibration, so these results may be subject to revision at a later date.

The very best chemical information about Martian materials comes from 12 very special meteorites. These meteorites are considered to be from Mars because gases implanted in them during the shock of their ejection from their parent body is essentially identical to the atmosphere of Mars as measured by the Viking landers and unlike gases obtained from any other terrestrial or

TABLE II Chemical Compositions of Selected Martian Materials

<sup>e</sup> Total iron, regardless of oxidation state. Reported as Fe<sub>2</sub>O<sub>3</sub> for column 2 and FeO for columns 3–6.

extraterrestrial sample. Eleven are igneous in nature and are only one-third the age (1.3 Ga to 180 Ma) of practically all other meteorites, and the twelfth has an older age more typical of most meteorites. Collectively called SNC meteorites, seven are basalts or lherzolites/harzburgites like the Shergotty (S) meteorite, three are clinopyroxenites or wehrlites like Nakhla (N), Chassigny (C) is the sole dunite, and ALH84001 is a ~4.5-Ga orthopyroxenite with veins of carbonate in which are controversial features that may (or may not) be evidence of primitive life from early in Martian history.

The SNC meteorites have told us a lot about Mars in general, but we unfortunately have no evidence for where on the Martian surface they came from. The abundance of volcanic rocks among the available group is consistent with the extensive coverage of Martian volcanic plains discussed above, but the young crystallization ages cannot be used to calibrate the geologic epochs on Mars without knowledge of what specific unit they came from. Some of the nonbasaltic rocks may have come either from slowly cooled cores of thick lava flows where limited fractionation may have taken place or possibly even from a plutonic body. ALH84001 likely came from somewhere in the cratered highlands of

Mars, portions of which must date from practically the formation of the planet. In spite of this wealth of chemical detail, it will require the return of documented samples from known localities on Mars before we can relate the rock histories to regional or local geologic materials.

## IX. VOLCANIC HISTORY OF MARS

The information presented in this article can be summarized into a general picture of the volcanic history of Mars. Without constraints on the cratering record for Mars, absolute ages cannot be associated with any of these stages. However, the stratigraphy of geologic units at least gives us a fairly clear picture of how volcanic eruptions developed throughout Martian history.

The oldest terrain on Mars is the Noachian densely cratered highlands, and if ALH84001 is representative of this era, at least some magmatic activity took place during this time of intense cratering. Isolated volcanic centers developed within the cratered highlands, most of which are preserved today only as deeply scoured

small hills scattered throughout the southern highlands. The Hesperian epoch witnessed massive eruptions of fluid lava that produced volcanic plains that covered extensive portions of the Martian surface. The composition of these plains-forming materials was likely basaltic in nature, although Pathfinder results suggest that more evolved lavas (such as basaltic andesite) also may have been present. Several volcanic centers developed on the rim of the Hellas impact basin and within what is now the Syrtis Major dark region. These volcanoes involved the generation of considerable amounts of ash, leading to a very low overall profile and intense channelization by either fluvial or magmatic fluids. The unique Alba Patera feature may represent a volcano caught in the transition from the more ash-rich eruptions of the highlands to the more lava-rich eruptions typical of most subsequent eruptions.

The late-Hesperian and Amazonian epochs involved voluminous eruptions that resulted in both broad volcanic plains and numerous central volcanic constructs. Volcanic activity concentrated around the Elysium and Tharsis regions; crater densities suggest that effusive activity was most prolonged in the Tharsis region, where some volcanic surfaces are very sparsely cratered and thus may be quite young. Thousands of small domes in the northern lowland plains may be the result of either localized Strombolian activity (cinder cones) or the interaction of lava with water or wet sediments (pseudocraters). Not all of the volcanic activity in the Amazonian period may have been gentle effusion of lava; significant ash deposits may be present west of the Tharsis Montes, although the true nature of these enigmatic materials remains controversial. Volcanic materials are likely still being redistributed by current winds, such as in the Syrtis Major dark region.

#### X. FUTURE STUDIES

Several issues about Martian volcanism remain unresolved at present, and hopefully the series of missions NASA has planned for Mars over the coming years will help to address some of these questions. The Pathfinder results have raised the possibility that lavas more evolved than basalt may have been important in Martian history. If this prospect turns out to be true on a global scale, it could have a major effect on our concepts of magmatic evolution on the terrestrial planets. Similarly, the question of the abundance and origin of pyroclastic deposits on Mars remains unclear at present, but this too could

have an important influence on issues such as the volatile content of Martian magmas. The absolute age of all Martian terrains, volcanic as well as sedimentary or metamorphic in origin, remains a glaring uncertainty in all studies of the emplacement of volcanic materials on Mars. The return of documented samples from diverse localities on Mars would be the most definitive way to answer these and other outstanding questions about Martian volcanism, and fortunately NASA is actively planning toward that end. The Mars Surveyor program is an ambitious series of landers and orbiters targeted at addressing a host of science questions through repeated visits to Mars, culminating with the return of samples cached by mobile rovers. In preparation for the lander missions, sophisticated remote-sensing data will be collected from new technology sensors in orbit around Mars, as evidenced by the dramatic new data currently being returned by the Mars Global Surveyor spacecraft. All of these new data will undoubtedly add considerable detail to the volcanic history of Mars outlined in this article.

## GLOSSARY

**albedo** Reflectivity of the surface, ranging from 0 (perfectly absorbing) to 1 (perfectly reflecting), important in determining surface temperature.

**clathrates** Cage structures formed by H<sub>2</sub>O ice having 8 cavities for each 46 water molecules that can trap large “guest” molecules of nonpolar volatile gasses.

**cryoclastic eruption** Eruption of water or other liquids that is driven by the exsolution of more volatile gasses such as CO or CH<sub>4</sub> and may form frosty “ash” deposits as the liquid condenses and expands.

**cryovolcanism** Eruption of liquid or vapor phases (with or without entrained solids) of water or other volatiles that would be frozen solid at the normal temperature of an icy satellite’s surface.

**eccentricity** A measure of the ellipticity of an orbit, defined as the ratio of the distance between the two foci of the ellipse to the length of its major axis.

**inclination** Tilt of a satellite’s orbit plane with respect to the plane of the planet’s equator, important for determining seasonal variations in insolation.

**orbital period** Time taken for a satellite to complete one orbit of the planet, usually equal to the satellite’s spin period (the length of a “day”).

**orbital resonance** A commensurability between the orbits of two or more satellites, such that their orbital periods are related as the ratio of small integer numbers.

**photolysis** Dissociation of molecules by absorption of energetic photons.

**radiolysis** Dissociation of molecules by impact of charged particles.

**resurfacing** Any internal geologic process such as volcanism or tectonism that eradicates older surface features.

**solid-state greenhouse** Trapping of solar energy by ices that are transparent to visible light but opaque to longer wavelength thermal radiation.

**sputtering** Ejection of solid surface materials by the impact of energetic charged particles (an efficient erosion mechanism for satellites and rings located within planetary radiation belts).

---

## I. INTRODUCTION AND SCOPE

Cryovolcanism is the eruption of water and other liquid- or vapor-phase volatiles onto the frigid surfaces of the

icy satellites of the giant planets. It is known to occur on only one of these worlds: Triton, a moon of distant Neptune, where geyser-like plumes of nitrogen were discovered during the explorations of Voyager 2. There is indirect evidence that cryovolcanic processes may have taken place elsewhere in the outer solar system and might even be active today. In this article we examine the mechanisms and manifestations of cryovolcanism, beginning with a review of the materials that make up these unusual "magmas" and the means by which they might erupt and concluding with a volcanologist's tour of the farthest reaches of the solar system.

The Voyager spacecraft encountered a bewildering zoo among the natural satellites of Jupiter, Saturn, Uranus, and Neptune (Table I). Several are larger than our own Moon, and two (Ganymede at Jupiter and Titan at Saturn) are bigger than the planet Mercury and would be considered planets in their own right if not for the fact that they are in orbit about larger worlds. Water

ice is the most important constituent of the surfaces of most of these moons, with the notable exception of Io, where water either never was abundant or was driven off by eons of sustained geologic activity (see "Volcanism on Io"). Many of the icy satellites are heavily cratered, having surfaces that passively recorded the bombardment of impactors, undisturbed by internal activity. Others appear relatively youthful, with areas "resurfaced" so that part of the cratering record was erased by endogenic processes such as tectonism and volcanism. A focus of scientific study of these satellites is the nature of the processes by which they were resurfaced, and in fairness, it should be pointed out that our knowledge of the materials and mechanisms of this geologic activity is still somewhat rudimentary. Much of the uncertainty concerns whether the resurfacing materials were in the liquid or solid state at the time they were emplaced or deformed. By confining our attention to cryovolcanism, here defined as the extrusion of liquids and vapors of

TABLE I Physical Properties of the Larger Natural Satellites of the Outer Solar System<sup>a</sup>

<sup>a</sup> Not listed are moons smaller than about 200 km in diameter, which number at least 40. Pluto and the Earth's Moon are included for reference.

materials that would be frozen solid at the planetary surface temperatures, we deliberately exclude processes such as icy tectonism, diapirism and solid-state convection, and intrusive magmatism, which probably played important roles in resurfacing the icy satellites. This somewhat arbitrary definition calls into question whether rhyolites should be considered “volcanic,” given that they have crystal fractions sometimes exceeding 50%, but it admits an example of cryovolcanic activity here on Earth: the so-called “icefoots” on the shores of Lake Superior, where waves generated over open water in winter pump liquid water through cracks in the ice at the lake margins, forming icy mounds around the “vents.”

Two conditions must be met for cryovolcanic activity to take place on any icy moon: liquids must be generated in the interior, and the melt must then migrate to the surface of the satellite. These conditions are much more easily met on the larger satellites of the solar system than on smaller objects. A number of heating mechanisms contribute to the generation of fluids in the moons’ interiors. The most important energy sources are gravitational (due to accretion and differentiation), radiogenic (through the decay of long-lived radioisotopes), and tidal (frictional heating caused by the daily changes in the shape of the satellite). Solar heating probably drives the nitrogen plumes on Triton, and Io’s prodigious heat flow may be fueled in part by electromagnetic induction in addition to the tidal heating known to be important. The planetary factors that determine whether cryovolcanism can occur include size, composition (particularly silicate fraction, which determines radiogenic heating), location in the solar system (related both to composition and surface temperature, which ranges from 38 K at Triton up to more than 165 K in the hottest parts of Callisto), and the history of the moon’s orbit from formation through to the present. The orbital history dictates the degree of tidal heating, since the daily tidal distortions are due to noncircular or oblique orbits around the primary planet. Noncircular orbits are commonly induced by gravitational interactions with satellites on neighboring orbits, through orbital resonances that gradually increase the orbital eccentricity (Table I). For example, Jupiter’s moon Europa is caught in a tidal “tug-of-war” between Io, which orbits nearer to Jupiter with a period exactly half that of Europa, and Ganymede, which orbits farther than Europa with a period exactly twice as long. The orbital eccentricity forced by this “Laplace resonance” raises tides that may be sufficient to maintain a molten layer of liquid water beneath the satellite’s surface. Orbital obliquity (inclination of the satellite orbit with respect

to the planet’s equator) is generally the result of collision or capture, extremely energetic events that may have contributed to the melting of Triton, for example. Gravity and composition control the manner of magma ascent, as we shall see later. The morphology of lava flows and other volcanic constructs, once erupted, are influenced by magma viscosity and effusion rate in ways familiar from terrestrial experience but also by planetary factors such as gravity, surface temperature, and atmospheric pressure (for example in the case of Saturn’s moon Titan, which has an atmosphere denser than Earth’s).

---

## II. MATERIALS AND MECHANISMS

### A. Composition of Cryomagmas

Several lines of evidence provide us with incomplete and sometimes contradictory information about the composition of the outer solar system satellites. Direct spectroscopic detection is possible only for optically active materials—those with identifiable absorption features in their spectra—and tells us only about what lies on the uppermost surface, generally after processing by solar and charged-particle irradiation, sublimation, and a host of other “space-weathering” processes. Observations of the presumably “raw” icy materials seen in cometary outflows and in distant extrasolar nebulae provide important added constraints. Satellite densities and moments of inertia determined from gravitational measurements allow us to infer their interior structures and place limits on bulk composition and degree of differentiation. Theoretical modeling, constrained by samples of unprocessed protoplanetary materials in the form of primitive meteorites known as carbonaceous chondrites, provides some of the most valuable clues. Fundamental to the understanding of the icy satellites’ composition is the idea of equilibrium condensation: the notion that the constituents of the early protoplanetary system, initially present in cosmic relative abundances, condensed and chemically reacted in accordance with the temperatures and pressures found in their local environments, which varied with distance from the early sun and proximity to the still-forming giant gaseous planets. By these calculations a “frost line” is predicted beyond the orbit of Mars, beyond which H<sub>2</sub>O ice is expected to have condensed in abundance. Spectroscopic observations confirm that water ice is the dominant constituent of the satellites of Jupiter, Saturn, Uranus, and Pluto. Methane

and ammonia should have also been present in the high-pressure nebulae surrounding Jupiter and Saturn, while their oxidized forms (CO, CO<sub>2</sub>, and N<sub>2</sub>) were favored in the cold outermost solar system, where reactions were too sluggish to proceed to equilibrium. While not predicted by the models, compounds such as methanol (CH<sub>3</sub>OH) and formaldehyde (H<sub>2</sub>CO) are observed in comets and may be minor components of the most distant satellites. Some properties of these ices are listed in Table II.

As a geologic material, H<sub>2</sub>O has a number of unusual properties. Its common hexagonal form (ice Ih) is stable at the low pressures (a few tens of megapascals) attained in the interiors of small satellites such as Enceladus and Miranda, in the thin ice/water crust of Europa, and at depths of up to a few hundred kilometers in the larger satellites. Pressures of hundreds to thousands of megapascals are reached in the interiors of Ganymede, Callisto, and Titan, so that dense high-pressure ice polymorphs should be stable. At the opposite extreme, metastable cubic and amorphous phases of ice can be

deposited at the low temperatures (<150 K) and pressures of the icy satellite surfaces. Ice can also form solid cagelike structures known as clathrates which can trap adsorbed gasses such as CH<sub>4</sub>, CO, and N<sub>2</sub> which are too volatile to condense otherwise, except in the Neptune and Pluto systems. Unlike silicate minerals and rocks, ice Ih undergoes a volume reduction upon melting so that the liquid is denser than the solid. This presents a profound problem for cryovolcanism, since liquid water magmas should not rise through a pure water ice crust but instead are expected to sink. Water is also an extraordinary solvent, and there is an abundance of highly soluble salts (up to 20% by mass, mostly Mg and Na sulfates and sulfate hydrates) available in the chondritic materials from which the silicate fractions of the icy satellites were formed.

Melting of water-rich magmas can be greatly promoted by adding “antifreeze” in the form of salts or particularly ammonia, which should account for up to 15% of the mixture of ices from a fully equilibrated and condensed primordial nebula. Ammonia has not been detected spectroscopically on any satellite surface but is seen in comets and extrasolar nebulae and may be rapidly photolyzed to nitrogen upon exposure to the space environment. The ammonia–water system closely parallels the system MgO–SiO<sub>2</sub>, with ammonia dihydrate (NH<sub>3</sub> · 2H<sub>2</sub>O) taking the place of enstatite as the minimum-temperature melt product. Addition of ammonia to H<sub>2</sub>O ice lowers the melting point of the mixture to 176 K, conceivably attained in the interiors of even modestly sized satellites. Partial melting in the ammonia–water system slightly ameliorates the density problem of pure water magmas, since the melt is more ammonia-rich (28–34%) than its frozen equivalent, making it marginally positively buoyant with respect to the solid ice mixture. On the other hand, addition of salts to water only slightly depresses the melting point and greatly exacerbates the magma density problem, since the eutectic brines tend to sink with respect to solids of comparable composition. Fractional crystallization of brines results in segregation of salts from the solid, similar to the freezing of terrestrial ocean water, and might produce diapirism of the relatively buoyant solid H<sub>2</sub>O phase. (Sulfates rather than chlorides are expected to dominate extraterrestrial brines because of the vastly greater primordial S abundance.) Methane does not significantly lower the melting point of ice, but clathrates of methane can break down to form ice Ih and gas or fluid when the vapor pressure of the contained methane exceeds the confining pressure; at low pressures (<0.03 MPa) this can occur when methane clathrates are warmed to only 176 K by an ammonia-rich water magma. Likewise,

TABLE II Major Ices Detected or Suspected to Be Present on the Outer Solar System Satellites

Name	Formula	Freezing point (K)	Boiling point (K)
Water	H <sub>2</sub> O	273.2	373.2
Hydrogen peroxide	H <sub>2</sub> O <sub>2</sub>	272.7	Decomposes
Sulfur dioxide	SO <sub>2</sub>	200.5	263.1
Ammonia	NH <sub>3</sub>	195.5	239.8
Carbon dioxide	CO <sub>2</sub>	194.7	Sublimes
Hydrogen sulfide	H <sub>2</sub> S	190.3	211.4
Formaldehyde	H <sub>2</sub> CO	181.2	252.2
Methanol	CH <sub>3</sub> OH	175.4	337.8
Methane	CH <sub>4</sub>	90.7	111.7
Ozone	O <sub>3</sub>	80.7	161.3
Carbon monoxide	CO	68.1	81.6
Nitrogen	N <sub>2</sub>	63.3	77.4
Oxygen	O <sub>2</sub>	54.8	90.2

<sup>a</sup> H<sub>2</sub>O, NH<sub>3</sub>, CH<sub>4</sub>, and H<sub>2</sub>S (the reduced forms of the common elements O, N, C, and S) are expected to make up the bulk of ices condensed from a hydrogen-rich nebula in equilibrium. The other species may have been produced by disequilibrium condensation or by photolysis and radiolysis. The freezing and boiling points listed are for a pressure of 1 bar (0.1 MPa).

methane marginally reduces the melting point of nitrogen on Triton to a chilly 62 K.

The plausible candidate cryomagmas cover a range of viscosities and densities that can be compared with those of silicates (Figs. 1 and 2). Briny solutions at their melting points are many orders of magnitude less viscous than even the most fluid silicate lavas and are unlikely to construct observable topography. Ammonia–water liquids attain viscosities similar to those of silicate magmas and may form solid crusts and partially crystalline slurries that aid their ability to build flow fronts and other constructive features found in terrestrial volcanism. The liquid/solid density contrasts that drive silicate volcanism reach up to 15% (in the case of perido-

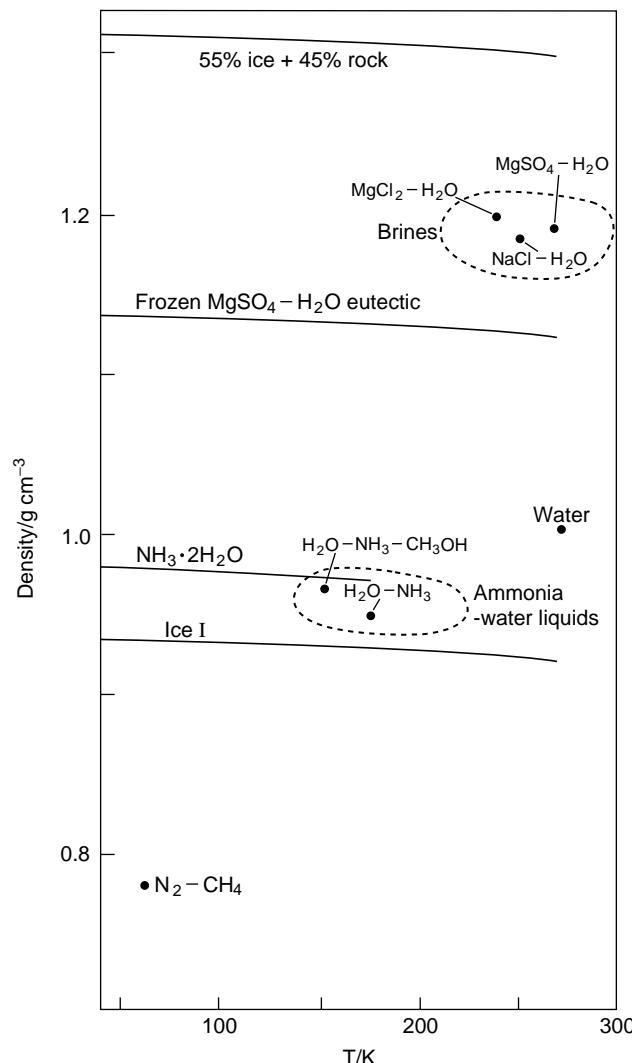

FIGURE 1 Densities of candidate cryomagmas and solids as a function of temperature. (From Kargel, 1990.)

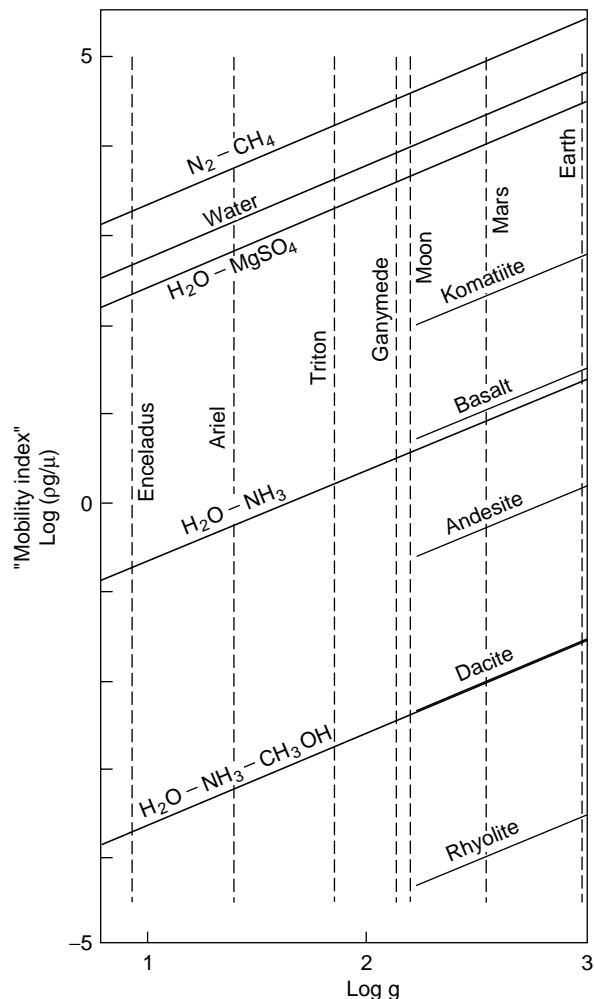

FIGURE 2 Mobilities of crystal-free cryomagmas at their liquidus temperatures compared with those of silicate lavas. (From Kargel, 1990.)

mite), whereas a paltry 1% expansion is achieved in the best case by the melting of ammonia dihydrate. Moreover, the surface layers may be rather porous due to fragmentation by repeated impacts. The ascent of cryomagmas must be assisted by increasing the density of the crust, by pressurizing the liquid lavas, or by even more exotic means.

## B. Eruptive Processes

Cryovolcanism may have been common early in the histories of the icy satellites, while their primordial surfaces were still rich in rocky material prior to differentia-

tion. Even dense brines would have been positively buoyant with respect to sufficiently silicate-rich crusts. Magmas may have migrated upward along fluid-filled fractures and faults, much the same way as crevasses in terrestrial glaciers allow ponded water to sink downward through the ice, the cracks closing again afterward. In such a situation the effects of gravity control the mechanics of the eruption: the low gravity of the small satellites results in slower ascent speeds and lower effusion rates, but greater eruption volumes, than their counterparts on the larger icy moons (because of the larger crack depths possible on smaller objects). This early volcanism would have been a self-limiting process, shutting itself off after crustal composition and density stratification were achieved.

Other ways to overcome the magma density problem are to overpressurize the liquid or add volatiles to provide effervescence for the eruption. Overpressurization can happen in the late stages of satellite evolution by the cooling and freezing of a subsurface liquid layer.

The volume expansion due to freezing of water can then fracture the surface and expel the last melt like an artesian spring. This is an attractive mechanism since much of the tectonism observed on the outer solar system satellites is attributed to global expansion, perhaps in such episodes of freezing. Alternatively, ices can be superheated by volcanism in the underlying silicates or by solar insolation, the latter being the probable explanation for Triton's geysers. The likely incorporation of supervolatiles into solid ice clathrates suggests the possibility of gas-driven cryovolcanism, the icy analog of terrestrial pyroclastic eruptions. The physics of these putative phenomena (dubbed "cryoclastic" eruptions) is similar to explosive volcanism on Earth, with methane and CO taking on the roles of H<sub>2</sub>O, CO<sub>2</sub>, and SO<sub>2</sub>.

Other processes, not yet theoretically explored, have also been suggested to contribute to the widespread resurfacing of the outer solar system satellites described in the next section. Fluids could be derived from pressure-release melting in the course of solid-state convec-

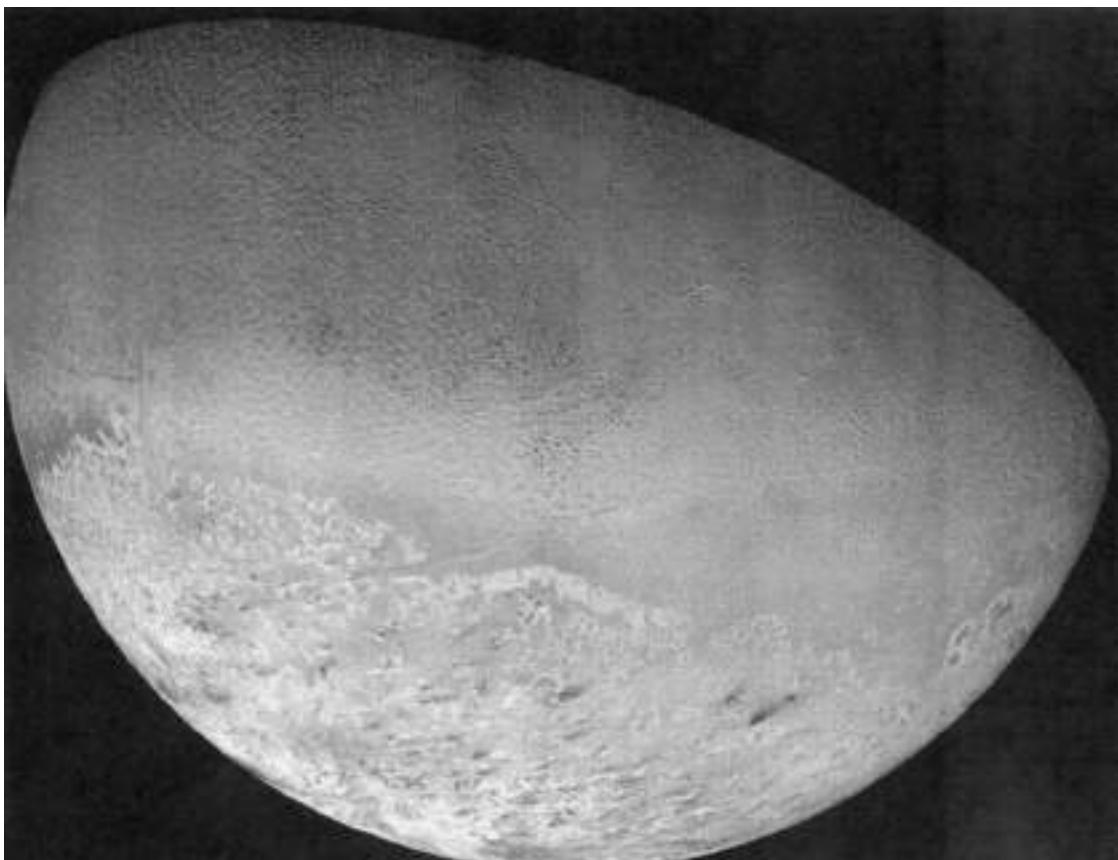

FIGURE 3 Triton. This is a view of the south pole of Neptune's only planet-sized moon. The bright polar cap is made up of relatively mobile N<sub>2</sub> ice, subliming in the summer sunshine. The dark streaks mark the sites of active or recent plumes. (Voyager 2 image mosaic, courtesy of NASA.)

tion, provided that the composition of the convecting material differs from H<sub>2</sub>O ice Ih (which has the opposite behavior with respect to pressure). A mechanism of mechanical pumping of wet slurries from the interior has been proposed to account for the curious double ridges of Europa. In all cases, the liquids reaching the surface would be subjected to instantaneous freezing and boiling at the cryogenic temperatures and near-vacuum of the space environment. A solid crust that is meters in thickness would form within hours of such an eruption, but not before the surface surrounding the vent was painted with frost deposits (along with any entrained contaminants) that could be quite extensive under the low gravity of small satellites.

pole every Triton-year, keeping the surface nearly isothermal.

Triton's "geysers" (Fig. 4) are probably caused by solar sublimation of the polar cap, despite the fact that the satellite is so distant that the Sun would merely appear as a particularly bright star. Triton's year is about 165 Earth-years long, and it was just approaching southern summer solstice at the time of the Voyager flyby. Triton's orbit is oblique with respect to Neptune's equator, and it is retrograde (opposite to the planet's spin direction), indicating that the satellite did not form anywhere in the vicinity of Neptune. Because of its obliquity, the orbit precesses every 688 Earth-years, causing the latitude of the subsolar point (the tropics)

### III. TRITON

Active volcanic venting was observed in the last place one would expect to find it. Triton is the coldest and most distant of the moons yet visited by spacecraft, and the last to be imaged before Voyager 2 was hurled out of the solar system on August 25, 1989. In stereo pictures taken as the spacecraft passed under the south pole of the satellite, at least two plumes can be seen jetting from the surface to heights up to 8 km, with trails reaching 150 km downwind. More than 100 dark windblown streaks decorate the polar cap (Fig. 3), testifying to widespread previous plume activity. At lower latitudes, an even more interesting episode earlier in the moon's history is suggested by bizarre "cantaloupe" terrain and flowlike features that may have resulted from volcanic flooding of older surface topography. Triton's north polar region was shrouded in darkness from Voyager's cameras and remains unknown.

At 38 K, Triton's surface temperature is well below the freezing point of nitrogen, the material that makes up the south polar cap. It is near the transition temperature for stability of the cubic and hexagonal forms of nitrogen ice, suggesting that seasonal phase changes are possible. Both N<sub>2</sub> and CH<sub>4</sub> have been spectrally identified on its surface, and CO and CO<sub>2</sub> ices have been detected in minor quantities. H<sub>2</sub>O is also expected to be abundant in the crust, but its spectral signature is masked by the more volatile surface constituents. Triton's thin (14  $\mu$ bar) atmosphere is made up largely of nitrogen vapor with clouds of N<sub>2</sub> ice crystals and traces of CH<sub>4</sub> and CO and is responsible for transporting a couple of meters thickness of nitrogen ice from pole to

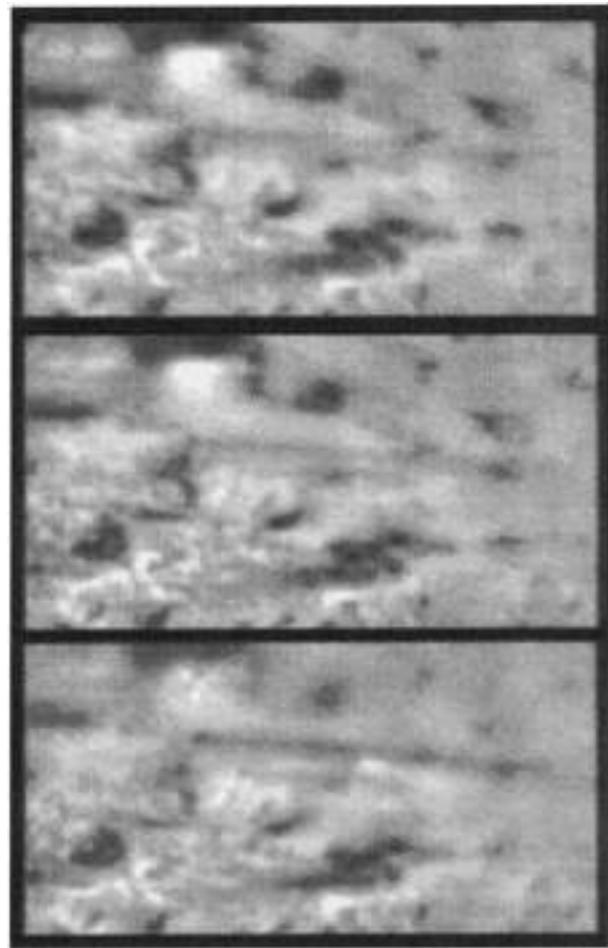

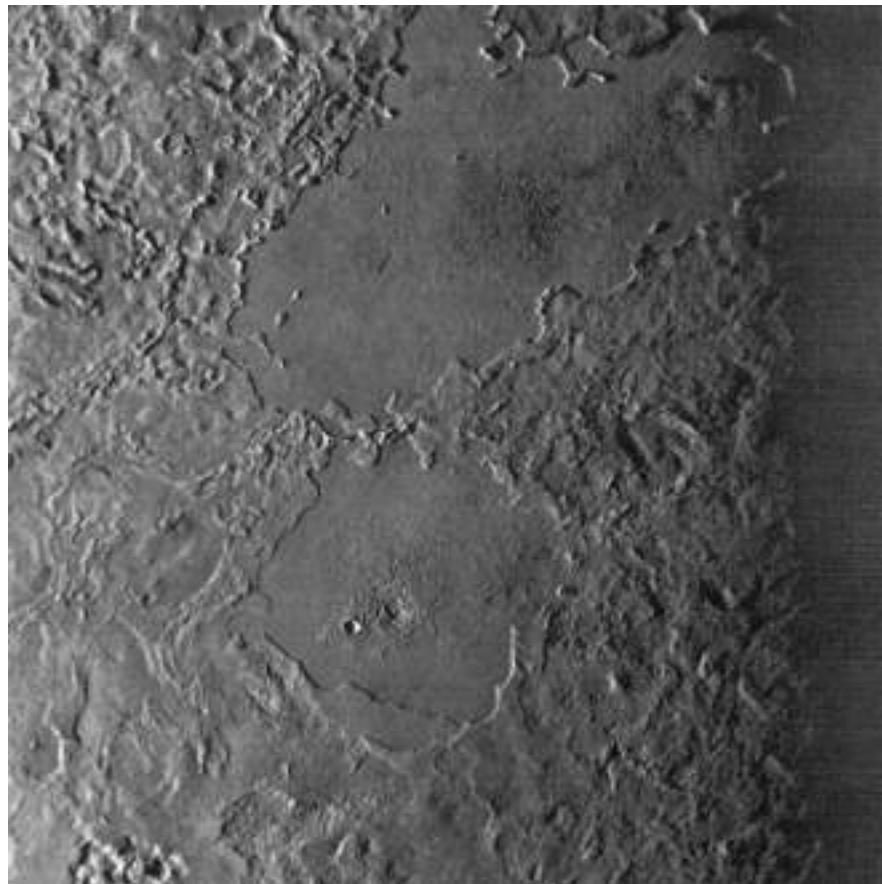

FIGURE 4 Nitrogen geyser on Triton. Two active plumes have been definitively identified in Voyager stereo pictures, and several more are possible. This is Mahilani, located at 49°S, 2°E. In these three separate views, Mahilani (left) can be seen to rise 8 km from the surface, with a dark tail that extends 150 km downwind (toward the right). (Voyager 2 images, courtesy of NASA.)

to vary from year to year, with periodic excursions up to  $55^{\circ}$  from the equator. It happens that Voyager visited on one of these extreme years, while the Sun beat down on the seldom-illuminated polar reaches of Triton.

All of the active plumes identified on Triton are found between  $49^{\circ}\text{S}$  and  $67^{\circ}\text{S}$ , near the latitude of the subsolar point. One model of their eruption suggests a solar “solid-state greenhouse” in which sunlight penetrates a transparent layer of low-thermal-conductivity nitrogen ice but is absorbed and trapped by dark carbon-rich impurities a few meters beneath the surface. This mild heating is enough to induce explosive venting of the gas, since an increase of only 10 K above the surface temperature is sufficient to raise the vapor pressure of  $\text{N}_2$  100-fold. The wind streaks are likely caused by circulation in the tenuous atmosphere, as the flow from the south toward the colder northern hemisphere is deflected by coriolis forces eastward, due to the satellite’s

retrograde rotation. Photolysis products of methane might make up the carbon-rich absorbers and the dark particulates of the “cryoclastic” wind streaks.

A young, sparsely cratered surface is visible to the north of the polar cap, particularly on the leading hemisphere. About a third of the imaged area is imprinted with regular quasi-circular depressions bounded by ridges, nicknamed “cantaloupe terrain,” which may be the surface manifestation of diapirism or solid-state convection in the interior. In other places, older cratered terrain was resurfaced by seemingly liquid or ductile material that flooded craters and other low-lying topography (Fig. 5). The source of the material could be four large depressions up to 200 km across that resemble terrestrial calderas. Steep scarps on the flows suggest that they are made up of relatively refractory  $\text{H}_2\text{O}$  ice, since little topography can be supported by solid nitrogen over geologic timescales, even under Triton’s low

**FIGURE 5** Cryovolcanic flows on Triton. The least ambiguous example of cryovolcanism in the solar system, Triton shows evidence of extensive melting, perhaps when the moon was gravitationally captured into orbit about Neptune. This view shows two large caldera-like features near the equator. Rimless pits to the right of the impact crater (in the lower “lake”) may be the source of the smooth materials. (Voyager 2 image, courtesy of NASA.)

gravity. If these interpretations are correct, an episode of intense heating must have taken place in the past in order to stir up the icy interior and produce water- or ammonia-rich melts. Enormously energetic heating probably occurred when Triton was captured into Neptune's orbit, perhaps by gas drag in Neptune's extended atmosphere or by collision with another satellite. Most of this energy was dissipated within Triton's first orbit around the planet, but a good deal of heating took place soon afterward as its initially elliptical orbit was circularized by tidal friction. Triton's likely origin is from far beyond Neptune in the Kuiper Belt, the outer solar system counterpart to the asteroid belt, home of the Pluto–Charon system and the likely source of short-period comets. Triton could be compositionally similar to Pluto and its large moon Charon and potentially provides us with an indirect look at these so far unseen worlds.

#### IV. MOONS OF URANUS

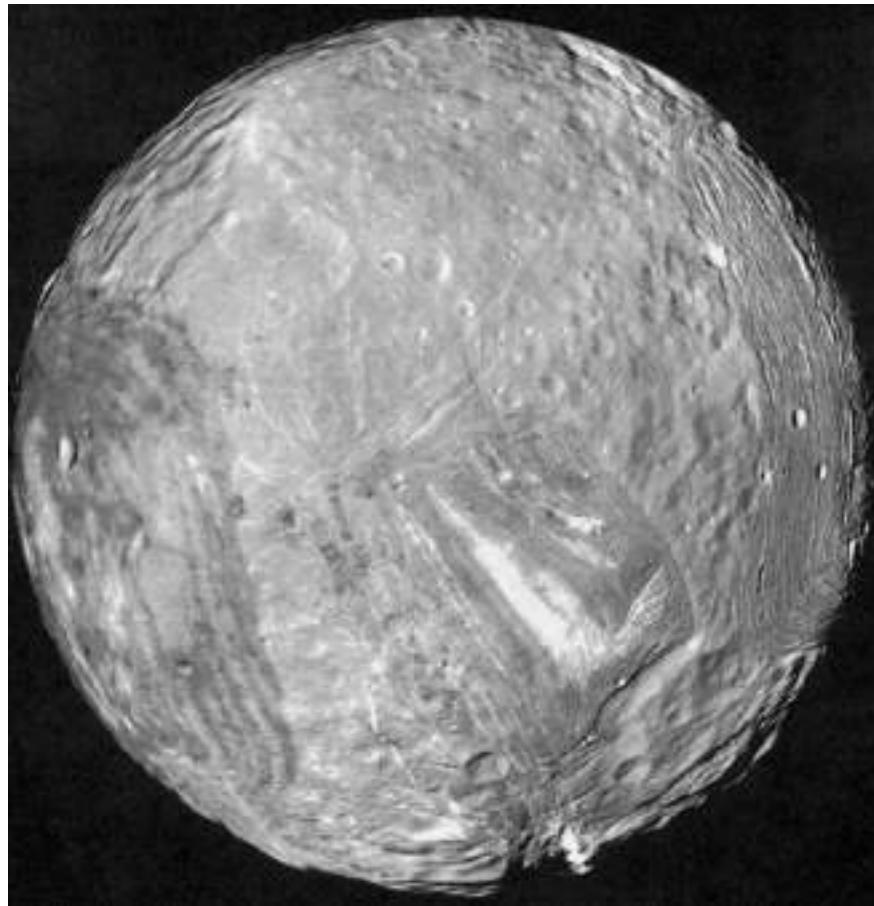

Prior to the Voyager encounter in January 1986, the moons of Uranus were thought too small to have any signs of geologic activity on their surfaces. To explain the extensive resurfacing seen on such small satellites as Miranda, only 242 km in diameter, requires exotic compositions and such violent mechanisms as catastrophic disruption. Titania, the largest uranian moon, is rifted by a system of planet-sized fissures that form 20- to 75-km-wide grabens up to 1500 km long with fault scarps 2–5 km high. Umbriel and Oberon are both heavily cratered and show no indications of internal activity. Only about 35% of Ariel was imaged by Voyager 2, but its surface has the lowest crater density of the uranian satellites. Ariel appears to have been active in the past, with broad grabens similar to those of Titania, suggesting an episode of crustal extension brought about by global expansion, despinning, or relaxation of the satellites' tidal bulges. These grabens appear floored by possible volcanic flows. Smooth deposits within the grabens show flow features such as sinuous medial grooves that appear similar in morphology to familiar lava tubes and channels (Fig. 6). Material spilling out from the ends of the grabens seems to have flooded older cratered terrain, including a 30-km-diameter crater now half buried. The flows show substantial relief, suggesting that the resurfacing material was fairly viscous at the time it was emplaced. Based on the cross sections of the kilometer-thick putative flows, the rheology seems

FIGURE 6 Ductile material on Ariel. The central channels (right) resemble collapsed lava tubes. Arrow indicates a 30-km-diameter crater now half buried by viscous flows. (Voyager 2 image, courtesy of NASA.)

similar to that of terrestrial dacitic to rhyolitic magmas. The flow morphologies would seem to require an ammonia-rich composition, at least partially solidified, perhaps with methanol or some similar material added to thicken the soup.

Miranda's surface is astonishingly complex for such a tiny moon. Three unique tectonic structures are seen on the hemisphere viewed at close range by Voyager (Fig. 7). These so-called coronae consist of central chaotically deformed regions with patchy albedo markings, ringed by broad belts of concentric parallel faults and ridges. A steep fault scarp 10 km high can be seen near Inverness Corona, the chevron-shaped feature near the middle of the picture. All three coronae are large in comparison to the radius of Miranda and seem to reflect some planetary process not active on other solar system objects. One interesting hypothesis is that Miranda might have been disrupted by a catastrophic collision with another satellite and later reaccreted in a haphazard fashion, leaving dense materials on its surface and trapping lighter ices in the interior. Some time after reassembly, these density differences drove solid-state flow

**FIGURE 7** Miranda. The tectonic features (from left to right: Arden, Inverness, and Elsinore Coronae) appear to be due to density instabilities, despite the fact that the tiny satellite has little gravity to drive such deformation. (Voyager 2 image mosaic, courtesy A. Tayfun Oner.)

in the ice to produce the observed surface features through diapirism or subsidence as heavy materials sank to the center. Liquids may also have been generated in the process, if two small smooth areas in Elsinore Corona are cryovolcanic flows as has been suggested. Despite the vast difference in size, Miranda resembles giant Ganymede in having ancient heavily cratered terrain that has been partly resurfaced by tectonic deformation on a planetary scale.

#### V. SATURNIAN SATELLITES

Only slightly larger than Miranda, Saturn's moon Enceladus also shows evidence of extensive resurfacing and, paradoxically, is considered a prime candidate for cur-

rent activity despite its diminutive size. It has the highest albedo of any solar system satellite (comparable to that of freshly fallen snow) and has a surface composition of nearly pure H<sub>2</sub>O frost. These fresh frost deposits are the first clue of recent or active cryovolcanism, since the satellite must be continually bombarded by cometary impactors that contaminate and darken the surface over time. Large areas of the satellite appear smooth and uncratered and have clearly been erased by internal tectonic or volcanic activity (Fig. 8). Narrow fractures cut across the crust, including a prominent strike-slip fault visible in the lower part of the picture. The energy source for all this activity is puzzling—like Miranda, Enceladus is too small for gravitational or radiogenic heating to have been effective. Tidal heating due to its present-day orbital resonance with Mimas is not sufficient to account for the heating, but resonant orbits with other satellites in the past may have been more

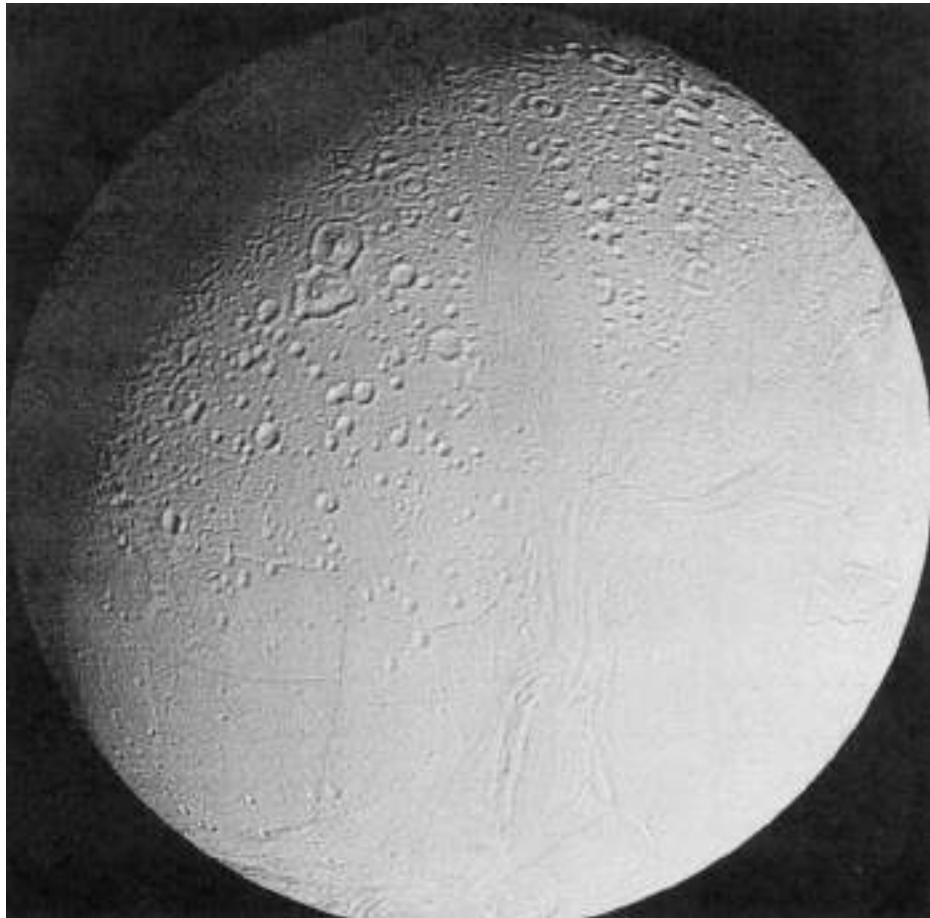

FIGURE 8 Enceladus. Is its snow-white surface the source of the E-ring particles, or the result of them? (Voyager 2 image, courtesy of NASA.)

efficient. Interestingly, Enceladus appears to be the source of the particles that make up the outermost member of Saturn's famous ring system. The faint E ring extends from 3 to 8 Saturn radii from the planet, and the orbit of Enceladus is embedded within the ring's densest part. Ice crystals in the ring are rapidly eroded by charged-particle sputtering and are swept up by Enceladus or gravitationally scattered into unstable orbits and escape the ring. The dynamical lifetime of the E ring is thought to be exceedingly short—on the order of only  $10^5$  years. If Enceladus is the source of the ring particles, then either a giant impact or perhaps vigorous volcanic venting must have recently taken place. The question for now remains unanswered, since only one side of the satellite was imaged by Voyager. Enceladus will be an important target for scrutiny by the Cassini spacecraft starting in 2004.

Even more mysterious is Titan, Saturn's only planet-sized moon, which is obscured by a dense, hazy atmosphere that made close-up observation impossible dur-

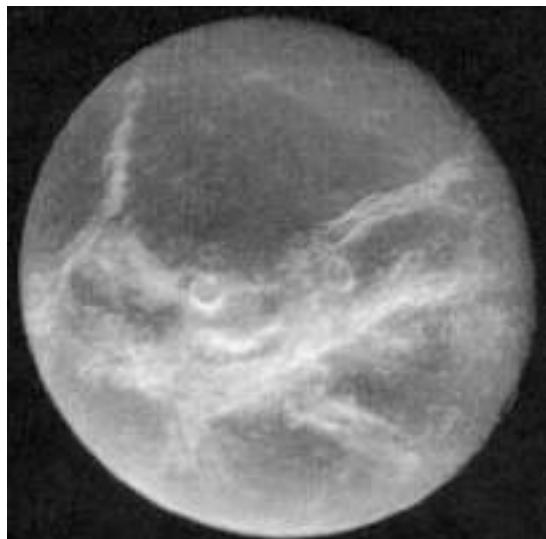

ing the Voyager encounters. Titan's great mass and density suggest that abundant gravitational and radioactive energy was available for melting the interior, added to by tidal friction from its eccentric orbit. Its surface is warmed to 97 K by solar greenhouse heating in the atmosphere, which like our own and Triton's atmospheres is mostly made up of N<sub>2</sub>. Titan's atmosphere is over four times as dense as Earth's, but because of the low gravity the surface pressure is only 1.5 bar. Methane is present in the atmosphere at the 2–10% level, and traces of organics (photolysis products of methane such as ethane, propane, and acetylene) have been detected as well. HCN, CO, and Ar are probably also present. Titan's atmosphere and its composition have fueled much speculation about geologic processes on Titan and the nature of the satellite's surface. One suggestion is that the atmosphere started out as ammonia erupted from Titan in massive outgassing events and was later converted to nitrogen by ultraviolet photolysis and escape of hydrogen. Methane is also rapidly de-

stroyed by photolysis, and some present-day source of methane at the surface or in the interior of the satellite is needed to replenish the atmospheric supply. Conceivably the gas could come from volcanic venting. At Titan's temperatures, methane behaves much like water on our own planet: liquid lakes of methane and ethane have been proposed for its surface, and methane rain or snow is possible. Volcanic processes on Titan can only be guessed at, but it seems likely that the satellite's dense atmosphere and possible liquid lakes would inhibit vesiculation in icy magmas, instead favoring effusive eruptions and perhaps forming extraterrestrial "pillow lavas."

Two other satellites of Saturn deserve mention as possible sites of cryovolcanic activity. Tethys and Dione are both rifted by large graben similar to the uranian moons, and Dione has the highest density of the Saturn system except for Titan. Bright wispy terrain occurs on Dione's poorly imaged trailing hemisphere (Fig. 9), which may be frost deposited during a cryoclastic eruption. These bright streaks sometimes grade into graben on the better seen Saturn-facing side of the satellite.

## VI. THE JUPITER SYSTEM

Our first close-up looks at icy satellite surfaces were provided by the Galileo mission, which began studying

**FIGURE 9** Dione. A bright, wispy albedo pattern can be seen on the leading hemisphere, perhaps frost deposited during a cryovolcanic eruption. (Voyager 1 image, courtesy of NASA.)

the Jupiter system in 1995. Although hampered by a malfunctioning high-gain antenna, Galileo has imaged details on the giant planet's moons as small as a few meters across and revealed a surprising diversity of landforms unsuspected from previous observations. Jupiter's four large "Galilean" satellites exhibit a compositional gradation that mimics that of the solar system, with densities and rock fractions that decrease with distance from the planet. Rocky Io is the innermost of the four moons and due to constant tidal reworking is the most volcanically active body known. Europa is also largely made up of silicates but has a thin outer layer of ice and perhaps liquid water extending to depths of 50 to 150 km below the surface. Ganymede and Callisto both have large ice fractions, but here their similarity ends. Callisto is an only slightly differentiated mixture of ice and rock with an ancient, heavily cratered surface unbroken by internal geologic activity. Ganymede, on the other hand, has a dense core and an exterior that was extensively rifted in a past episode of activity probably associated with differentiation and core formation.

Prior to Galileo's arrival, much of Ganymede's resurfacing (Fig. 10) was thought to have been volcanic in nature. As high-resolution images began to arrive from Galileo, the evidence for cryovolcanism eroded. The younger grooved terrain, which appeared smooth at the scales visible to Voyager, could be seen to be intensely shattered. Two scales of tectonic deformation can be recognized in the grooved terrain (Fig. 11), both likely caused by crustal extension. Broad topographic undulations probably resulted from ductile necking of the crust, while finely spaced fractures were produced by brittle failure. No fluid flow features can be seen issuing from the fractures, so it appears that most of the resurfacing was achieved by tectonism rather than cryovolcanism. (This example should serve to throw considerable "cold water" on our earlier speculations about the satellites of Saturn and Uranus, which are also based on low-resolution images!) Some evidence of early cryovolcanic activity may be preserved in the form of scalloped depressions found in the older cratered regions of Ganymede (Fig. 12). The origin of these caldera-like features is obscure.

In contrast to its moribund neighbors Ganymede and Callisto, Europa appears to be bristling with signs of recent activity. Europa has long been suspected of harboring a subsurface sea, based in part on its lack of topography: its greatest peaks reach heights of only a few hundred meters, and the largest craters excavate to even shallower depths. Relatively few impact craters scar the satellite, indicating that its surface is comparatively young—by some estimates, as little as 100 million years

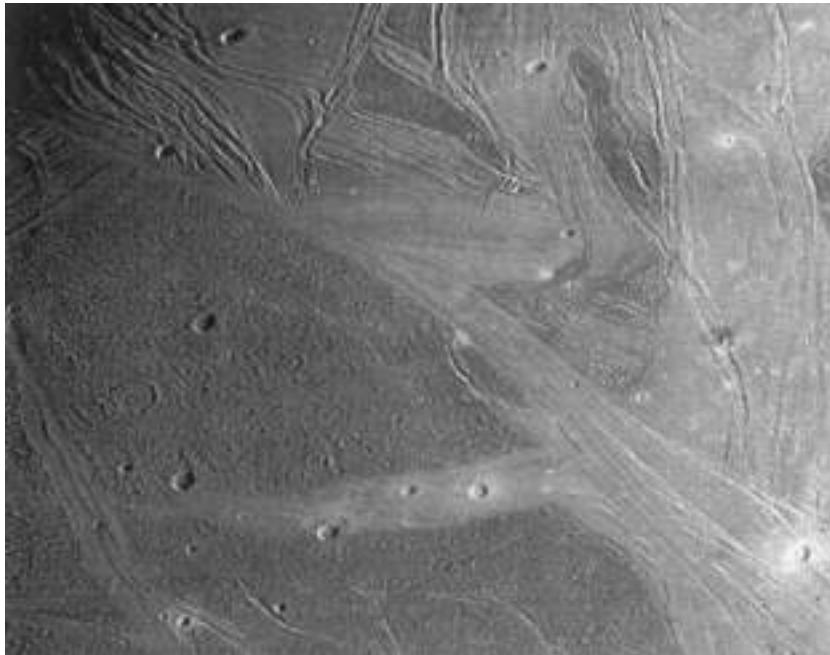

FIGURE 10 Ganymede. Terrains of two distinct ages are seen on the solar system's largest moon. Dark, heavily cratered terrain similar in appearance to Callisto is broken by bright young groove lanes. (Galileo image, courtesy of NASA.)

old. Some of the craters look familiar and seem to have formed in a solid target, but the largest impact structures are exceedingly flat and are ringed by evenly spaced concentric fractures unlike any previously seen. These unique features could have been created when kilome-

ter-sized impactors penetrated the crust to a fluid layer beneath the surface. Two competing processes act to erase Europa's craters. A dense tangle of ridges resurfaces much of the satellite, representing many generations of repeated ridge-building activity over the course

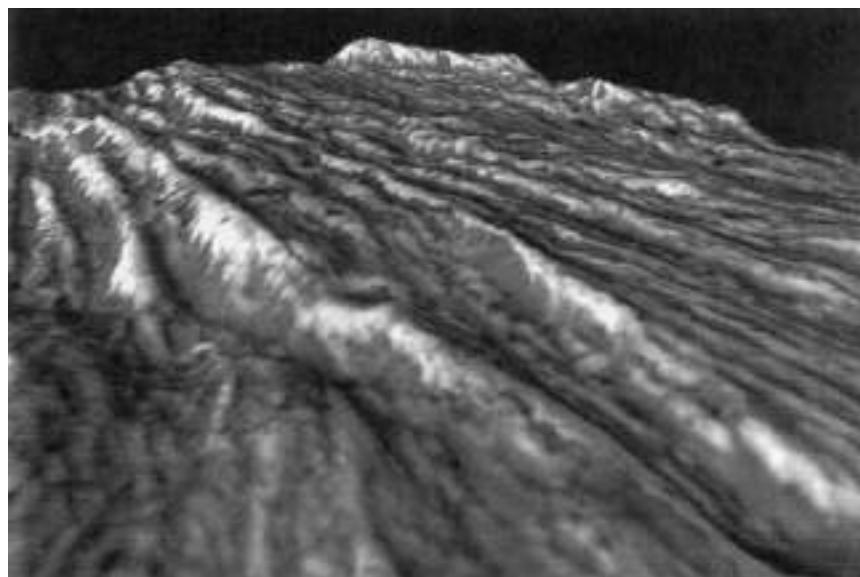

FIGURE 11 Topography in Uruk Sulcus, Ganymede. Stereo pictures have been used to render relief on this high-resolution image of a groove lane, formerly thought to be volcanic. (Galileo image, courtesy of NASA.)

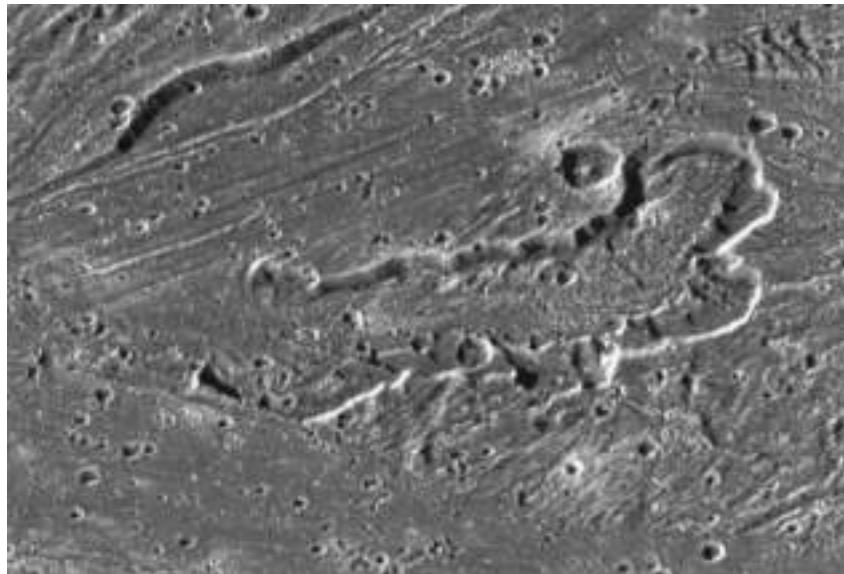

FIGURE 12 Scalloped depression on Ganymede. This feature, found on the older heavily cratered terrain, does not appear to be of impact origin. Perhaps it is evidence of early volcanism. (Galileo image, courtesy of NASA.)

of its short history. In other places, particularly along the equator, the crust has been disrupted by localized heating from below, leaving floe-like fragments that have drifted across the sunken surface (Fig. 13). In fact, the entire ice shell of the satellite may be drifting gradually to the east with respect to the silicate interior, due to tidal torques exerted by Jupiter as Europa circles in its eccentric orbit. If so, it implies that the crust is mechanically decoupled from the interior, as if underlain by ductile ice or floating on a liquid layer.

The origins of Europa's perplexing surface features are still being widely debated. Not far below the surface, the ice could be warm enough to flow like terrestrial glaciers, particularly if it is in thermal contact with liquid water at its melting point. The ridges and thermally disrupted areas might be due to diapirism and convection in the solid ice shell. In these models, the cold ice at the surface is denser than the warmer ice beneath it and tends to sink when disturbed by activity such as solid-state convection taking place in the interior. Buoyant ice from below might also be extruded through fractures in the brittle surface, forming the ubiquitous ridges. Not all of the characteristics of the ridges and disrupted zones are easily explained by solid-state deformation, however. In particular, the last surviving crustal blocks in the areas of thermal disruption are among the largest and presumably heaviest and appear to have floated on a substrate that was even denser. Thus Europa's smooth spots and "maculae," once thought to have been volcanic flows, are probably places where the icy

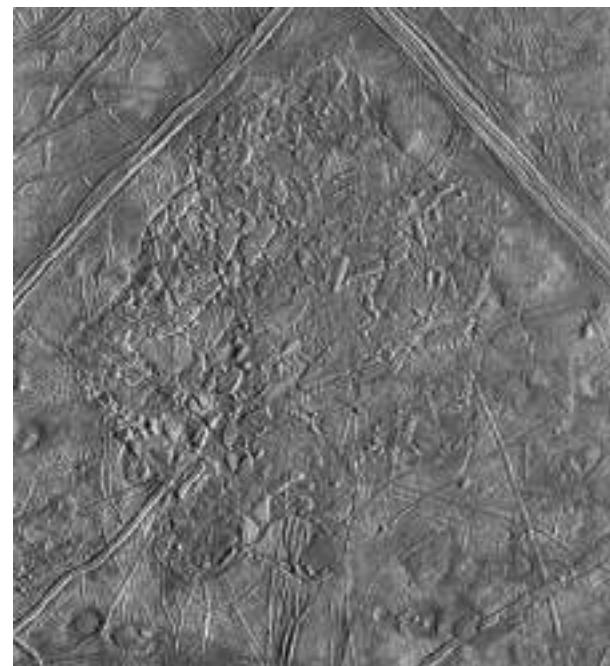

FIGURE 13 Conamara Chaos, Europa. Here the icy crust has been melted through by intense heating from below. A few remaining blocks retain the imprint of the original surface. These "flocs" have shifted, rotated, and tilted as if floating on a dense water substrate. (Galileo image mosaic, courtesy of NASA.)

crust was heated to the melting point from below. An unusual example of a possible zone of melt-through is shown in Fig. 14. Even small-scale relief has been erased from this 3-km-diameter “puddle,” either by thermal topographic relaxation (implying surface temperatures near the melting point) or by fluid extrusion and flow. The source of such energetic and localized heating is a mystery. Europa receives only one-fifteenth of the tidal heating that churns its violent neighbor Io, but it would not be surprising if some high-temperature silicate volcanism was taking place in the subsurface of Europa as well.

Cryovolcanism may help to explain Europa’s peculiar ridges (Fig. 15), which occur in pairs or sets that are symmetric and uniform over distances often comparable to the radius of the satellite. The margins of many ridge sets are darkened and discolored by a non-ice contaminant, perhaps vented from fractures between the ridges. Double ridges are difficult to produce by diapirism and seem to require some cyclic process of extrusion and

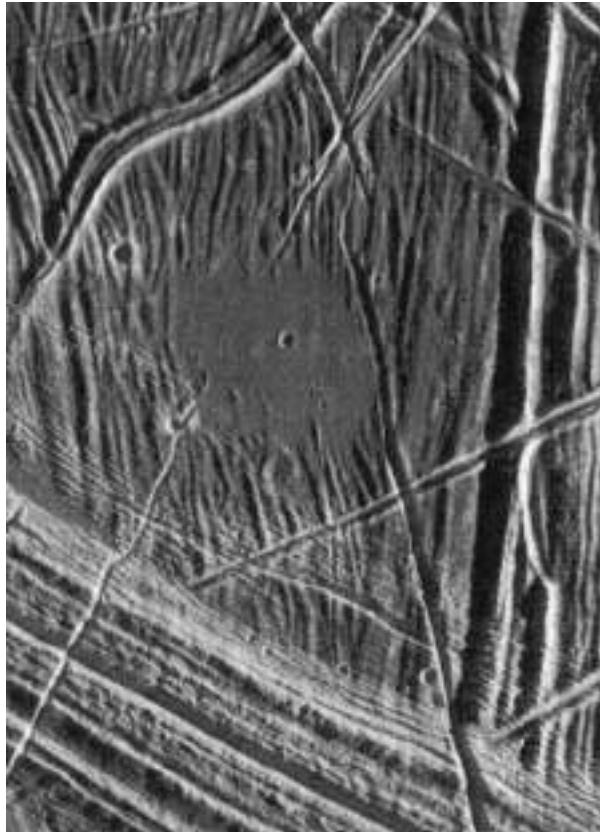

FIGURE 14 The “puddle” on Europa at 11°N, 328°W, imaged at 27 m/pixel. Even small-scale relief has been erased from this 3-km-diameter feature, either by thermal topographic relaxation or by fluid extrusion and flow. (Galileo image, courtesy of NASA.)

FIGURE 15 Freshly formed doublet ridge on Europa. The origin of these ubiquitous ridge pairs is mysterious. Perhaps they formed when icy slurry was pumped up through fractures by the daily tidal flexing. (Galileo image, courtesy of NASA.)

withdrawal in order to form their central valleys. One possible mechanism is the pumping of fluids along cracks by tidal flexing. If the interior is liquid, tides tens of meters high should be raised each europan “day” (3.5 Earth-days) as the satellite circles Jupiter. Any fractures that penetrate the icy crust are pulled apart for half of each orbit and slammed shut again for the other half. If liquid can seep into the fractures from below, some slush may be squeezed out of the cracks and onto the surface with each daily cycle. Bright plumes or frost deposits should be produced by this process, but so far no such telltale sign of activity has been detected by Galileo.

## VII. FUTURE EXPLORATION

The existence of a liquid layer on Europa is by no means proven by the Galileo observations and will be debated

for years to come. By looking at the surface of the satellite, we can only make indirect inferences about what is going on down below. However, the possibilities of a subsurface ocean and perhaps seafloor silicate volcanism on Europa cannot be ruled out by the new data and might have profound implications for the likelihood of finding life on the icy world. Soon after the Galileo discoveries, planning began for a follow-up mission designed to directly determine whether a liquid layer lurks beneath the satellite's surface. Europa Orbiter, as the new mission is called, will use gravimetry and altimetry to take the "pulse" of the moon by measuring the height of the tides. Only centimeters of flexing should occur each day if the ice is frozen to the bedrock, in contrast to the massive tides expected if the interior is fluid. Europa Orbiter may also employ a radar sounder similar to those used in the Earth's polar regions to penetrate the ice and return reflections from any liquids within a few kilometers of the surface. The spacecraft will also completely map the moon from orbit, a feat that was impossible with the limited downlink from Galileo.

Another ambitious mission is already on its way to Saturn. The Cassini spacecraft will investigate the planet, its rings, and its moons for 4 years beginning in 2004. Cassini will drop an instrumented probe to the surface of mysterious Titan, fitted with an imaging system and designed to float if it is lucky enough to land in an ethane lake. Cassini will also study the satellites from Saturn orbit with optical and radar remote sensing, hopefully shedding light on the manner in which they were resurfaced. Going even farther afield, a project called the Pluto Kuiper Express will launch (also by the year 2004) a spacecraft that will travel nearly a decade

before speeding past Pluto and Charon. Gauging by our past experiences, we may well be surprised by the geologic processes that have gone on in this curious binary system in which the moon is fully a tenth as massive as the planet.

# VOLCANIC INTERACTIONS

A magma body that resides at shallow levels beneath a volcano is not static; it is in dynamic interaction with its surrounding environment. As a result, many fascinating phenomena, including volcanic gases, hydrothermal systems on land and under the oceans, and volcanic lakes, are observed. The interactions may be hazardous, releasing gases dangerous to human health, draining crater lakes catastrophically, and causing explosive eruptions. Yet these interactions also are beneficial to humans; geothermal energy can be harnessed to produce electricity, and ore deposits can be mined for our natural resource needs.

Many volcanoes release billowing clouds of gas, not only during an eruption but also when a volcano is seemingly quiet between eruptions. The opening chapter of this section, Volcanic Gases, examines the different types of gases that are found at volcanoes. The gases can be emitted at high temperatures from fumaroles in active crater areas and at low temperatures on the flanks of volcanoes. The compositions of the gases are controlled by factors such as their solubilities in magma, the temperature and pressure at which they reside, the infiltration of surface waters, and the tectonic setting of the volcano.

Volcanoes are favorable sites for geothermal systems, which are discussed in the following chapter. As groundwaters percolate through a faulted, permeable volcanic edifice, they encounter a heat source, normally magma and hot rocks. The interaction of the water and the magma creates convection cells whereby hot water is circulated within a permeable zone. The hot water reacts with country rocks, dissolving the rock and adding various chemical elements to the hydrothermal fluid.

Geothermal systems are found not only at active vol-

canoes but also in other regions of high heat flow, typically along tectonic plate boundaries. Geothermal systems can be exploited commercially for electric production, and this aspect is discussed further in Part IX, in the chapter Exploitation of Geothermal Resources.

Geothermal and hydrothermal systems created by interaction of waters with magma and hot rocks form impressive manifestations at the surface; the chapter Surface Manifestations of Geothermal Systems delves into the details of these manifestations, which may include spectacular fumaroles, acid crater lakes, acidic hot springs, and even acid streams.

High-temperature hydrothermal systems at volcanoes may be dominantly liquid, vapor, or a combination of the two. Lower-temperature systems also are found at volcanic centers; these may be cooling and decaying systems that were once at high temperature. These systems may form certain types of ore deposits (as discussed later in this section in the chapter Mineral Deposits Associated with Volcanism).

Water–magma interaction occurs not only on land but also occurs in the oceans. The chapter Deep Ocean Hydrothermal Vents examines the remarkable hydrothermal systems that are formed in regions of active submarine volcanism. Most of our knowledge regarding these systems is based on discoveries in the past twenty years. As two tectonic plates form and move apart at mid-ocean ridges, the magma that is generated serves as a heat source. Seawater percolates into the fractured oceanic crust and is heated by the magmatic source, setting up hydrothermal convection cells. In fact, submarine hydrothermal circulation is a principal means by which Earth loses its heat. As the heated water circulates, it dissolves rock. The chemically charged water transports metals upward, forming ore deposits when pressure–temperature conditions are reduced. Researchers have even observed and filmed spectacular hydrothermal chimneys, termed “black smokers,” venting at the sea floor. In the vicinity of the hydrothermal vent, unique forms of life are nurtured by the hot mineral-rich water.

Back on land, the next chapter, Volcanic Lakes, shows that lakes can form on volcanoes when surface waters are available in large amounts. These lakes typically are situated in craters at the tops of volcanoes and can be hot, containing large amounts of dissolved solids. In some cases, the lakes are actually concentrated mixtures of sulfuric and hydrochloric acid! Some lakes may host molten sulfur bodies, while others have high levels of carbon dioxide dissolved at the bottom. Acidic crater lakes are another surface manifestation of interaction between groundwaters and a degassing magma; they also can be considered the uppermost part of a magmatic-hydrothermal system that may be forming an ore deposit at deeper levels. Volcanic lakes can be hazardous, because they are associated with hydrovolcanic eruptions (see the chapters Phreatomagmatic Fragmentation; Surseyan and Related Phreatomagmatic Eruptions; Pyroclastic Surges and Blasts), gas bursts of CO<sub>2</sub> (see Hazards of Volcanic Gases), and lahars (see Lahars; The Hazard from Lahars and Jökulhlaups).

We have seen above how volcano interactions potentially can form mineral deposits. These ore deposits are explained in the final chapter of this section, Mineral Deposits Associated with Volcanism. The ores may form directly from the magma, from magmatic fluids when the magma becomes saturated in volatiles, or from hot groundwaters that circulate within a magmatic-hydrothermal system. The type of ore deposit that is formed depends on its tectonic environment. Above mantle plumes, flood basalt and komatiite eruptions host nickel-copper ores and platinum-group deposits. At mid-ocean ridges, black smokers form massive sulfide ore deposits by precipitation of metallic minerals as the hot hydrothermal solution is quickly cooled by seawater. This type of deposit also is formed at oceanic subduction zones. Subduction-related volcanoes on land having hydrothermal systems may host large deposits of gold, copper, and other metals.

## GLOSSARY

- connate water** Water entrapped in the interstices of pores of a sedimentary rock at the time of its deposition.
- convergent plate volcano** A volcano located on the boundary between two lithospheric plates that are moving toward each other and being subducted.
- divergent plate volcano** A volcano located on a boundary between two lithospheric plates that are moving apart, with mantle material and new oceanic crust moving in to fill the gap.
- half-life** The time required for one half of a given number of radionuclides to decay.
- hot spot** A volcanic center, 100 to 200 km across and persistent for at least a few tens of millions of years, that is thought to be the surface expression of a persistent influx of hot mantle material. A hot spot may or may not be associated with divergent plate boundaries.
- isotope** Atoms with the same number of electrons and

protons, but a different number of neutrons and therefore different masses. Most chemical elements occur in nature as two or more isotopes. The relative abundances of isotopes of a given chemical element are not constant in all natural materials. Hydrogen, carbon, oxygen, and sulfur, which are prominent elements in volcanic gases, all have stable isotopes. As opposed to radionuclides, stable isotopes do not undergo spontaneous decomposition.

**hydrothermal system** A groundwater system that has a source (or area) of recharge, a source (or area) of discharge, and a heat source. When a magma supplies the heat source and volatiles, the hydrothermal system qualifies as a magmatic hydrothermal system.

**magmatic volatile** An element (e.g., sulfur, chlorine, fluorine) or compound (e.g., water, carbon dioxide) dissolved in a magma that forms a gas at relatively low pressure and magmatic temperature.

**meteoric water** Waters of any age that originate from precipitation: rain, snow, ice, river, lake, and most low-temperature groundwaters. They are derived from ocean water through the atmospheric circulation process.

**MORB** Abbreviation for mid-ocean ridge basalt, which is erupted at an oceanic divergent plate volcano (sea-floor spreading axis).

**redox potential** A variable that describes the reduction-oxidation equilibria of chemical reactions that involve transfer of electrons between species having different valence states.

**subduction** The process of one lithospheric plate descending beneath another. Subduction zones are long, narrow belts in which subduction takes place.

## I. INTRODUCTION

Volcanic gases are a fundamental part of volcanic activity. Ranging from dramatic emissions of acidic vapors released by highly active volcanoes to invisible emanations of carbon dioxide through soils, volcanic gases play an important, if not dominant, role in influencing the behavior of a volcano. In general, increasing availability of gas within a volcano results in increasingly explosive activity. Thus, the most explosive eruptions are probably the consequence of gas-rich magmas and large pressure buildups within the volcano as the magma releases gas during its ascent to shallow levels. Other volcanoes emit huge quantities of gas passively, i.e., without erupting.

By studying gases, volcanologists can gain insight into a number of phenomena. First, they can assess whether there is magma present at shallow levels in a volcanic edifice. Second, they can determine if a magma is comparatively rich or poor in dissolved gas. Third, they can estimate the various sources of the gas, e.g., from the mantle, from subducted material as a tectonic plate slips beneath another, from sedimentary rocks in the crust, or from fluids at shallow levels in the volcano, such as a hydrothermal system, groundwater, or even rainwater. Fourth, by making repeated measurements over time, scientists can use gas data to help forecast eruptive activity, particularly when this information is integrated with other types of data that are being collected to monitor the state of the volcano, such as seismicity and ground deformation.

Typically, a volcano releases high-temperature acidic gases from its active crater, the gases being released both diffusely and as highly concentrated vapors through fumarolic cracks and vents. Some volcanoes also release low-temperature gases diffusely through their flanks, which are distant from the active crater area. This chapter gives an overview of gases that are released by these two styles of degassing. The chapter is organized in the following fashion. First, we discuss the nature and origin of high-temperature gases and the different factors that control their composition and behavior. Then we present six examples of gas studies that have shed important light on volcanic processes. We then discuss and illustrate diffuse low-temperature gases on volcano flanks, and we conclude by summarizing our state of knowledge

concerning volcanic gases: where we stand today and where we are going in the future.

---

## II. CHEMICAL COMPOSITION OF VOLCANIC GASES AND CAUSES OF VARIABILITY

Until the middle of the 19th century, scientists believed that each volcano released one particular type of gas: sulfur dioxide at Etna (Italy); hydrogen chloride at Vesuvius (Italy); and carbon dioxide at Puracé (Colombia). Charles Sainte-Claire Deville, a French mineralogist who pioneered the chemical analysis of volcanic gases in the 1850s, demonstrated that this was not the case; he showed that the same gases occur on each volcano, although in different proportions. Volcanic gases indeed exhibit extreme chemical variability, which complicates attempts to read their message.

Over the past 20 years, gas geochemists armed with sophisticated analytical techniques and a good theoretical knowledge have made efforts to understand what dictates the composition of volcanic gases. The controlling factors are the chemical reactions in the gas phase itself, the tectonic and geologic setting, the solubility of gases dissolved in magma (i.e., the magmatic volatiles), and the interaction with a hydrothermal system, groundwater, or rainwater at shallow levels within the volcano.

### A. Constituents of Volcanic Gases

Volcanic gases contain a restricted number of chemical elements as various molecular species (Table I). Major elements consist of hydrogen (H), carbon (C), oxygen (O), sulfur (S), nitrogen (N), and halogens including chlorine (Cl), fluorine (F), and bromine (Br). Minor elements include the rare gases helium (He), neon (Ne), argon (Ar), krypton (Kr), and xenon (Xe). Trace amounts of metals (e.g., sodium, vanadium, chrome, bismuth, copper, zinc, gold) occur in high-temperature fumarolic gas discharges. Hydrogen is largely present as water ( $H_2O$ ), with the other H-bearing species, such as molecular hydrogen ( $H_2$ ), methane ( $CH_4$ ), or ammonia ( $NH_3$ ), occurring in minor or trace amounts. Of the carbon species, carbon dioxide ( $CO_2$ ) is dominant, while methane ( $CH_4$ ) and carbon monoxide ( $CO$ ) occur in lesser amounts. Sulfur dioxide ( $SO_2$ ) and hydrogen sulfide ( $H_2S$ ) mainly compose the sulfur species, the remaining

<sup>a</sup> div. pl. and conv. pl. are for divergent plate and convergent plate volcano, respectively. Data compiled from Giggenbach and Sheppard (1989), Giggenbach et al. (1990), Symonds et al. (1994), Giggenbach (1996), Symonds et al. (1996), Fischer et al. (1997), and Fischer et al. (1998).

gas consisting of molecular sulfur (S<sub>2</sub>) and sometimes carbonyl sulfide (COS). Chlorine, F, and Br occur principally as acids, with hydrogen chloride (HCl) predominating over hydrogen fluoride (HF) and hydrogen bromide (HBr). Nitrogen exists almost exclusively as molecular nitrogen (N<sub>2</sub>). When present in the gas phase, metals are transported largely as chloride or sulfide salts and, to a minor extent, as elemental volatile species.

As illustrated in Table I, the concentrations of the chemical compounds in fumarolic gas samples vary significantly. However, it is safe to state that H<sub>2</sub>O is consistently dominant and normally accounts for more than 60% of the total molar gas content in crater fumaroles. The next most abundant species is CO<sub>2</sub> with typical molar contents between ~10 and ~40%. The highest CO<sub>2</sub> concentration was measured in gas emanations collected during the 1918–1919 summit eruption of Kilauea volcano, Hawaii (Table I). In most fumarolic gas samples, the amount of total sulfur (S<sub>total</sub> = SO<sub>2</sub> + H<sub>2</sub>S) is lower than that of CO<sub>2</sub>, but usually higher than that of HCl, although the relative abundances of S<sub>total</sub> and HCl in volcanic gases can vary greatly. Hydrogen and nitrogen gases are typically less than 2% and 1% of

the total molar gas content, respectively, but the N<sub>2</sub> concentration is often modified by air contamination during or after sampling. Together, the remaining gas compounds (He, Ar, CO, etc.) generally account for less than 1%. Methane is usually absent in high-temperature fumaroles, although there are cases where it has been detected.

## B. Pressure, Temperature, and Redox Potential

Because of various internal reactions, the molecular composition of a gas phase separated from its magma (i.e., the magmatic gases) may change as the gases ascend toward the surface. The reaction

is important, because it reaches chemical equilibrium rapidly and involves the major gas species H<sub>2</sub>O, SO<sub>2</sub>, H<sub>2</sub>S, and H<sub>2</sub>. Thermodynamic modeling indicates that the reaction shifts to the right at high pressures (i.e.,

the magma degasses at great depths), thus favoring H<sub>2</sub>S at the expense of SO<sub>2</sub> as the dominant sulfur species in the gas. Cooling of the rising magmatic gases leads to a similar effect. Conversely, hot gases escaping from a magma body emplaced at shallow levels in the crust will tend to be SO<sub>2</sub>-dominated, as frequently observed in the field.

Besides pressure and temperature, the redox potential of the magmatic gas phase also influences its composition. This variable can be conveniently expressed by the H<sub>2</sub>/H<sub>2</sub>O ratio measured in the volcanic gas sample, but the mechanisms that control this ratio remain controversial. As shown by the work of Terrence Gerlach on Kilauea volcano (Hawaii), the redox potential of magmatic gases seems to be governed by that of the molten rock (i.e., the magma). On the basis of observations made at White Island volcano (New Zealand), Werner Giggenbach suggested that when the hot gases separate from magma and rise rapidly up to the surface, the above process is no longer valid. Instead, the reaction shown earlier exerts the major control on the redox potential. The H<sub>2</sub>/H<sub>2</sub>O ratios in fumaroles then reflect the relative proportions of SO<sub>2</sub> and H<sub>2</sub>S gases. However, at temperatures lower than about 350°C, the H<sub>2</sub>/H<sub>2</sub>O ratio of fumarolic gas is likely to depart from this high-temperature behavior, because of prolonged interaction of the rising gases with the rocks surrounding the volcanic conduits. Giggenbach's predictions are consistent with many field observations. An alternative view to this scenario was proposed to explain the redox state of the fumarolic gases from the Showa-Shinzan dome, Usu volcano (Japan). In this case, admixture and reequilibration of meteoric water (e.g., rain that permeates through the volcano) with the hot gases moving up toward the surface govern the redox potential of high-temperature fumarole discharges.

### C. Tectonic and Geologic Setting

Gases dissolved in magmas can be supplied at depth from various sources, including the mantle, the crust, and subducted material during magma generation and magma ascent. Since these sources have distinct compositions, different types and amounts of volatiles are added to magmas depending on the tectonic and geologic setting of the volcano. The chemical composition of gases released from magma and discharging at the surface as high-temperature fumaroles will vary accordingly. To trace the deep origins of volcanic gases, and thus of magmas, geochemists use both the chemical and isotopic signatures of major and minor gas species.

High-temperature fumarolic gases associated with convergent plate volcanoes have proportionately more H<sub>2</sub>O and Cl than gases from divergent plate and hot spot systems. This is a result of addition of significant amounts of seawater to convergent plate magmas during subduction of the oceanic crust and sediments, which both contain hydrated minerals. Several researchers have noted that H<sub>2</sub>O in high-temperature fumaroles from convergent plate volcanoes displays high contents of deuterium (D) and oxygen-18 ( $\delta^{18}\text{O}$ ), which are the heavy isotopes of hydrogen and oxygen, respectively (Fig. 1). Until recently, the accepted view was that the isotopic composition of H<sub>2</sub>O in fumarolic gases resulted from mixing of a "primary magmatic water" with local meteoric water, the isotopic composition of this primary magmatic water ( $\delta\text{D} = -65 \pm 15\text{\textperthousand}$  and  $\delta^{18}\text{O} = +8 \pm 2\text{\textperthousand}$ ) corresponding to that of water extracted from mid-ocean ridge and hot spot rocks. It now seems more likely that the distinct isotopic compositions of H<sub>2</sub>O in convergent plate gases point to the existence of a common "subduction-related magmatic water" component, whose source is recycled D- and  $^{18}\text{O}$ -rich seawater ( $\delta\text{D} = 0\text{\textperthousand}$  and  $\delta^{18}\text{O} = 0\text{\textperthousand}$ ) which was stored initially in hydrated minerals of the subducted oceanic crust and sediments. This "subduction-related magmatic water" may have a very uniform isotopic composition, with

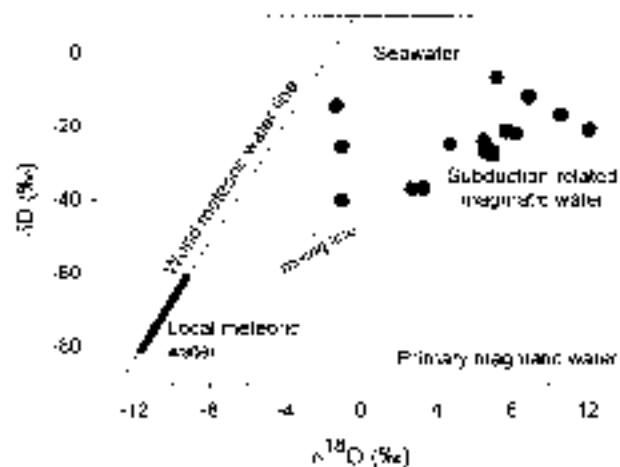

FIGURE 1 Isotopic composition ( $\delta\text{D}$  and  $\delta^{18}\text{O}$ ) of water from high-temperature fumarolic gases associated with convergent plate volcanoes (black circles) and compositional fields for "subduction-related magmatic water" and "primary magmatic water." The world meteoric water line represents the range of compositions followed by most surface waters. The dashed line connecting "subduction-related magmatic water" to local meteoric water represents the isotopic compositions obtained by mixing these two components in different proportions.

$\delta D = -20 \pm 10\text{‰}$  and  $\delta^{18}\text{O} = +10 \pm 2\text{‰}$ , and mixes with local meteoric water at shallow levels in the volcanic edifice to produce a characteristic fumarole isotopic composition (Fig. 1). Although rare, there are also examples of island volcanoes whose isotopic and chemical trends suggest shallow contamination of the fumaroles by marine fluids permeating through the volcanic conduit.

Geochemists also use the stable isotopes of carbon and sulfur present in fumarolic gas discharges to infer the deep sources of magmatic volatiles and their respective contributions. This approach is based largely on the assumed isotopic compositions for the Earth's surface reservoirs that contain these chemical elements. The isotopic compositions of  $\text{CO}_2$  ( $\delta^{13}\text{C}_{\text{CO}_2}$ ) and  $\text{SO}_2$  ( $\delta^{34}\text{S}_{\text{SO}_2}$ ) measured in high-temperature gases emitted by divergent plate (e.g., Ertá Ale, Ethiopia) and hot spot (e.g., Kilauea) volcanoes indicate a mantle origin for carbon and sulfur ( $\delta^{13}\text{C} = -4.0 \pm 2.5\text{‰}$ ,  $\delta^{34}\text{S} = 0 \pm 1\text{‰}$ ). By contrast, subduction-related high-temperature gases display more variable  $\delta^{13}\text{C}$  and  $\delta^{34}\text{S}$  values ( $\delta^{13}\text{C} = -12$  to  $+2.5\text{‰}$ ,  $\delta^{34}\text{S} = 0$  to  $+12\text{‰}$ ), indicating contamination by crustal and subducted material.

Helium is a good tracer of volcanic gas sources. It has two isotopes:  $^3\text{He}$ , which was formed during accretion of the Earth, and  $^4\text{He}$ , which is produced by radioactive decay of uranium and thorium in the crust. The helium isotope ratio of gas samples is usually expressed relative to the  $^3\text{He}/^4\text{He}$  ratio of the atmosphere ( $R_A$ ), which is  $1.4 \times 10^{-6}$ . Basalts erupted from oceanic divergent plate volcanoes, termed MORB, have  $^3\text{He}/^4\text{He}$  ratios eight times higher than atmospheric values (expressed as  $8R_A$ ). However, these ratios are significantly lower than values of about  $40R_A$  in the primitive mantle, and so the mantle source for MORB is considered to have been degassed and depleted of  $^3\text{He}$ , while  $^4\text{He}$  has been added to it over time by uranium and thorium decay. At the same time, the  $^3\text{He}/^4\text{He}$  ratios are significantly higher than atmospheric, so the MORB source has retained some primordial He. The  $^3\text{He}/^4\text{He}$  ratio is thus a useful measure of the degree to which the mantle gases contribute to volcanic gas discharges.

Some hot spots such as Hawaii exhibit very high  $^3\text{He}/^4\text{He}$  ratios reaching up to  $30R_A$ . These hot spots are considered to tap comparatively pristine, undegassed parts of the mantle. Significant  $^3\text{He}$  enrichments have been measured in volcanic gases from Hawaii ( $^3\text{He}/^4\text{He} \approx 15R_A$ ), in accordance with the inferred mantle origin. The  $^3\text{He}/^4\text{He}$  ratios measured in fumarolic gases at convergent plate volcanoes typically range from 5 to  $7R_A$ , with some values as high as  $8R_A$  and as low as  $4R_A$ . The He data thus indicate that these gases contain a MORB

component which has been variably diluted by crustal material with lower  $^3\text{He}/^4\text{He}$  ratios ( $^3\text{He}/^4\text{He} \approx 0.02R_A$ ).

Helium also may be used as a reference to estimate various contributions to a volcanic gas. Other important constituents of volcanic gases are  $\text{CO}_2$  and  $\text{N}_2$ , which do not react extensively with rocks inside the volcano. Using the  $\text{CO}_2/\text{He}$  and  $\text{N}_2/\text{He}$  ratios, it readily can be seen that convergent plate volcanoes discharge gases with high  $\text{CO}_2$  and  $\text{N}_2$  contents. As shown in Fig. 2, these gases typically display  $\text{CO}_2/\text{He}$  ratios of 65,000 to 900,000, which are 3 to 15 times higher than those found in divergent plate and hot spot settings. The  $\text{H}_2\text{O}/\text{He}$  and  $\text{H}_2\text{O}/\text{CO}_2$  ratios in gases are also higher in convergent plate volcanoes than in divergent plate and hot spot volcanoes. Similarly,  $\text{N}_2/\text{He}$  ratios for gases from convergent plate settings are considerably higher ( $\text{N}_2/\text{He} > 1,500$ ) than those observed in divergent plate and hot spot environments ( $\text{N}_2/\text{He} < 250$ ). The most likely source of this excess  $\text{CO}_2$ ,  $\text{N}_2$ , and  $\text{H}_2\text{O}$  is again the material (sedimentary rocks, altered crust, and organic matter) carried by the subducted slab to the magma generation zone in the mantle. Based on the  $\delta^{13}\text{C}$  values and  $\text{CO}_2/^3\text{He}$  ratios measured in fumarolic gases from convergent plate volcanoes, up to 80% of the carbon in these environments may be derived from subducted material (carbonate in the crust and limestone sediments) with comparatively small mantle inputs. When the relative contents of  $\text{N}_2$ , He, and Ar are plotted for subduction-related and non-subduction-related gases (Fig. 3), the two groups exhibit distinct positions. Both types of volcanic gases can be contaminated at shallow

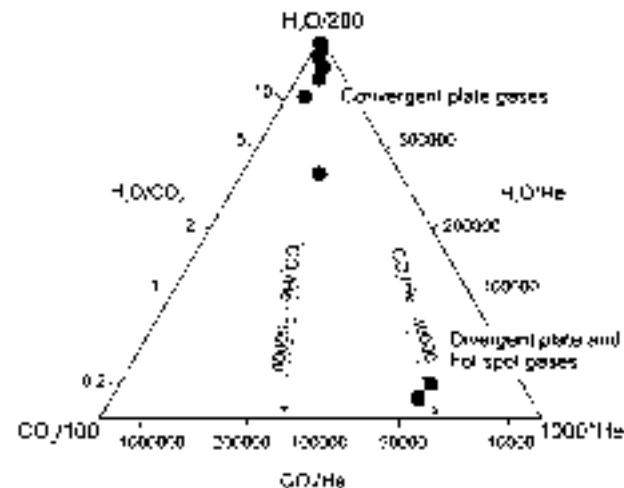

FIGURE 2 Relative  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ , and He contents of fumarolic gases associated with convergent plate, divergent plate, and hot spot volcanoes.

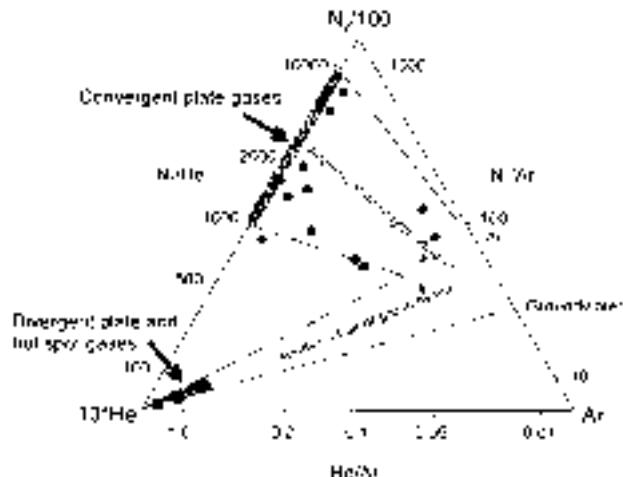

FIGURE 3 Relative Ar, N<sub>2</sub>, and He contents of fumarolic gases and inferred compositional fields for volcanic gases associated with convergent plate, divergent plate, and hot spot settings. Also shown are the air and groundwater (air-saturated water) compositions.

levels in the volcanic edifice by air or air-saturated groundwater, leading to a decrease of their N<sub>2</sub>/Ar and He/Ar ratios.

#### D. Magmatic Volatile Solubility

Despite the distinct classes of fumarolic gas compositions associated with the tectonic setting, there is still considerable variability within these groups. Some of these variations may originate from differences in magmatic volatile solubility, and degree of degassing of the magma. Less soluble species such as N<sub>2</sub> and CO<sub>2</sub> are released initially from a magma emplaced at shallow levels in the crust, whereas H<sub>2</sub>O and the more soluble sulfur- and halogen-containing compounds remain dissolved in the magma. With time, and if there is no new supply of magma from depth, a high-temperature gas discharge may evolve from a CO<sub>2</sub>-rich to a comparatively CO<sub>2</sub>-poor composition, with a corresponding decline in the CO<sub>2</sub>/S<sub>total</sub> ratio in the gas. Similarly, the higher solubility of Cl over S in magma can lead to emission of HCl-rich volcanic gases from degassed magma intrusions. Volcanologists have documented these phenomena by monitoring the compositional changes in fumarolic gases over the course of months or years. These observations suggest that the volatile solubility in magmas decreases in the order HF > HCl ≈ H<sub>2</sub>O > S<sub>t</sub> > CO<sub>2</sub>.

Another complicating factor in the interpretation of volcanic gas compositions is related to the complicated solubility behavior of sulfur and chlorine in magmas as a function of pressure. At Mt. Etna (Italy) variations in the Cl/S ratio of the gas plume were attributed to changes in magma degassing regimes from deep to shallow levels; high Cl/S gas ratios would correspond to volatile escape deep in the magma plumbing system, whereas low ratios would indicate gas release at shallower depths, with most of the sulfur being degassed from the magma. This apparent relationship between depth of gas–magma separation and gas composition may not be straightforward, however, because the solubility of sulfur also depends on other variables such as the redox potential of the magma, temperature, and magma composition.

#### E. Shallow, Nonmagmatic Processes

Although tectonic setting and magma degassing history control the chemical composition of high-temperature volcanic gases, most temporal and spatial variations appear to be the result of nonmagmatic processes related to the presence of a hydrothermal system or meteoric water in the shallow parts of the volcano. Upon contact with these shallow reservoirs, the hot gases released by a magma react to produce a fumarolic discharge that bears a small remnant of the initial magmatic gas composition.

Water, SO<sub>2</sub>, H<sub>2</sub>S, and HCl are the gas species that are most readily affected by these secondary processes. Addition of H<sub>2</sub>O may occur when the rising gas phase encounters hydrothermal water, groundwater, or rainwater. Conversely, condensation of magmatic water on contact with cooler water reservoirs may decrease the H<sub>2</sub>O content in the fumarolic gas. Water in low-temperature gas discharges that is affected by interaction with hydrothermal fluids, groundwater, or rainwater generally will have depleted D and <sup>18</sup>O contents compared to high-temperature volcanic gases. Isotopically diluted fumaroles tend to approach the composition of local meteoric water.

Sulfur dioxide gas also may react with liquid water in the hydrothermal system to produce sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) and H<sub>2</sub>S, thus modifying the SO<sub>2</sub>/H<sub>2</sub>S ratio in the fumarolic gas. In some instances, this reaction yields elemental sulfur, whose deposition decreases the sulfur content of the gas. Formation of elemental sulfur is commonly associated with cooling of the hot rising gas phase. The reverse process, revolatilization of previously

deposited elemental sulfur during passage of hot gases, increases the total sulfur content in the fumarole. Finally, the high solubility of HCl vapor in water makes it susceptible to condense in shallow low-temperature zones of the volcanic–hydrothermal system. Interaction of hot magmatic gases with shallow groundwater or a hydrothermal system results in a volcanic gas discharge characterized by relatively high CO<sub>2</sub> and low HCl contents (Fig. 4) and low SO<sub>2</sub>/H<sub>2</sub>S ratios (e.g., the Nevado del Ruiz gas composition in Table I). In addition, CH<sub>4</sub> commonly appears in low-temperature fumaroles; its origin is thought to be hydrothermal.

### III. CASE STUDIES

We now present six case studies of volcanoes where detailed investigations of the fumarolic gas discharges have made major advances to our understanding of both the gases and the volcanoes themselves. The Kudriavy study is an excellent example of determining the ultimate sources of gases. The Mt. St. Helens and Usu cases demonstrate how degassing of magma and progressive contamination by meteoric water alter the fumarolic gas compositions. The White Island, Vulcano, and Galeras examples highlight the nearly ubiquitous interaction of magmatic gases with shallow hydrothermal systems and groundwaters. Importantly, the nature of this interac-

tion can be different from one volcano to the next, depending on factors such as the state of activity and rock permeability.

#### A. Sources and Fluxes of He, CO<sub>2</sub>, and N<sub>2</sub> at Kudriavy (Kurile Islands, Russia)

Kudriavy volcano is one of the many volcanic edifices of the Kurile convergent plate island arc. Its active summit features several fumarole fields that have been degassing continuously at high temperatures (up to 950°C) for at least 100 years, without eruption. The SO<sub>2</sub> emission rate measured remotely by correlation spectrometer (COSPEC) was 70 ± 25 metric tonnes per day in 1995. The chemical and isotopic compositions of the high-temperature fumaroles (Table I) and the COSPEC measurement allowed scientists to estimate the contributions of the mantle, crustal, and subducted material required to balance the long-term magmatic He, CO<sub>2</sub>, N<sub>2</sub>, and H<sub>2</sub>O output from this subduction-zone volcano. Their study nicely illustrates how an integrated dataset on volcanic gases can be used to derive information on magma sources and the cycling of volatiles through subduction zones from the Earth's mantle to the surface.

Volcanic gas discharges from the Kudriavy high-temperature fumaroles are a good example of magmatic gases in subduction zone volcanoes. The <sup>3</sup>He/<sup>4</sup>He ratio of these gases range from 6.4 to 6.8R<sub>A</sub>, similar to values observed at other volcanoes in this tectonic setting. The ratio indicates that 84% of the He is of mantle origin, while the rest is from a radiogenic source in the crust. The total output of He from the volcano allowed calculation of the amount of mantle material that is degassing and contributing to the He flux over time. The CO<sub>2</sub>/<sup>3</sup>He ratios of the magmatic gases indicate that about 12% of the degassing CO<sub>2</sub> is of mantle origin, with the remainder derived from subducted marine carbonates in the oceanic crust and organic sedimentary carbon. Nitrogen degassing from the mantle accounts only for about 2% of the total N<sub>2</sub> discharges from the volcano, with the sediments of the subducted oceanic crust contributing most of the total N<sub>2</sub> flux. The study also supports the view that dehydration of minerals in the subducted oceanic crust is the major source of H<sub>2</sub>O degassing from subduction zone volcanoes.

For the case of Kudriavy, it is possible to balance the flux of nonmantle gases with the volatiles supplied to the system by the subduction process, taking into account the rate of subduction, thickness, and composition of the subducted sediments and oceanic crust. The re-

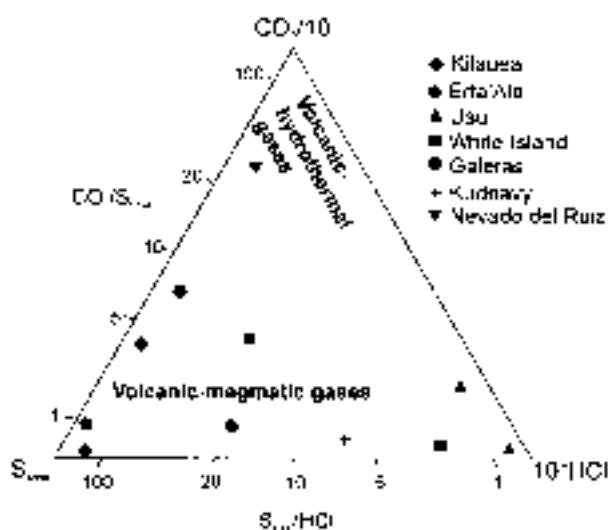

FIGURE 4 Relative CO<sub>2</sub>, S<sub>total</sub>, and HCl of fumarolic gases and inferred compositional fields for magmatic-dominated volcanic gases and hydrothermal-dominated volcanic gases. The gas compositions refer to those in Table I.

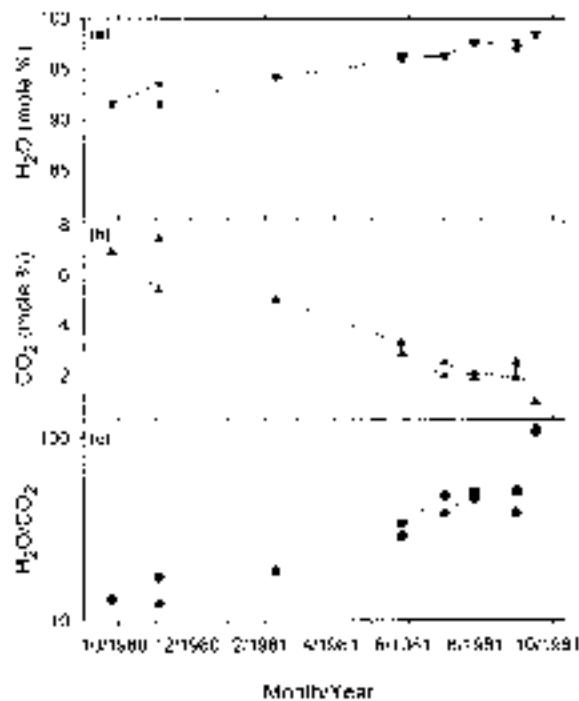

FIGURE 5 Temporal evolution of the (a)  $\text{H}_2\text{O}$  content, (b)  $\text{CO}_2$  content, and (c)  $\text{H}_2\text{O}/\text{CO}_2$  ratio in fumarolic gas discharges from Mt. St. Helens, 1980–1981. Data compiled from Gerlach and Casadevall (1986).

sults show how subduction zones not only recycle solid material (rocks) back to the surface of the Earth, which contributes to the formation of continents, but also recycle volatiles through degassing of volcanoes, which contributes to the composition of the Earth's atmosphere.

#### B. Magma Degassing and Development of a Hydrothermal System at Mt. St. Helens (USA) and Usu (Japan)

Following the catastrophic eruption of 18 May 1980 at Mt. St. Helens, a dome formed within the newly excavated crater. Many fumaroles appeared on the dome and on the crater floor, providing an opportunity to investigate the chemical changes during noneruptive periods of degassing between September 1980 and October 1981. During this time, the  $\text{H}_2\text{O}/\text{CO}_2$  ratio in the gas discharges increased, because of the steady decrease of the  $\text{CO}_2$  content and concomitant increase of the  $\text{H}_2\text{O}$  content (Fig. 5). Although showing more scatter, the trend for  $\text{S}_{\text{total}}$  was similar to that for  $\text{CO}_2$ . These changes were accompanied by a decline in the maximum

fumarole temperature from 828 to 600°C. These variations developed in response to progressive dilution of the magmatic gases by hydrothermal steam. The hydrothermal steam component was produced as surface waters started to infiltrate the system and boiled. Admixture of meteoric water accounted for 20–30% of the  $\text{H}_2\text{O}$  content in the fumarolic gases. In addition, decline in the magmatic volatile flux, probably due to a magma that progressively lost its gas, also contributed to the chemical changes in the fumarolic gases (i.e., decrease of  $\text{CO}_2$ ).

A similar scenario was observed at Showa-Shinzan, a dome that grew during the 1943–1945 eruption of Usu volcano (Japan). The gas survey spanned a period of 31 years from 1954 through 1985, during which time the maximum temperature of the high-temperature fumaroles decreased from 800 to 336°C. In parallel, the gas compositions became increasingly  $\text{H}_2\text{O}$ -rich with time because of the progressive infiltration of meteoric water into the dome (Fig. 6). The evolution of the gas chemis-

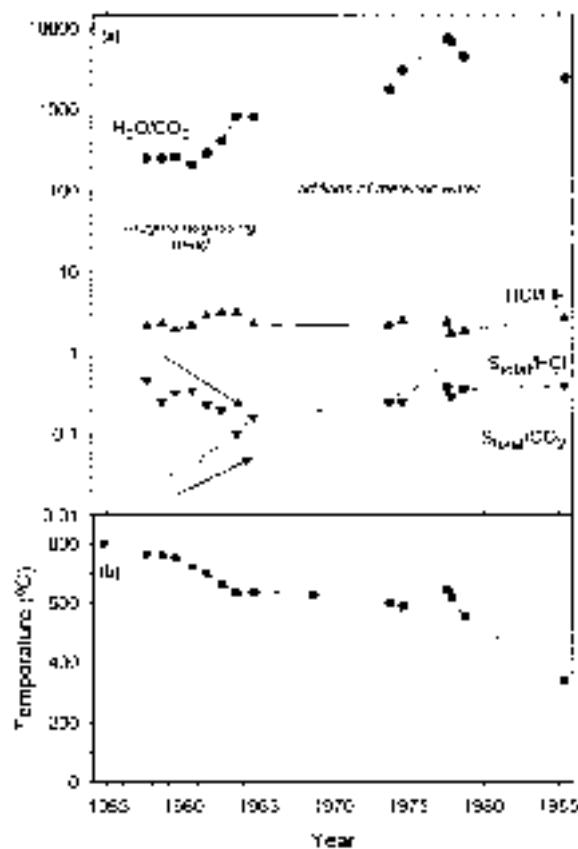

FIGURE 6 Temporal evolution of the (a)  $\text{H}_2\text{O}/\text{CO}_2$ ,  $\text{S}_{\text{total}}/\text{CO}_2$ ,  $\text{S}_{\text{total}}/\text{HCl}$ , and  $\text{HCl}/\text{HF}$  ratios and (b) maximum temperature in a high-temperature fumarolic gas discharge from Mt. Usu, 1954–1985. Data compiled from Symonds et al. (1996).

try between 1954 and 1964 also was controlled by the degassing of the dome. During this period, the  $S_{\text{total}}/\text{CO}_2$  and  $S_{\text{total}}/\text{HCl}$  ratios of the fumarolic gas increased and decreased dramatically, respectively, while the  $\text{HCl}/\text{HF}$  ratios remained more or less constant (Fig. 6). These trends indicate the early degassing of  $\text{CO}_2$  (i.e., the less soluble component), followed by  $S_{\text{total}}$ , and then  $\text{HCl}$  and  $\text{HF}$  from the magma body.

Early escape of  $\text{CO}_2$  from magmas is also responsible for the different  $\text{CO}_2$  contents of high-temperature volcanic gases vented by Kilauea during summit lava lake and east rift zone eruptions. In the first case, continuous supply of magma from below results in relatively  $\text{CO}_2$ -rich gases being released at the summit. In the second situation, the rising magma is subsequently transported laterally along the rift zone, resulting in enhanced degassing, depletion of  $\text{CO}_2$ , and gases with distinctly lower  $\text{CO}_2$  contents than at the summit (see the two Kilauea gas compositions in Table I).

### C. Temporal Variations in Gas Chemistry at White Island (New Zealand) and Vulcano (Italy)

White Island is an active volcano on an uninhabited island located 50 km offshore at the northeastern end of the Taupo volcanic zone on the North Island of New Zealand. It has been releasing fumarolic gases for more than 150 years and has experienced several periods of eruptive activity. The temperatures of crater fumaroles during this time have ranged from 100 to above 700°C. Regular sampling of White Island fumaroles since 1971 has allowed volcanologists to track the activity of the magma and its associated hydrothermal system. The gas survey results serve to constrain a model for the physical structure of magma-hydrothermal systems. According to this model, a column of high-temperature gases released by a magma body at depth is surrounded by an envelope of highly mineralized hydrothermal water (a brine) and vapor.

As shown in Fig. 7, the high-temperature gases ( $> 400^\circ\text{C}$ ) displayed cyclic changes in temperature and in gas ratios (e.g.,  $\text{H}_2\text{O}/\text{CO}_2$ ,  $S_{\text{total}}/\text{CO}_2$ , and  $\text{HCl}/\text{CO}_2$ ) before the start of the 1976–1982 eruptive period. These changes are largely due to variations in the relative contributions from three major components: (1) shallow groundwater; (2) deeper highly acid and hydrothermal brine; and (3) magmatic gases. During periods of low magmatic gas release, the brines invade the main conduit feeding the fumaroles, and interaction of rising hot mag-

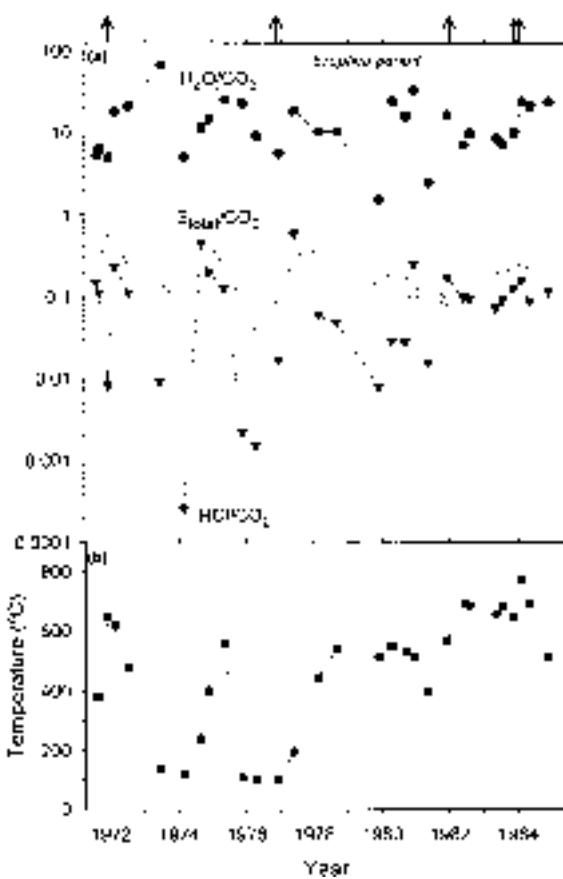

FIGURE 7 Temporal evolution of the (a)  $\text{H}_2\text{O}/\text{CO}_2$ ,  $S_{\text{total}}/\text{CO}_2$  and  $\text{HCl}/\text{CO}_2$  ratios and (b) maximum temperature in high-temperature fumarolic gas discharges from White Island, 1971–1984. Arrows indicate eruptions. Data compiled from Giggenbach and Sheppard (1989).

matic gases with the brines leads to drastic reductions in fumarole temperatures and absorption of more water-soluble gases such as  $\text{HCl}$ ,  $\text{HF}$ , and  $\text{SO}_2$ . Part of the sulfur content of the gas is removed as elemental sulfur, causing a corresponding decrease in the fumarole  $S_{\text{total}}/\text{CO}_2$  ratio. Carbon dioxide seems to be less affected by these processes than  $\text{HCl}$  and  $\text{SO}_2$  because of its lower solubility in the brines, and thus is a good “reference” gas to evaluate changes in the more reactive and soluble species. When magmatic gas pressures build up again in the conduit, the process is reversed as reheating evaporates the brines and remobilizes elemental sulfur deposits. As a result, previously absorbed volatiles are quickly released, sometimes producing gas compositions significantly enriched in  $\text{HCl}$  and  $S_{\text{total}}$  (i.e., high  $S_{\text{total}}/\text{CO}_2$  and  $\text{HCl}/\text{CO}_2$  ratios). Two complete absorption-desorption cycles were observed during the 5 years preceding the 1976–1982 eruption.

Vulcano is one of the Aeolian Islands located north of Sicily. The island is renowned for its tourist facilities. Vulcano is a very active volcano, and the last explosive eruption in the Gran Cratere La Fossa occurred in 1888. This eruption was preceded by an increase in the temperature and output rate of the fumarolic gas discharges. A new heating phase of the crater fumaroles, accompanied by significant oscillations in gas chemistry, began in late 1977 and peaked in May 1993 when maximum temperatures reached 690°C. Aware of the potential risk for eruption, Italian volcanologists have conducted numerous studies aimed both at developing a reliable geochemical model of the fumarolic system and at defining a strategy for the geochemical surveillance of the island to help forecast eruptions.

Similar to White Island, deep magmatic gases interact with shallow hydrothermal fluids. However, the hydrothermal component seems to consist mainly of hot steam generated by evaporation of brines entering the high-temperature zone surrounding the conduit of rising magmatic fluids. This hot steam further acquires acid gases (HCl, HF, SO<sub>2</sub>, and H<sub>2</sub>S) as it reacts with rock minerals and previously deposited salts within the hydrothermal reservoir. Thus, most variations in the acid gas contents of the fumarole gas discharges reflect fluctuations in these reactions, which correlate with changes in subsurface temperature conditions. In parallel, the magmatic component present in the gas discharge also experienced significant short-term increases during periods of high seismic activity beneath the crater. An interesting aspect of Vulcano is that the fumaroles appear to incorporate a marine fluid signature, as inferred from the temporal evolution of its water isotopic compositions ( $\delta D$  and  $\delta^{18}\text{O}$ ). The marine contaminant may be seawater that directly enters the magma-hydrothermal system at shallow levels or water trapped in the sedimentary rocks (i.e., connate water) surrounding the magma that is heated and evaporated.

#### D. Cyclic Sealing of the Magma-Hydrothermal System at Galeras (Colombia)

Galeras is an active 4200-m-high volcano in the Colombian Andes near Ecuador. In 1988, increases in seismicity, gas emission rates, and fumarole temperatures marked the start of a new period of unrest. A lava dome was emplaced in the active cone in October 1991, which was later destroyed by an explosive eruption on July 16, 1992. Five subsequent explosive eruptions occurred in 1993; the 14 January event killed six scientists who were

working in the crater. The chemical compositions of volcanic gases collected between 1989 and 1994 showed the effects of long-term magma degassing. During this period, the H<sub>2</sub>O/CO<sub>2</sub>, S<sub>total</sub>/CO<sub>2</sub>, and HCl/CO<sub>2</sub> ratios increased slightly in the fumarolic gas discharges (Fig. 8). Again, these observations support the idea that CO<sub>2</sub>, the least soluble of the major magmatic volatiles, degasses more readily than H<sub>2</sub>O, S<sub>total</sub>, and HCl. In 1995, all the gas ratios had decreased significantly, possibly indicating degassing of a new CO<sub>2</sub>-rich magma batch.

In contrast to this long-term trend, variations in the chemical and isotopic compositions of fumaroles both preceded and followed explosive eruptions over the course of days, weeks, or months. Although the SO<sub>2</sub> emission rate measured by COSPEC declined significantly prior to the July 16, 1992 eruption, the gas discharges became more CO<sub>2</sub>-rich and the maximum fumarole outlet temperatures dropped. The HCl/CO<sub>2</sub> gas ratio decreased dramatically over the space of 2 weeks prior to July 16, but the S<sub>total</sub>/CO<sub>2</sub> ratio experienced comparatively minor changes (Fig. 8). At the same time, unusual low-frequency seismic events began to be observed, with the rate of occurrence and duration of individual signals increasing before the eruption. Afterward, the seismicity abruptly disappeared.

These variations show the interaction of high-temperature magmatic gases with a shallow hydrothermal system that selectively absorbed the more water-soluble

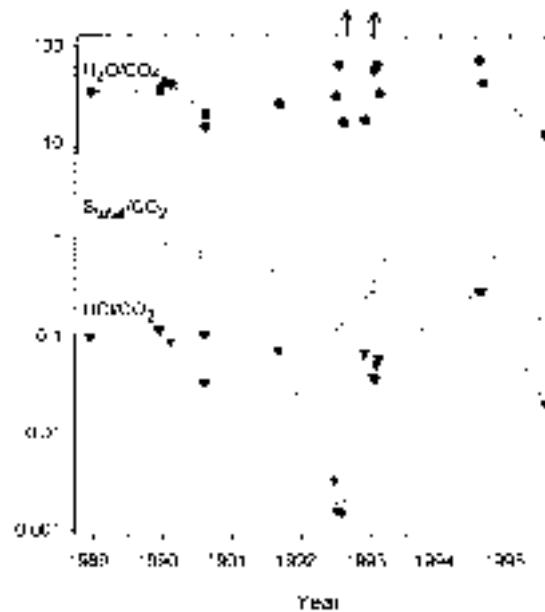

FIGURE 8 Temporal evolution of the H<sub>2</sub>O/CO<sub>2</sub>, S<sub>total</sub>/CO<sub>2</sub>, and HCl/CO<sub>2</sub> ratios in fumarolic gas discharges from Galeras, 1989–1995. Arrows indicate eruptions. Data compiled from Fischer et al. (1997).

gases ( $\text{SO}_2$ ,  $\text{H}_2\text{S}$ , and  $\text{HCl}$ ) into the liquid phase. The failure of hot magmatic gases to escape the volcano appear to be related to the “sealing” of the gas conduits. This sealing process is not well understood but is clearly important, both to the understanding of the shallow magmatic–hydrothermal system and to the development of overpressure within the volcano as gas release was impeded. The low-frequency seismicity that was observed before the Galeras eruptions is a clear indication of the pressure buildup, which eventually resulted in the explosive failure of the seal. The seal may have developed as hydrothermal minerals such as silica were deposited within fractures and openings in the conduit system, clogging the gas pathways to the surface. It is also possible that overpressure was developed in the cooling magma itself that filled the conduit system. Whatever the cause of the sealing and associated pressure buildups, it is clear that magmatic–hydrothermal interaction was important for understanding the explosive 1992–1993 eruptions of Galeras. It is also clear that this type of interaction exists at many volcanoes, and an improved understanding of these processes is a future challenge to permit better forecasting of explosive eruptions.

#### IV. DIFFUSE FLANK DEGASSING

On a volcano, magmatic gases are clearly channeled through the central conduit or conduits. Magmatic gases also may percolate through a volcano’s porous flanks to the surface. Since this type of degassing cannot be seen directly, in contrast to the frequently spectacular crater emissions, diffuse flank degassing tends to be overlooked. Yet this source also may emit significant quantities of gas to the atmosphere. The types of gases that tend to be emitted are nonreactive and do not contain species that are highly acidic (e.g.,  $\text{SO}_2$ ,  $\text{HCl}$ , HF). They also tend to be emitted at low temperatures through the soil and springs. Such gases include  $\text{CO}_2$  and He. Radon is also emitted through the flanks, but it is not clear whether it is derived from the magma or from shallow levels within the volcano, even the soil itself.

Although estimates of diffuse  $\text{CO}_2$  flank degassing have been made from a number of volcanoes, the numbers vary substantially. There is thus no real consensus at present about the relative importance of flank degassing and how much volcanic gas it contributes to the atmosphere. Nonetheless, as more studies of flank degassing are made, it is becoming increasingly obvious that faults and fractures play an important role in channelling the gases to the surfaces. In fact, the presence or

absence of faults having surface expression may be the principal control on whether a volcano is able to degas through its flanks.

#### A. Diffuse Emissions of Carbon Dioxide

Only several volcanoes have been studied in any detail for their diffuse emissions of  $\text{CO}_2$ . Chief among these is Mt. Etna, which is a prodigious emitter of volcanic gas. Copious quantities of  $\text{CO}_2$ ,  $\text{SO}_2$ , and other species are released at the summit crater. In addition, it appears that large amounts of  $\text{CO}_2$  may be escaping through the volcano’s flanks. The problem is how much; estimates range from 2700 to 35,000 metric tonnes per day! Thus, the exact amount of diffuse degassing remains uncertain, and it probably varies temporally with the activity of the volcano. Yet the various chemical measurements indicate that much if not most of the  $\text{CO}_2$  is derived from a deep magmatic source. For example, the isotopic ratio of carbon falls within the magmatic field ( $\delta^{13}\text{C} \sim -4\text{\textperthousand}$ ), and He gas associated with the  $\text{CO}_2$  has  $^3\text{He}/^4\text{He}$  values of  $5\text{--}8R_A$ , clearly showing the mantle-derived nature of the gas. At Etna, it is generally recognized that the diffuse gas emissions are concentrated along fractures and faults.

Another interesting example of diffuse  $\text{CO}_2$  emissions is Mammoth Mountain, a rhyodacite dome complex located on the southwestern rim of Long Valley caldera (California, USA), which is currently exhibiting restlessness. After a period of elevated seismicity in 1989–1990 in the area, tree kills were observed to develop on the slopes of Mammoth Mountain. These kills were the result of localized emissions of  $\text{CO}_2$  passing diffusely through the soil at low temperatures. In places, soil gas concentrations reached nearly 100% in the winter when the  $\text{CO}_2$  was retained in the soil by the snow pack. The diffuse flux of  $\text{CO}_2$  at Mammoth is 100–500 metric tonnes per day, the fluxes varying with time. Similar to Mt. Etna, carbon isotopic values are magmatic ( $\delta^{13}\text{C} = -3$  to  $-5\text{\textperthousand}$ ), as are the mantle-like  $^3\text{He}/^4\text{He}$  ratios ( $\sim 5R_A$ ). Also similar to Mt. Etna, the tree kills appear to be situated on or near mapped faults on Mammoth Mountain. The  $\text{CO}_2$  release could be related to dike intrusion, to fracturing of conduits above an older magma body, or to shaking and release of  $\text{CO}_2$  bubbles from a magma chamber, triggered by seismicity.

Many interesting questions remain regarding this style of degassing. The carbon isotopic values are suggestive of a magmatic source, but they are not definitive proof. The measured values also can be interpreted as a mixture of mantle and sedimentary carbonate compo-

nents, or a mixture of mantle and organic components. A third possibility is that the carbon isotopic ratio is fractionated and changes during the degassing process itself. Studies using noble gas isotopes may help to shed light on the sources of the CO<sub>2</sub>.

### B. Radon, Helium, and Hydrogen

Radon (Rn) is a naturally occurring radioactive gas, with a half-life of 3.82 days, which appears to be a sensitive indicator of permeability within soil or at shallow levels beneath the surface. It can therefore be used to delineate faults and fractures. There is also a clear association between seismicity and Rn concentrations in the soil. However, Rn also is influenced by climatic variations (e.g., dry vs wet seasons) and by soil properties (porosity, humidity, etc.). Its short half-life indicates that on a volcano, much of the Rn measured in the soil is derived from shallow levels and not from the magma or deep faults, unless it is transported rapidly to the surface.

Helium also is present in soil gas and can be indicative of flank degassing. Since its atmospheric concentration is about 5 parts per million (ppm), it is sometimes difficult to observe the magmatic component of He in soils, since concentrations rarely exceed 20 ppm. The isotopic <sup>3</sup>He/<sup>4</sup>He ratio is a very useful indicator of magmatic gas, as noted earlier. However, measuring this ratio in soil gas can be difficult because of the large atmospheric contamination of the soil gas.

Hydrogen is another gas that can be present in soils, but very little is known of its distribution on volcanoes. In zones of active faulting, however, H<sub>2</sub> is generated by the pulverization and fragmentation of rock during faulting. Thus, high concentrations of H<sub>2</sub> in soil can indicate zones of active faulting, with gas generation at relatively deep levels. Consequently, H<sub>2</sub> is also a potentially useful gas for studying faulting and fracturing on volcanoes.

### C. Mechanisms of Diffuse Flank Degassing

The association between faults and fractures on the one hand and diffuse degassing on the other hand seems clear. Yet a general model of diffuse flank degassing on volcanoes does not exist. Are there changes in the relative proportions of crater and flank degassing, whereby changes in permeability in the crater region affect the flank degassing in more distant regions? Are upper slopes of volcanoes, with their cover of recent lavas,

relatively impermeable so that they prevent or hinder diffuse degassing, whereas lower slopes which may be more fractured and faulted allow for increased diffuse emissions? Or are the upper slopes of volcanoes a recharge zone where CO<sub>2</sub> is dissolved into groundwater and then transported to lower elevations where it is released? Indeed, cold groundwater appears to transport a small but appreciable fraction of the CO<sub>2</sub>. These questions will form the basis for future research on diffuse flank emissions of volcanic gas.

### D. Gases Discharging in Hot and Cold Springs

Hot springs and cold springs are a common feature on the flanks of active volcanoes. They contain gases dissolved in their waters, some of which may be of magmatic origin. In addition, cold and hot springs often display gas bubbles discharging from the bottom of the spring to the surface. These gases are predominantly CO<sub>2</sub>, but H<sub>2</sub>S and other trace gas species (CH<sub>4</sub>, N<sub>2</sub>, noble gases) may also be present. High <sup>3</sup>He/<sup>4</sup>He ratios are a good indication of the magmatic sources of these gases. Monitoring of the chemical and isotopic composition of gas discharges from springs can contribute significantly to the monitoring of soil gases and help scientists to understand the activity of a volcano and forecast its time of reactivation.

---

### V. CONCLUSIONS

We have made great advances in our understanding of volcanic gases in the past 30 years, but as is often true in science, many important questions still remain to be solved. We can safely say that the next 30 years will be an exciting time for volcanic gas research. In fact, as the millennium approaches, we may be on the verge of making some fundamental breakthroughs in our understanding of volcanic gases. In this respect, the development of remote sensing techniques that will allow regular measurements of gas plume compositions from a distance marks a new era in the study of volcanic gases.

Our knowledge of how gas is transported and stored within a volcano is rudimentary. We do not have a clear understanding of the complexity of the conduits, fractures, and other pathways that channel gas to the surface. Neither do we have a good model of how diffuse gases are transported through the flanks of a volcano.

We need a reliable geochemical model, based on thermodynamic understanding and gas solubilities, to be able to confidently predict the temporal evolution of individual gas species. We have a reasonable knowledge of the major components of volcanic gas, but we know almost nothing about the many minor and trace species that coexist with the major gases. These low-concentration species (e.g., boron) have great potential for shedding light on deeper processes within a volcano and for improving our eruption forecasting ability.

The behavior of volcanoes that release large amounts of gas on a continuous basis is fundamentally different from that of volcanoes that store gas over long periods. This dichotomy between “open” and “closed” systems is fundamental, yet we do not know why a particular volcano is open or closed, nor is it clear why a volcano’s behavior may suddenly change from one style to the other. Some volcanoes emit huge quantities of gas but almost no solid material; this enigmatic behavior is probably the result of a near-continuous magma supply beneath the volcano, but our understanding is primitive. Although the study of volcanic gas is no longer in its infancy, we still have important challenges in front of us.

- VIII. Summary

**G**EOTHERMAL SYSTEMS consist of three main elements: (1) permeable reservoir rock, (2) water to carry heat from the reservoir to the earth's surface, and (3) a heat source. Practically any rock type can serve as a host for a geothermal reservoir, and groundwater, usually consisting of ancient to modern precipitation or seawater, circulates to depths of many kilometers virtually everywhere in the crust. Thus, hotter-than-normal rock and water at a relatively shallow depth is the primary characteristic that distinguishes geothermal systems from other groundwater systems.

Geothermal systems commonly produce hot springs and fumaroles as surface expressions of underlying hot reservoirs. Hot and mineral springs have been universally revered for their soothing, therapeutic qualities and cleansing characteristics. Hot spring and fumarole areas were exploited for sulfur and other minerals throughout ancient times. During the Middle Ages the commercial

value of Italian hot-spring deposits led to wars among local republics. Electricity was first produced from a steam well at Larderello (Italy) in 1904 and commercial electricity was first marketed in 1913. Since that time, geothermal power has been developed by many countries as an alternative to burning imported or domestic fossil fuels. About 8000 MW of electric power are now produced from geothermal systems worldwide, equivalent to about 80 million barrels of petroleum annually. Although low-temperature resources have been used extensively for many years and are becoming more widely utilized as drilling methods and heat extraction technologies improve, we will focus herein on high-temperature ("high enthalpy") geothermal systems because of their common association with volcanism and tectonic activity, and their ability to produce electric power.

---

## I. RESOURCE LOCATIONS AND TYPES

Geothermal resources are most prevalent in regions of elevated heat flow and vigorous fluid circulation. These regions are commonly located along or near convergent plate margins, near transform plate boundaries, within spreading centers and rifts, and within hot spots. As a result, geothermal resources are not distributed evenly over the globe (Fig. 1) and certain countries or regions are blessed with resources while others are relatively

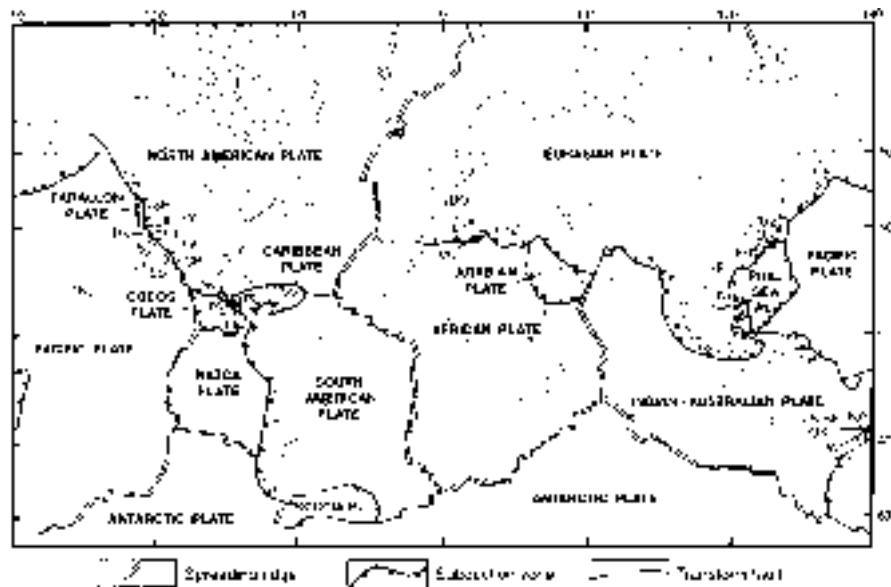

FIGURE 1 The global distribution of geothermal resources is highly correlated with lithospheric plate boundaries, although some sites occur at hot spots or within rifts. Locations mentioned in this article are shown by dots: A (Ahuachapán, El Salvador), B (Bulalo, Philippines), CP (Cerro Prieto, Mexico), D (Dixie Valley, USA), DO (Dogger, France), F (Fuzhou, China), FU (Fushime, Japan), K (Kamojang and Darajat, Indonesia), KL (Kilauea, USA), KW (Kawerau, NZ), L (Larderello, Italy), LA (Lassen, USA), LV (Long Valley, USA), LY (Lafayette, USA), M (Miravalles, Costa Rica), MA (Matsukawa, Japan), O (Oku-aizu, Japan), OK (Ohaaki, NZ), P (Pacaya-Amatitlán, Guatemala), PL (Platanares, Honduras), R (Rotorua, NZ), RK (Rotokawa, NZ), S (Steamboat Hills, USA), SH (Mount St. Helens, USA), SS (Salton Sea, USA), T (Tiwi, Philippines), TG (The Geysers, USA), W (Wairakei, NZ), V (Valles caldera, USA), VU (Vulcano, Italy), Y (Yellowstone, USA), Z (Zunil, Guatemala). Locations of other geothermal fields are shown by open circles. Geothermal prospects are not shown. barren. Not surprisingly, the 10 leaders in electrical generation occur in regions of active volcanism (Table I). In addition, some countries have been more effective at exploiting either high- or low-temperature resources than others, depending on technology levels, energy requirements, and prevailing economics. Probably the largest and most abundant high-temperature systems on Earth occur along submarine rifts and transform boundaries, yet we know the least about these systems because they are so difficult to explore.

There are five principal types of geothermal systems based on geologic, geophysical, hydrologic, and engineering criteria. The first three exploit natural reservoirs of hot water and are generically called hydrothermal systems. The second two require pumping a fluid, generally water, into the ground and then out again to extract heat. These systems are technically feasible under certain conditions, but commercially impractical with present economics because of the low cost of fossil fuels.

1. *Young igneous systems* are associated with Quaternary volcanism and magmatic intrusions. About 95% of volcanic activity occurs along plate boundaries and within hot spots. Such environments are usually associ-

<sup>a</sup> Energy usage may be less than installed capacity (MWe = megawatts electrical; MWt = megawatts thermal; 1 MWe ≈ 7 MWt).

ated with major tectonic activity and seismicity. Fluids derive their heat from the margins of crystallizing or recently crystallized magma. These geothermal systems are generally the hottest ( $\leq 370^{\circ}\text{C}$ ) and reservoir depths are commonly  $\leq 1.5$  km, although some are deeper.

2. *Tectonic systems* are those with elevated heat flow but essentially devoid of igneous activity. They occur in backarc environments, regions of crustal extension, collision zones, and along fault zones of any displacement or length. Tectonic systems are usually associated with elevated seismicity due to Quaternary faulting and with elevated heat flow due to thin crust. Deep circulation of fluids into the crust and ascent of these fluids along faults moves heat upwards into favorable geologic structures. Tectonic systems capable of electricity generation usually have reservoir temperatures  $\leq 250^{\circ}\text{C}$  and occur at depths  $\geq 1.5$  km.

3. *Geopressured systems* are found in sedimentary basins where subsidence and deep burial of fluid-bearing strata has formed hot, “overpressured” reservoirs. Wells drilled into geopressured reservoirs exhibit very high artesian pressures. Heat flow and seismicity are comparatively low to normal. Most systems of this type have characteristics resembling oil and gas fields. Energy stored as excess pressure and as dissolved methane is potentially more valuable than the fluid enthalpy. Geopressured systems often require deeper drilling than young igneous and tectonic systems. Typical depths and temperatures are 1.5 to 3 km and 50 to  $190^{\circ}\text{C}$ .

4. *Hot dry rock systems* exploit heat stored in low-porosity, impermeable rocks at varying depths and temperatures. A deep fracture network comprising the “reservoir” is created artificially in such a way that at least two wells intersect permeable structures. Surface water is pumped down an injection well, through the fractures, and out the production well(s), literally mining heat from the rocks. Experimental hot dry rock systems have been developed in several countries (United States, England, France, and Japan) since the mid-1970s, but none are presently capable of commercial production. Drilling and completion costs are high in deep, hot, dense (usually crystalline) rocks. Each system has unique engineering challenges, and most systems have large leak-off rates while water is pumped through the reservoir. Production temperatures and depths have ranged from 120 to  $225^{\circ}\text{C}$  and 2 to 4 km in experimental systems.

5. *Magma tap systems* involve drilling into shallow magma bodies, installing a heat exchanger, and circulating a fluid (probably water) through the exchanger to extract heat. Experiments on this concept have been conducted at a lava lake on Kilauea Volcano, Hawaii, but materials that can withstand the high temperatures and corrosive properties of magma are exceptionally

costly. Extending this concept to greater depths adds exploration and drilling challenges that are presently too expensive to overcome. Nevertheless, magma is the purest form of natural heat in the shallow crust ( $\leq 1200^{\circ}\text{C}$ ).

## II. HEAT FLOW IN THE EARTH

Heat is transferred by conduction, convection, and radiation. However, only the first two mechanisms are important when considering geothermal resources. The basic equation of conductive heat flow,  $q$ , is

$$q = k(dT/dz), \quad (1)$$

where  $k$  = thermal conductivity of rock,  $T$  = temperature,  $z$  = depth, and  $dT/dz$  = geothermal gradient ( $^{\circ}\text{C}/\text{km}$ ). Units of heat flow are  $\text{mW m}^{-2}$  and HFU (heat flow units, where 1 HFU =  $41.8 \text{ mW m}^{-2}$ ). Thermal conductivity of rock is highly variable (typically  $\leq 3.5 \text{ W/m}$ ) and also depends on temperature. Values of  $k$  for crystalline rocks at  $250^{\circ}\text{C}$  are about 20% less than values at  $25^{\circ}\text{C}$ . Crystalline rocks also have virtually no pore spaces and are more conductive than water-rich sedimentary rocks ( $\leq 1 \text{ W/m}$ ). Thermal conductivity is also affected by permeability, fracture density, and hydrothermal alteration.

Most of the heat in the Earth is generated by its gravitational force and eventually flows through the mantle and crust to the surface. Additional heat is generated by decay of radioactive elements, particularly U, Th, and K. Because these elements have differentiated throughout Earth history, they reside mainly in older continental crust. Heat generation factors have been calculated for all rock types. Granitic crystalline rocks, which may be comparatively rich in radioactive elements, typically contribute a  $\Delta q$  of 0.5 to  $2.5 \text{ mW m}^{-2}$  per 1 km of crustal thickness, or 5 to 10% of total heat flow in older continental crust. Sedimentary rocks contribute  $\Delta q$  values of 0.2 to  $1.0 \text{ mW m}^{-2}$  depending on water content. By comparison, Mg- and Fe-rich ultramafic rocks such as occur in the mantle contribute  $\Delta q$  of  $\leq 0.01 \text{ mW m}^{-2}$ ; thus, heat generation by radioactive decay is only important in some continental environments.

Within the crust as a whole,  $q$  varies from high values at or near zones of magmatism, tectonism, and thin crust to low values in most older continental crust (Fig. 2). Within restricted regions,  $q$  is more or less constant, but local geology profoundly influences  $dT/dz$ , which is rarely the same at all depths in the crust. Consider a

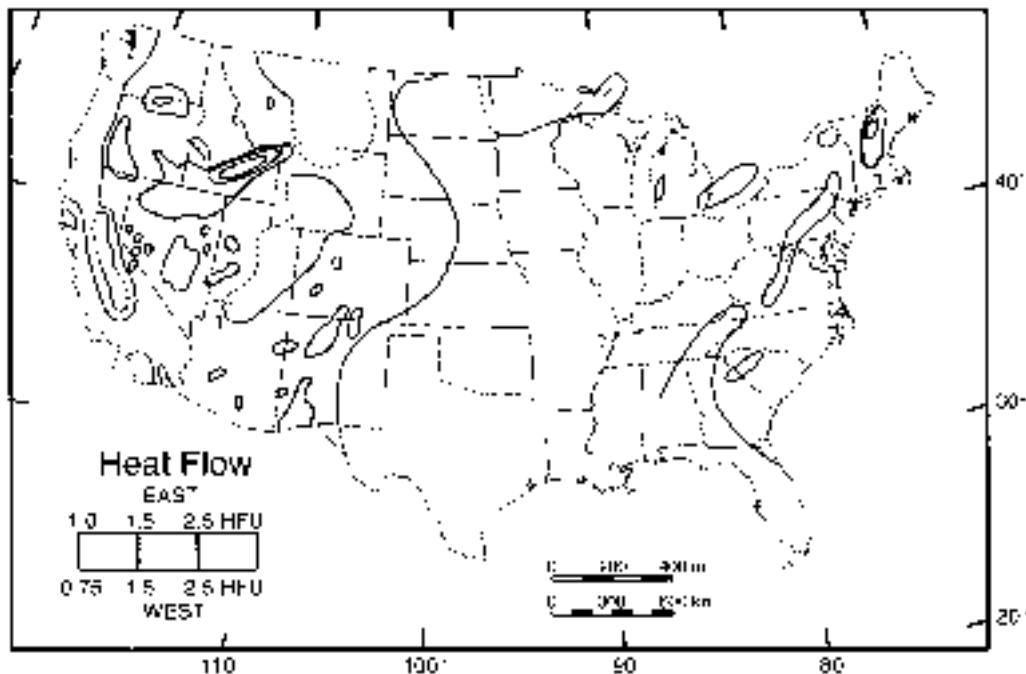

FIGURE 2 Heat flow maps, such as this example for the conterminous United States, show contoured data from wells distributed throughout a given region. Conductive heat flow is relatively low in tectonically stable regions such as the eastern United States, whereas it is relatively high in the volcanically and tectonically active regions such as the western United States.

region where  $q = 50 \text{ mWm}^{-2}$  consisting of 2 km of shale ( $k = 1.5 \text{ W/m}$ ) overlying granite ( $k = 3 \text{ W/m}$ ). To maintain constant heat flux, the geothermal gradient ( $dT/dz$ ) in the shale must be  $33^\circ\text{C}/\text{km}$ , or about twice the value in the granite. Sedimentary basins may have higher near-surface gradients than adjacent terrains because the basin is filled with unconsolidated sediments of low  $k$ . As a result, the depth to a given temperature is often less in the basin than around its margins. In effect, low-conductivity sediments act as an insulating blanket over crystalline rocks. Such geologic relations explain why deep sedimentary basins contain fluids at commercially viable temperatures even though  $q$  is relatively low.

Upward movement of water or magma transports heat to the Earth's surface more effectively than conduction. Cold waters move downward through favorable pathways in the crust and become heated. Hot water is less dense and relatively buoyant compared to cold water and tends to rise through the crust. Convection cells involving rising hot fluids and descending cooler fluids can occur within a reservoir or can include fluid leakage to the surface. Such convection cells are characteristic features of hydrothermal systems and may produce spectacular surface manifestations such as geysers, fuma-

roles, and hot springs. The equations describing convective behavior are complex, involving conservation of energy, mass, and momentum. Vapor–liquid separation also must be considered. Information on porosity and permeability of pathways along fractures and strata boundaries is required to determine flow characteristics and storage capacity of the reservoir. Boundaries between flow regimes may be sharp. Hydrothermal systems often contain zones of hot water that overlie formations containing much cooler waters (see Section IV).

### III. HEAT CONTENT AND HEAT FLOW OF MAGMATIC INTRUSIONS

Heat content of a magma chamber is dependent mostly on magma volume and temperature. Average silicate magma at  $850^\circ\text{C}$  has latent heat of crystallization of  $270 \text{ J/g}$ , heat capacity of  $1.25 \text{ J/g}^\circ\text{C}$ , and mean density of  $2.5 \text{ g/cm}^3$ . The total heat liberated by magma cooling from  $850$  to  $300^\circ\text{C}$  is about  $960 \text{ J/g}$ . If  $1 \text{ km}^3$  of magma has a mass of  $2.5 \times 10^{15} \text{ g}$ , the heat liberated by  $1 \text{ km}^3$  of magma cooling to  $300^\circ\text{C}$  is  $2.4 \times 10^{18} \text{ J}$ . Large

intrusions such as those that produce calderas contain immense quantities of heat. For example, the Bandelier pluton that created Valles caldera (USA) is estimated to have contained 3000 km<sup>3</sup> of magma; thus, it would have released roughly  $7.2 \times 10^{21}$  J while cooling from 850 to 300°C.

Heat flow surrounding a magma chamber depends on many variables, especially emplacement temperature, depth, and time. For large magma bodies, surface heat flow  $q$  as a function of time,  $t$ , after instantaneous intrusion is given by

$$q(t) = T_e k (\pi K t)^{-1/2} \exp(-z^2/4\pi t), \quad (2)$$

where  $z$  = depth to top of the magma body (in meters),  $T_e$  = intrusion temperature minus ambient temperature,  $k$  = thermal conductivity of overlying rocks, and  $K$  = thermal diffusivity of magma. The maximum achievable heat flow,  $q_{\max} \approx 0.5 T_i k / z$  (where  $T_i$  is the emplacement temperature), is reached at time  $t = z^2/2K \approx 0.016 z^2$ . As an example approximation, a large intrusion emplaced at 850°C whose top lies at 5 km depth beneath rocks with average  $k = 1.5$  W/m produces a maximum heat flow of about 125 mWm<sup>-2</sup> roughly 400,000 years after emplacement. This value of  $q_{\max}$  is about two times the average heat flow of the stable crust in the eastern United States ( $\sim 55$  mWm<sup>-2</sup>). Shallower emplacement depth raises  $q_{\max}$  and decreases the time required to achieve the maximum value.

The calculations just described above rely on several assumptions: (1) all heat transfer around the magma body is by conduction; (2) preliminary heating stages of the magma body and the rocks it has consumed or displaced are ignored; (3) replenishment of the magma body by new magma batches, a characteristic of plutons and stocks that form volcanic fields or volcanic complexes, is ignored; (4) removal of heat by circulating groundwater is ignored. These processes have contrasting effects on  $q$  and  $dT/dz$  within volcanoes.

Convection hydrothermal fluids can produce geysers, hot springs, fumaroles, and subsurface flows of hot waters that remove heat from a magmatic system much faster than heat loss by conduction alone. The rate of convective heat removal is highly dependent on circulation depth, reservoir temperature, and mass flow of water through the system. For example, deep heat flow ( $\geq 3$  km) around larger magmatic systems is about 150 to 300 mWm<sup>-2</sup>, but near-surface heat flow at the largest fumarole areas is commonly  $\geq 5000$  mWm<sup>-2</sup>. Contrasts such as these illustrate the important role of convecting fluid to the dynamics and lifetime of a geothermal system.

#### IV. CONCEPTUAL MODELS OF GEOTHERMAL SYSTEMS

##### A. Young Igneous Model

Figure 3 shows a conceptual model for a geothermal system hosted in a potentially active stratovolcano. Emplacement temperatures for andesitic intrusions usually range from 850 to 1050°C. Meteoric waters percolate deep into the ground where they are heated by the intrusive bodies. As the hot water circulates, it becomes richer in Cl, F, Br, B, SO<sub>4</sub>, HCO<sub>3</sub>, silica, major cations, and soluble metals by reaction with country rocks. Magmatic volatiles such as H<sub>2</sub>O, CO<sub>2</sub>, sulfur compounds, HCl, HF, Hg, and As may be transferred to the evolving fluid. The fluid generally becomes “neutral-chloride” in character and rises buoyantly through the volcanic edifice because of its decreased density. Alteration minerals and veins form in the reservoir rocks. Frequently, the hot fluids rise through fractures to a level where boiling occurs and a vapor phase containing steam and noncondensable gases forms. These gases feed surface fumaroles. When the steam condenses and mixes with shallow meteoric water, H<sub>2</sub>S is oxidized to sulfuric acid, which chemically alters the rock and produces “acid-sulfate” hot springs. Neutral-chloride waters are typically deeper than acid-sulfate waters, and if the two types mix, hybrid acid-sulfate–chloride waters may result. Because of topography and the hydrologic gradient, the fluids tend to flow laterally away from the volcanic center, forming hydrothermal outflow plumes. Springs of neutral-chloride character are often found many kilometers from the heat source and primary reservoir. If the intrusive bodies have largely crystallized because of age or small size, or are very deep, the contribution of magmatic volatiles to the system may be relatively small and undetectable. This general model describes many features of subduction zone systems such as Miravalles (Costa Rica), Pacaya-Amatitlán (Guatemala), Ahuachapán (El Salvador), and Bulalo (Philippines).

Young igneous systems have many other configurations than the idealized model in Fig. 3. The tops of Plio-Pleistocene magmatic complexes at The Geysers and Larderello geothermal systems lie at depths of 2 to 7 km, respectively. Although these intrusions are not associated with significant surface volcanism, they provide widespread heat for geothermal reservoirs that circulate in overlying, structurally deformed, sedimentary and metamorphic rocks. Calderas are circular collapse structures formed when large magma bodies erupt ex-

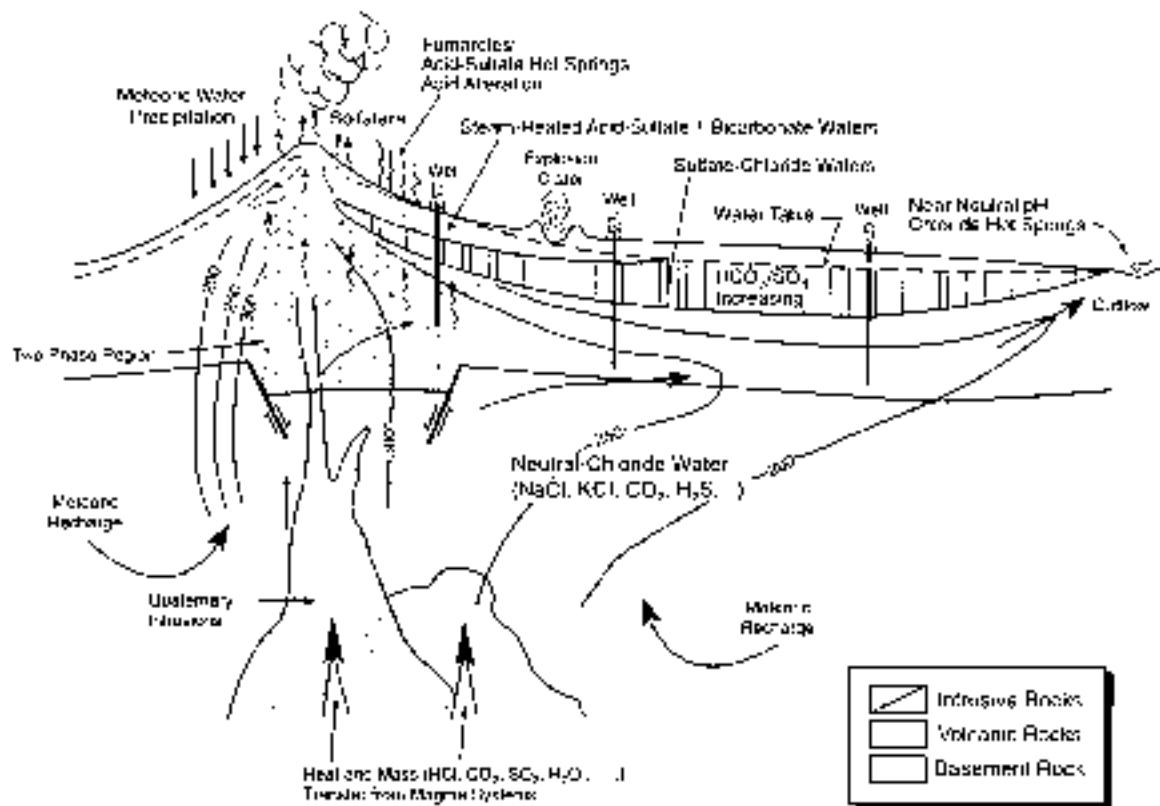

FIGURE 3 Conceptual model of a young igneous geothermal system hosted in an andesitic stratovolcano. The exploitable reservoir is usually found in horizons  $\geq 200^{\circ}\text{C}$ . Depth to typical reservoir is  $\leq 1.5$  km, whereas depth to intrusions varies from 2 to 10 km. Lateral dimension of reservoir and outflow may exceed 20 km.

plosively. Extensive aprons of tuffaceous rocks are usually deposited around the resulting hole. The faulted and fractured intracaldera rocks trap meteoric waters that are heated by subjacent magmas (usually  $\geq 5$  km depth). Because of their great size, calderas such as Yellowstone, Long Valley, and Valles (USA) host larger, longer-lived geothermal systems than those in typical stratovolcanos. Systems in some rifts, transform zones, and hot spots result from injection of dikes that heat waters circulating in grabens or other fault structures (Kilauea, USA).

## B. Tectonic Model

A conceptual model of a geothermal system hosted in an extensional tectonic environment is shown in Fig. 4. Where tectonic forces cause stretching and thinning of the crust, very hot mantle material will exist at a relatively shallow depth in the crust. The result is a higher than average thermal gradient and anomalous heat flow,

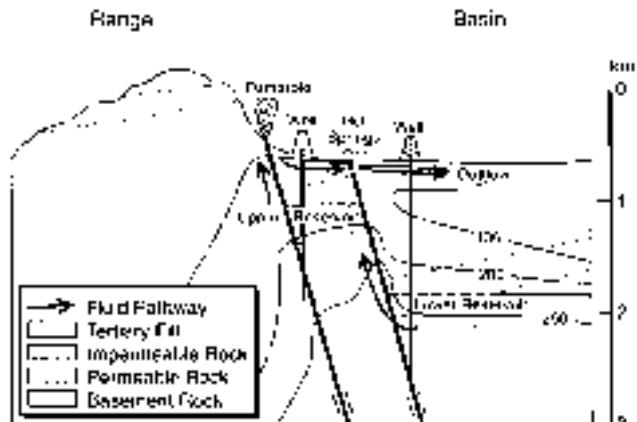

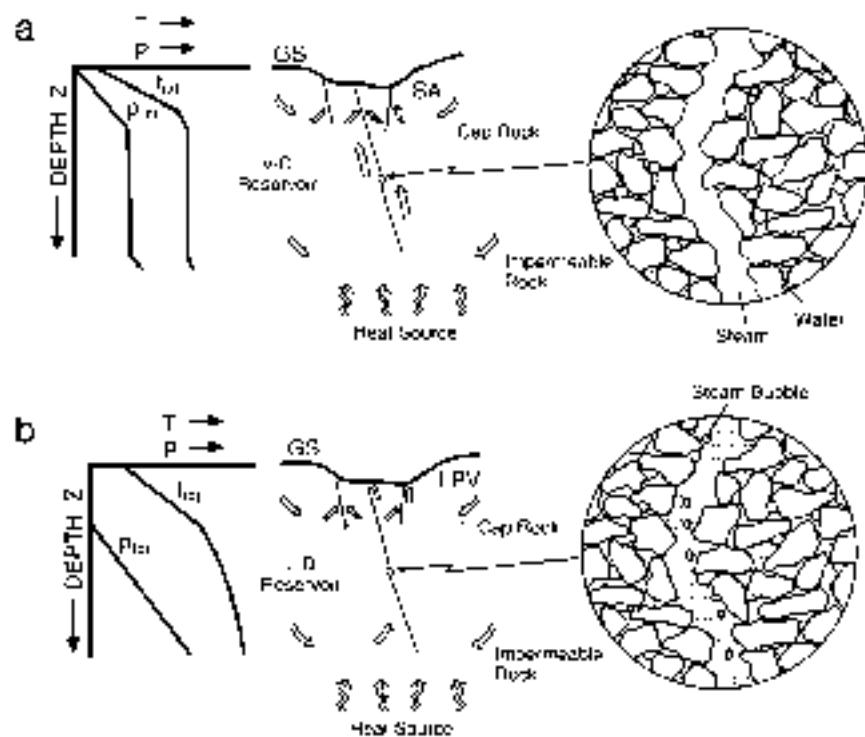

FIGURE 4 Conceptual model of a tectonic geothermal system hosted in an extensional environment. Fault density and displacement vary tremendously from site to site. Fumaroles are absent in lower temperature systems. Temperatures in  $^{\circ}\text{C}$ .

usually 1.5 to 3 times greater than normal heat flow. Basins form as a result of crustal extension and fill with low conductivity sedimentary deposits that enhance regional thermal gradients; 50 to 75°C/km is not uncommon. Deeply circulating groundwaters entering the graben form reservoirs at favorable stratigraphic horizons in down-faulted blocks. Fluid chemistry is dictated almost exclusively by rock–water interactions and temperature. Heated fluids rise buoyantly, usually along faults. Fumaroles may form along the fault traces that serve as upflow zones in hotter tectonic systems. Hydrothermal outflow plumes usually form in near-surface permeable sediments or fractured bedrocks. This generalized model describes many features of the Dixie Valley (Basin and Range Province, USA) and Platanares (back-arc environment near triple junction, Honduras) geothermal systems. Major faults with impressive displacements control the location of the preceding examples, but virtually any deep fault may act as a conduit for upwelling thermal waters (Fuzhou, China). Tectonic geothermal systems of varied geologic configuration and temperature occur throughout the world.

### C. Vapor-Dominated Systems

A generalized diagram describing conditions within a vapor-dominated geothermal system is shown in Fig. 5a. Relatively impermeable cap rocks locally saturated with shallow groundwater provide a lid over a reservoir in which steam is the continuous phase in open cracks, fractures, and faults. Liquid water fills intergranular pore spaces in the rock, particularly within fine dissolution cavities in veins and veinlets. Surface features consist of fumaroles and acid hot springs. Fluid temperature and pressure ( $T$  and  $P$ ) increase normally with depth in the impermeable cap. However, within the reservoir  $T$  and  $P$  are near the maximum enthalpy of “dry” steam (about 240°C and 3.3 MPa) and remain constant with depth until the bottom of the steam zone is penetrated. During production, boiling of interstitial water provides additional vapor and latent heat that enter the well.

This model implies that recharge by cool groundwaters is blocked by impermeable (hydrothermally altered) rocks on the margins as well as at the top of the reservoir. It also implies that a vapor-dominated system

**FIGURE 5** (a) Schematic model of conditions in a vapor-dominated system where steam prevails in open fractures but liquid water resides in pore spaces; GS means ground surface, SA means shallow aquifer. (b) Schematic model of conditions in a liquid-dominated geothermal system where liquid water saturates the rock; LPV means low-pressure vapor cap. [Modified from “Geothermal Systems: Principles and Case Histories,” Rybach and Muffler, 1981, copyright John Wiley & Sons, Ltd. Reproduced with permission.]

evolves by boiling down of an earlier liquid-dominated reservoir (described later). An alternative mechanism of formation results from descent of the upper surface of the liquid-dominated reservoir as the geohydrology of the system changes by uplift or erosion. Although the “brine” reservoirs that presumably underlie or predate vapor-dominated systems have never been found and sampled, their existence is documented by saline to hypersaline fluid inclusions captured in previously formed vein minerals.

Even though they are not as hot as some systems, vapor-dominated reservoirs are the most prized because, in contrast to liquid-dominated reservoirs, virtually all produced fluid is piped to the power turbines. Only five such systems are known: Larderello (Italy), The Geysers (USA), Matsukawa (Japan), and Kamojang and Darajat (Indonesia). These five fields contain about 35% of the world’s geothermal electrical capacity. The Geysers, the world’s largest commercial geothermal system, produced a maximum of about 1700 MWe in the mid-1980s but dropped to about 1200 MWe in 1998 because of reservoir depletion.

#### D. Liquid-Dominated Systems

Most geothermal systems are liquid-dominated. They contain liquid water in all channelways and interstitial pores, although bubbles of steam and gas may be present in the water (Fig. 5b). Groundwater recharge is not as restricted as in the vapor-dominated case, although alteration zones may be extensive. Hot waters from the reservoir commonly leak at the earth’s surface.  $T$  and  $P$  will increase steadily with increasing depth. If the rate of upflow is rapid, boiling springs or geysers will form and temperature changes with depth will closely follow the boiling-point curve.

Many liquid-dominated reservoirs are overlain by a low-pressure vapor zone that may extend hundreds of meters deep (Valles caldera and Lassen, USA). In this case fumaroles and acid hot springs occur at the surface as with true vapor-dominated systems.  $T$  rises gradually with depth, however, whereas  $P$  remains relatively low. Once the reservoir is encountered,  $P$  increases linearly because of the mass of liquid in the reservoir while  $T$  remains at or below the boiling point curve.

Liquid-dominated reservoirs have maximum temperatures of  $\leq 370^{\circ}\text{C}$  and have widely ranging salinities. When fluid is produced by wells, it must be depressurized (flashed) to produce steam for the turbines. This is done under controlled conditions with large steam

separators. The basic equation that relates fluid enthalpy,  $H$ , to steam fraction,  $y$ , is

$$H_r = yH_v + (1 - y)H_l, \quad (3)$$

where  $H_r$  is the enthalpy of the reservoir fluid,  $H_v$  is the enthalpy of separated steam at separation temperature, and  $H_l$  is the enthalpy of separated liquid at separation temperature. Steam tables are used for the calculations. For a well at  $250^{\circ}\text{C}$  supplying fluid to a separator set at  $170^{\circ}\text{C}$ ,  $y = 0.179$ , and 17.9% by mass of the produced fluid becomes steam. A separator receiving 800,000 kg/hour of fluid will produce 143,000 kg/hour of steam at 0.79 MPa absolute, which is piped to the power plant. The remaining 82% of the fluid is liquid water that must be disposed of in some manner, usually by reinjection. A well supplying  $350^{\circ}\text{C}$  fluid to the same separator yields  $y = 0.464$  and produces more than double the amount of steam. As steam separates, noncondensable gases such as  $\text{CO}_2$ ,  $\text{H}_2\text{S}$ , and  $\text{NH}_3$  partition into the steam phase while the residual brine becomes more concentrated in most chemical species.

---

#### V. GEOTHERMAL FLUID CHARACTERISTICS AND DEPOSITS

Geothermal fluids display wide variations in chemical and isotopic composition that reflect their evolution. Fluid composition may dictate the type of power scheme that is eventually designed to utilize a particular resource. Waste fluids generally contain constituents that can have adverse impacts on the environment if not disposed of properly. Some geothermal fluids contain valuable minerals or metals that are sold as by-products of energy utilization. Thus, knowledge of fluid characteristics is important to geothermal development and has applications to understanding volcanic-hosted ore deposits.

#### A. Gas Chemistry

Geothermal gases form during thermal breakdown of volatile-rich components in reservoir rocks, by reactions of circulating fluids with reservoir rocks, by contributions from degassing magma bodies, and by contributions from air-saturated meteoric water. The fluid produced at the well head from a vapor-dominated system

contains more noncondensable gases by weight than fluid produced from a typical liquid-dominated system because volatile components are preferentially transported with vapor (steam). However, the gas composition in the two types of systems is more or less similar (Table II). Reservoirs hosted in argillaceous rocks produce gases relatively rich in organic-derived components: H<sub>2</sub>S, CH<sub>4</sub>, NH<sub>3</sub>, and N<sub>2</sub>. Reservoirs hosted in carbonates or volcanic rocks tend to be richer in CO<sub>2</sub>. The proportions of noncondensable components in gas emitted from fumaroles (Fig. 6A) generally resemble those in underlying reservoirs. In contrast to volcanic gases emitted from magma, geothermal gases usually contain more CO<sub>2</sub>, less total sulfur, which is invariably

in the reduced form (H<sub>2</sub>S), rare acid halides, and higher contents of CH<sub>4</sub>, NH<sub>3</sub>, and N<sub>2</sub>.

## B. Water Chemistry

Geothermal waters range widely in composition (Table III). Total dissolved solids in high-temperature reservoir fluids ( $\geq 150^{\circ}\text{C}$ ) range from about 1000 to  $>350,000$  ppm (more than 10 times seawater). Liquid-dominated reservoir waters tend to be Na-K-Cl fluids (Fig. 6B; see also color insert), or Na-K-Ca-Cl in the very saline cases. Gas analyses indicate that dissolved CO<sub>2</sub> is usually

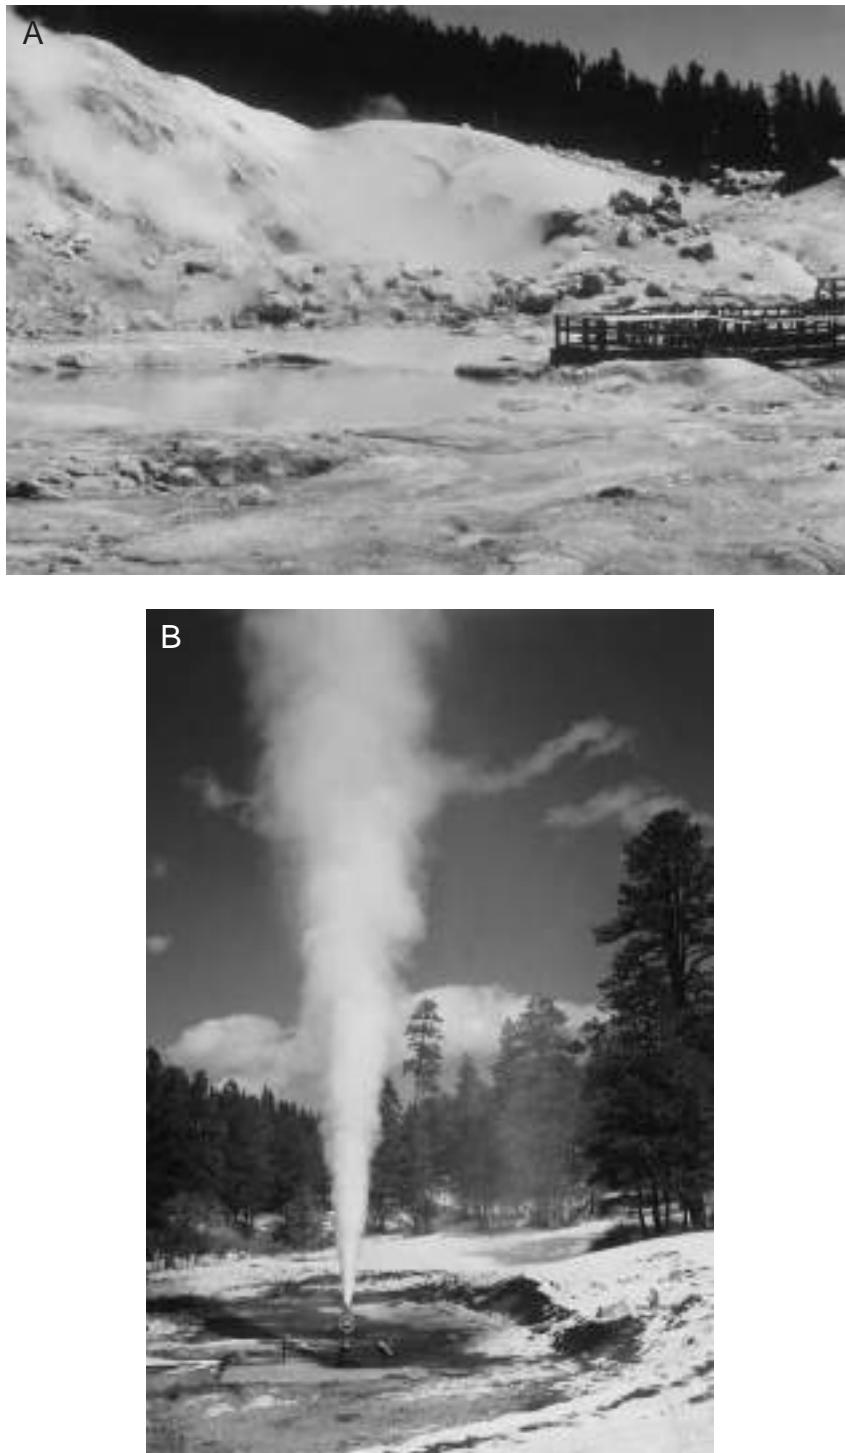

FIGURE 6 (A) Fumaroles, boiling acid-sulfate springs, and acid sublimates create a bleached wasteland at Bumpass Hell, Lassen Volcanic National Park, California. Fumarole temperatures may reach 160°C but are usually near the local boiling point. The pH and sulfate content of some pools are  $\leq 1$  and  $\geq 10,000$  ppm, respectively. (B) Neutral-chloride water erupts high in the sky during flow test of well VC-2B, Sulphur Springs, Valles caldera, New Mexico. Average temperature of fluids from production intervals during this test was 225°C, although bottom hole temperature is 295°C at 1762 m. The reservoir pH and chloride content recalculated for steam loss are 6.2 and 3000 ppm, respectively. Wellhead is 2.2 m tall. (See also color insert.)

the next major component. Divalent cation contents, particularly Mg, tend to be low because of inverse solubility of carbonates and sulfates with temperature. Silica levels and contents of trace elements As, B, Br, and Li are relatively high compared to most other groundwaters. The pH generally lies between 6 and 9, although extremely saline fluids may be more acidic. The chemistry of these fluids is dictated by temperature, reactions with reservoir rocks, volume of water relative to rock, residence time of water, and contributions of components from outside sources (cold groundwater, seawater, magma, etc.).

Neutral-chloride spring and geyser waters usually re-

semble their parent reservoir fluids. These fluids may be modified during flow to the surface by chemical reactions with wall rocks, by dilution with near-surface groundwaters of various types, or by boiling. Such waters are often oversaturated with silica or carbonates at surface conditions and form deposits of sinter or travertine, respectively.

Acid-sulfate springs form where rising steam and volatile compounds condense into near-surface groundwaters, and H<sub>2</sub>S that is carried in the steam is oxidized to form sulfuric acid (Fig. 6a). Additional components are added during acid dissolution of near-surface rocks.

Acid-sulfate fluids are comparatively rich in divalent and trivalent cations and low in Na, K, Cl and most trace elements. Sulfur, acid sublimates, and clays are often deposited.

### C. Chemical Geothermometers

By the 1960s several researchers had noted the temperature-dependent concentrations of some chemical species in geothermal fluids and were applying these relations to exploration and reservoir development. Chemical geothermometers are of two general types: (1) based on absolute concentrations of a constituent in solution, and (2) based on ratios of two or more constituents in solution. The temperature dependence of some chemical geothermometers has been calibrated by laboratory experiments under ideal conditions, while other geothermometers are based on empirical relations involving many fluids produced from different geothermal fields where reservoir temperatures are known. The solubility of silica polymorphs (quartz, chalcedony, cristobalite, etc.) in pure water as a function of temperature represents the prime example of a laboratory-calibrated geothermometer. Unique equations describe the solubility of each polymorph. In the second type, one or more chemical ratios (usually cation ratios) from production fluids and associated hot spring fluids are plotted against the inverse of reservoir temperature and a linear regression of the data defines the temperature dependence.

Many geothermometers have been developed and refined over the years to meet specific conditions. Four widely used geothermometer equations and their restrictions are as follows.

Quartz conductive:

$$T = \frac{1309}{5.19 - \log \text{SiO}_2} - 273.15 \quad (T = 150\text{--}250^\circ\text{C}) \quad (4)$$

$$\text{Na/K: } T = \frac{1217}{\log(\text{Na}/\text{K}) + 1.483} - 273.15 \quad (T = >150^\circ\text{C}) \quad (5)$$

Na-K-Ca:

$$T = \frac{1647}{\log(\text{Na}/\text{K}) + \frac{1}{3}[\log(\text{Ca}^{1/2}/\text{Na}) + 2.06] + 2.47} - 273.15 \quad (T = >100^\circ\text{C}) \quad (6)$$

$$\text{Gas: } T = \frac{24775}{2 \log \alpha - 6 \log \beta - 3 \log \gamma - 7 \log(P_{\text{CO}_2}) + 36.05} - 273.15, \quad (7)$$

$$\text{where } \alpha = \frac{\text{CH}_4}{\text{CO}_2}, \beta = \frac{\text{H}_2}{\text{CO}_2}, \gamma = \frac{\text{H}_2\text{S}}{\text{CO}_2}, \text{ and}$$

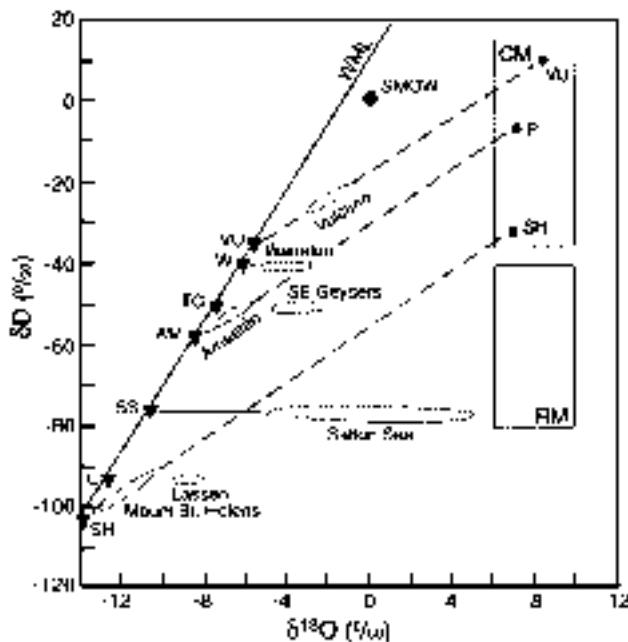

$$P_{\text{CO}_2} = \begin{cases} 0.1, & \text{if CO}_2 < 75 \\ 1.0, & \text{if CO}_2 > 75, \text{ and CH}_4 < 2\text{H}_2 \text{ or H}_2\text{S} < 2\text{H}_2 \\ 10, & \text{if CO}_2 > 75, \text{ and CH}_4 > 2\text{H}_2 \text{ and H}_2\text{S} > 2\text{H}_2, \end{cases}$$

Concentrations are in ppm except gas compositions (mol-%), and  $T$  is  $^\circ\text{C}$ . Calculated subsurface equilibration temperatures for fluids from selected wells and thermal manifestations are listed beneath the analyses in Tables II and III. The empirical geothermometers yield excellent results for reservoirs in young igneous systems because these hotter reservoirs have provided most of the data for the regressions. The geothermometers are less reliable for tectonic or geopressured systems of lower reservoir temperature, particularly with fluids of high Mg content. The preceding geothermometers are not applicable for volcanic gas condensates, acid-sulfate waters, and many sedimentary basin brines.

Application of geothermometer calculations has many potential pitfalls during exploration, mostly because fluid compositions can change during flow from the reservoir to the surface. Dilution, mixing, boiling, precipitation, and other reactions can modify original fluid chemistry as temperature declines during upflow. Also, many waters (e.g., soda water and fossil seawater) that achieve their initial compositions by reactions at low to moderate temperatures yield spurious calculated higher temperatures. Although several schemes exist to evaluate such processes, independent indicators of high temperature should always be sought. For example, presence of  $\text{H}_2\text{S}$ -rich gases, widespread distribution of boiling Cl-rich springs, and spring deposits of sinter ( $\text{SiO}_2$ ) usually indicate that a reservoir of  $\geq 150^\circ\text{C}$  lies at depth.

### D. Water Origins and System Ages

Although the hottest geothermal systems are obviously associated with magmatism, isotopic studies show that the water itself is derived primarily from ancient to modern precipitation (Fig. 7). Other systems contain recycled seawater, fossil seawater and variants, and metamorphic waters (waters released during metamorphism). Positive recognition of magmatic water in geothermal systems was made after studying fluids emitted from active volcanoes. In such systems, the magmatic contri-

**FIGURE 7** Plot of deuterium ( $\delta\text{D}$ ) versus oxygen-18 ( $\delta^{18}\text{O}$ ) for meteoric waters (inverted triangles) and reservoir fluids (clouds) at selected geothermal systems (values in permil relative to Standard Mean Ocean Water, SMOW). Virtually all rocks are isotopically enriched in  $^{18}\text{O}$  compared to most waters. Geothermal systems such as Wairakei, The Geysers, Salton Sea, and Lassen contain meteoric waters isotopically enriched in oxygen-18 because of high-temperature rock–water isotopic exchange. Systems such as Vulcano, Amatitlán, and Mount St. Helens contain mixtures of meteoric and magmatic waters (dots). WML is the world meteoric line for precipitation. CM is the box for convergent margin (subduction zone) magmatic waters whereas RM is the box for residual magmatic waters in intrusive bodies. Other labels identified in Fig. 1.

bution is usually <15% of the bulk reservoir fluid, although rare systems may contain as much as 40%.

Tritium,  $^{14}\text{C}$ , and  $^{36}\text{Cl}$  studies show that geothermal reservoir waters are usually older than 1,000 yr, commonly older than 10,000 yr, and rarely older than 100,000 yr. Hot springs derived from reservoir fluids sometimes contain younger water due to mixing with near-surface groundwaters.

Lifetimes of geothermal systems are dated from studies of alteration minerals and veins, spring deposits, and geologic relations. Systems such as Valles caldera have been continuously active for the last 1 million years even though the present reservoir is not large. Systems found in many arc volcanoes can be no older than the volcanic edifice, often <100,000 yr. Volcanic eruptions can create rapid changes in young igneous systems. For exam-

ple, the present hydrothermal system at Mount St. Helens ( $\leq 175^\circ\text{C}$ ) formed after the eruptions of 1980. Lifetimes of most tectonic systems are poorly studied although some are >1 million years based on dated spring deposits. Large geopressured systems are probably  $\gg 1$  million years because of slow burial and pressurization of the reservoir strata.

#### E. Hydrothermal Alteration and Mineral Deposits

Detailed studies of rocks and drill cores from many geothermal systems reveal alteration mineral and vein assemblages, and precious- and base-metal precipitates that resemble those in epithermal ore deposits. Common assemblages in 150 to  $350^\circ\text{C}$  reservoirs include quartz, calcite, illite, chlorite, adularia,  $\pm$  epidote,  $\pm$  anhydrite, and  $\pm$  wairakite. Fluids and fluid inclusions in active systems have similar ranges in formation temperatures and salinity as fluid inclusions found in ancient deposits. Most exploited geothermal fluids contain reduced sulfur species and precipitate common sulfide minerals (pyrite, pyrrhotite, galena, sphalerite, chalcopyrite, etc.) found in many ore deposits.

Although the deeper portions of geothermal systems are too hot to mine, near-surface manifestations are accessible.  $\text{CO}_2$ -rich (soda) waters are bottled for public consumption at many hot and mineral spring areas, and  $\text{CO}_2$  gas is compressed for industrial processing. Onyx and travertine deposits ( $\text{CaCO}_3$ ) are often mined for decorative stone.  $\text{SiO}_2$ ,  $\text{CO}_2$ , S, B, and  $\text{NH}_4$  compounds were mined at Larderello fumaroles until recently. S is commonly mined from acid-sulfate zones and is recovered as a by-product from several geothermal power plants. Hg was mined from hot spring areas east of The Geysers as recently as the 1950s, and Au and Hg at ppm levels occur in mucks around some alkaline hot springs in nearby mining districts. Sinter deposits and wellbore precipitates at some geothermal systems contain Au, Ag, Hg, Sb, and other metals. Ag-rich deposits from pipelines are recovered and sold at the Salton Sea field (USA). Sulfide precipitates at Oku-aizu field (Japan) contain  $\leq 115$  ppm Au,  $\leq 3.5$  wt-% Ag and common base metals. Salton Sea brines contain surprisingly high levels of Zn, Pb, and Mn ( $\leq 550$ ,  $\leq 110$ , and  $\leq 1200$  ppm, respectively). Similar metals are found in brines from Fushime system (Japan). Sub-ore grade  $\text{MoS}_2$  ( $\leq 0.5$  wt-%) and less abundant base metals are found in a shallow sector of the Valles caldera system. B and Cu as tourmaline and chalcopyrite are locally rich in meta-

morphosed rocks bordering the intrusive body beneath The Geysers. Borosilicates are also found deep within the Larderello reservoir.

## VI. GEOTHERMAL DEVELOPMENT

### A. Exploration

The primary objective of exploration is to discover reservoirs of steam or hot water that can sustain commercial development. Statistically, about 70% of geothermal areas with boiling features will host exploitable systems. Thus, regional exploration strategies initially focus on known areas of hot spring and fumarole activity or known areas of hot aquifers. First efforts are to evaluate young volcanic centers, delineate major geologic structures, assess regional heat flow, and calculate subsurface reservoir temperatures from the geochemistry of fluid samples (Tables II and III; see Table IV). Once prospective targets are chosen, exploration involves a more detailed approach to determine the age and structure of the reservoir rocks, a possible depth to the reservoir, fluid characteristics and pathways, and a conceptual model of the system. The model is then tested by drilling, which primarily confirms the presence (or absence) of a reservoir and its temperature.

Exploration drilling usually requires one to five holes that penetrate to depths of  $\leq 1.5$  km, depending on budget, knowledge gained and problems encountered during drilling, and the success of the first hole(s). Geophysical logs provide temperature-depth profiles, water levels, formation pressures, production zones, and other information. Cores provide details on stratigraphy, alteration mineralogy and history, fracture patterns, and porosity of the rocks. If high-temperature fluids are encountered, flow tests may be conducted to determine preliminary reservoir parameters. Fluid analyses establish background conditions, assess potential environmental impacts, and evaluate corrosion and precipitation properties. Surface and subsurface studies are then combined to formulate a model of the geothermal system. Model results are used to create an economic field-development strategy, which is used to obtain financing for production drilling and eventual exploitation of the resource. The entire exploration process at a given site should take no more than 1 to 3 years but has been known to take more than 10 years at some prospects because of various technical, economic, and political factors.

TABLE IV Principal Methods Used During Geothermal Exploration

- I. Geology
  - A. Geologic mapping of stratigraphy and structure
  - B. Remote sensing of thermal/geochemical variations
  - C. Photogeology of structure/fractures
  - D. Detailed maps of thermal areas
  - E. Hydrothermal alteration maps
- II. Volcanology
  - A. Age dates and petrology/geochemistry of units
  - B. Analysis of eruptive style, eruptive volumes, eruption temperatures
  - C. Evaluation of magma chamber depth, shape, volume, heat content
  - D. Hazards assessment at active volcanoes
- III. Hydrogeochemistry
  - A. Water and gas chemistry; calculation of chemical geothermometers
  - B. Stable isotope analyses; fluid sources and geohydrology
  - C. Radioisotope analyses for fluid ages
  - D. Gas flux measurements to determine fluid pathways
- IV. Geophysics
  - A. Temperature-gradient and heat-flow studies; define magnitude and extent of prospects
  - B. Gravity studies to locate structures, fault offsets, depth to magma bodies
  - C. Passive seismic studies to define major structure, subsidence, and location of magma
  - D. Active seismic studies to define stratigraphy and structure; location of magma
  - E. Electrical methods to define limits of potential reservoir, subsurface alteration, faults
  - F. Magnetics to define structure and depth to magma bodies
- V. Exploration holes (core or rotary)
  - A. Stratigraphy and fracture analysis
  - B. Temperature and other geophysical logs
  - C. Flow tests; geochemical sampling and analyses; injection tests
  - D. Physical property measurements of core/cuttings
  - E. Alteration and vein studies of core/cuttings

### B. Production

Geothermal systems that enter the development stage are called geothermal fields. Governments or private companies acquire ownership or development rights to the land necessary for drilling wells, creating infrastructure, and building power plants. Depending on technical feasibility, financial restrictions, and other factors, the

initial development plan determines how much power should be installed in a first phase. Large-diameter (20 to 60 cm) production wells are drilled to intersect fluid-producing fractures or stratigraphic horizons within the zone identified as the reservoir. As each well is completed, it is tested to determine fluid enthalpy, mass-flow rate, pressure declines, permeability thickness, and other parameters. Some wells are discharged simultaneously for an extended period to determine interference characteristics. After the first phase of development generates power, the field may be expanded in blocks (if economically feasible) in which additional wells are drilled to sustain more plants.

Of about 80 drilled geothermal fields, the mean installed capacity is roughly 100 MWe (Table I) and the mean reservoir temperature is  $250 \pm 40^\circ\text{C}$ . The present cost of a 55 MWe geothermal project including exploration, wells, infrastructure, and plant is about US\$110 million or about US\$2 million/MWe with an expected lifetime of 25 yr. Some fields have existed for  $>30$  yr. Mean development time after exploration is 6 to 7 yr.

### C. Power Generation

Basic plant designs for vapor- and liquid-dominated reservoirs are shown in Fig. 8. As mentioned earlier, vapor-dominated reservoirs are the most desirable because all

produced fluid is steam that can be sent to the turbines with minor treatment. In 1998, after 40 yr of exploitation, typical wells in The Geysers field produced steam with enthalpies of 2800 kJ/kg at flow rates ( $F_v$ ) of about 45,000 kg/hour. Neglecting conversion efficiency, available power,  $P$ , is approximately

$$P = F_v \Delta H, \quad (8)$$

where  $\Delta H$  is the enthalpy difference between production steam and ambient steam. Assuming the latter occurs at  $T = 25^\circ\text{C}$ , average power production at The Geysers is about 3 to 4 MW/well gross. Wells at Kamojang produce about 5 MW/well, whereas wells at Darajat produce roughly 15 MW/well. About 20% of the fluid mass is injected back into the reservoir after passing through the condensers. The remaining fluid enters the atmosphere from the condensers.

Liquid-dominated reservoirs above  $200^\circ\text{C}$  require steam separation to flash (boil) the fluid at conditions providing the maximum mass of steam at optimum pressure to drive the turbines. Wells cumulatively producing 800,000 kg/hour at 17.9% flash will yield 143,000 kg/hour steam at  $170^\circ\text{C}$  and 0.79 MPa at the separator (described above), producing about 10 MW gross. Typical wells produce 5 MW although rare wells will produce more than 30 MW. About 657,000 kg/hour of spent brine must be disposed, preferably by injection. Production and injection fluids are sometimes diluted with sur-

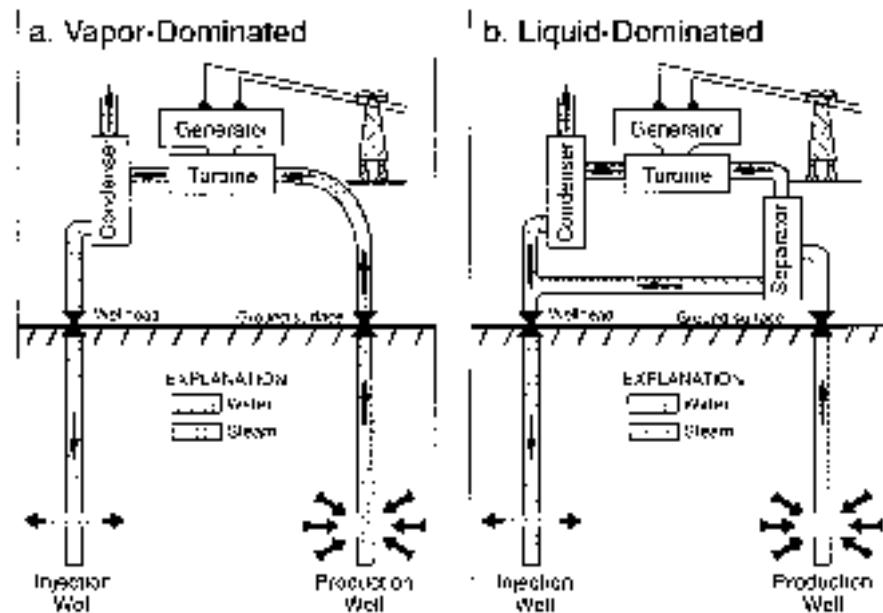

FIGURE 8 Diagrams showing power generation schemes for (a) vapor- and (b) liquid-dominated geothermal reservoirs.

face water or treated with chemicals to prevent or retard mineral encrustation and corrosion of wells, pipelines, and turbines. These methods are occasionally futile, requiring intermittent mechanical reaming of pipes and wells and replacement of turbine parts.

Reservoirs with temperatures below 200°C are often exploited with binary cycle power plants that use heat exchangers and organic working fluids to extract heat. For example, binary plants at Long Valley Caldera and Steamboat Hills (USA) use isobutane as the working fluid to extract heat from reservoirs at 170 to 175°C. One advantage of binary plants is that the production fluid is circulated under pressure without flashing, which prevents gas release and precipitation/corrosion problems. Although binary plants generate less power per unit mass of consumed fluid because of lower enthalpy, they are becoming more common for power production as technology improves. Binary cycles are often added to older flash plants to capture additional energy from waste fluids.

Power plant size depends on many variables including the need for immediate cash flow. Well-head generators can be placed on single wells to immediately produce as little as 500 kWe, but these installations are very inefficient. Large plants in well-established fields produce as much as 130 MWe, although 55 MWe plants are more typical.

#### D. Decline

Geothermal resources are not limitless, although they are often classified as “renewable” resources. With time, power output drops at most fields as reservoir pressures decline due to withdrawal of fluid. For example, average flow rates of wells supplying steam to NCPA Plant 1 in the southeast sector of The Geysers dropped anywhere from 7 to 24% annually during 1982 to 1990. During this period, average wellhead pressures dropped more than 50%. Additional steam was provided to the plants by drilling make-up wells within the producing block, but eventually this strategy was ineffective to maintain the total installed capacity of the plant. A new strategy injects treated waste waters from nearby towns to help increase reservoir pressure.

Long-term (>30 yr) sustainable power production requires a balance between fluid production rates and natural recharge of the reservoir. Injection of fluids from power plants and other sources, usually around the margins of the field, helps maintain this balance. However, many geothermal fields have multiple operators or other

economic characteristics that create financial incentives conflicting with sustainable production.

#### E. Nonelectrical Uses

Few high-temperature systems are developed for non-electrical uses. A noteworthy exception is Kawerau geothermal field (NZ), in which ≤280°C fluid generates electricity, strips bark from logs, runs mechanical equipment, provides silica, and dries paper at a large mill. Reservoirs with temperatures less than 130°C are usually not practical for electrical generation, even at high flow rates. The most common direct-use applications for intermediate- to low-temperature geothermal fluids are spas and health resorts, space heating, greenhousing, and fish/reptile farming. Fluids above 60°C can be used in many industrial applications (preheating, spraying, steaming, pasteurizing, deicing, and sterilizing). More specialized applications include fruit/vegetable drying, refrigeration, fermentation and distillation of alcohol, mushroom growing, advanced oil recovery, and heap-leach mining.

#### F. Monitoring

Reservoir characteristics, besides those relating directly to power utilization, are also monitored during production. These may include seismic monitoring, measurements of emissions to the atmosphere or groundwater, temporal changes in fluid chemistry and heat content of production fluids, and any changes in the behavior of thermal features, faults, landforms, streams, and nearby volcanoes. The data are used for legal, economic, environmental, safety, and scientific purposes.

---

### VII. ENVIRONMENTAL AND SAFETY ISSUES

Geothermal power plants release much less CO<sub>2</sub> to the atmosphere than fossil-fuel burning plants (≤7% of the total released by an equivalent gas-fired plant). Although geothermal energy is environmentally a relatively benign resource, there are many impacts that occur during development. Any large-scale construction and drilling operation will produce visual impacts on the landscape, create noise and wastes, and affect local economies.

Many countries have strict environmental regulations regarding some impacts, whereas others do not. The following list of common issues (with example sites mentioned) is usually addressed during the development stages at geothermal fields.

1. *H<sub>2</sub>S pollution of atmosphere.* H<sub>2</sub>S is a noxious gas that is immediately dangerous to life and health (IDLH) at levels above 142 mgm<sup>-3</sup> of air. During the early development years at The Geysers (pre-1975), there were many complaints about the odor from H<sub>2</sub>S that was released by power plants. Since then, H<sub>2</sub>S abatement systems have virtually eliminated this problem. About 1.5 t/day S is now scrubbed from a typical 55 MWe power plant at The Geysers and is usually sold for agricultural purposes. However, some developing countries have casual regulations on H<sub>2</sub>S pollution and no installed abatement systems. As a result, air quality at some power plants is obnoxious if not hazardous.

2. *Brine pollution of groundwater.* Spent brine from liquid-dominated systems commonly contains excessive quantities of As, B, Cl, SiO<sub>2</sub>, and other compounds with potential risks to humans, livestock, and crops. Many brines are considered toxic wastes in most developed countries and must be treated or disposed of to render them harmless. Because of obvious economic advantages, most producing fields inject the brine to help maintain reservoir fluid volume and pressure. However, there are fields where spent brine has been dumped into nearby streams or the ocean (Tiwi, Philippines; Ahuachapán). In some countries, brines produced during flow tests of new wells are dumped on the ground or into local streams, contaminating shallow groundwater systems. Usually, considerable dilution with cool near-surface waters brings the concentrations of contaminants down to acceptable levels.

3. *Hydrothermal explosions.* Many geothermal fields contain shallow vapor-rich caps that will occasionally exceed lithostatic pressure and periodically explode. In some geothermal systems, production of reservoir fluids has caused subsurface pressures to decrease, thereby inducing boiling and increasing fumarolic activity. Commonly, hydrothermal explosion craters form where fumaroles and acid springs already exist, attesting that these explosions are sometimes induced by natural processes. Ancient hydrothermal explosion craters often pock-mark portions of geothermal systems (Rotokawa, NZ). These areas may make poor drill pads and construction sites due to potentially acid conditions and unstable ground. However, it is not unusual for local inhabitants in underdeveloped countries to build houses around such areas because the natural heat flow reduces

heating costs and the hot springs are used for cooking. On rare occasions hydrothermal explosions near geothermal fields have killed people and collapsed buildings during unexpected showers of hot mud, steam, and rock (Ahuachapán).

4. *Landslides.* Many geothermal fields are located in volcanic and tectonic terrains having high relief and rainfall. Because thermal fluids react with the host rocks to produce clays, silica residues, and other alteration products, much of the ground on the slopes above some geothermal systems is unstable. Ancient and modern landslides are common features of many systems (The Geysers). Landslides are often attractive building sites because they produce flat areas. However, landslides in geothermal fields have destroyed roads and infrastructure, have cracked geothermal well casings due to creep, have decapitated wells causing "blow-outs," and have buried inhabitants during sudden collapse (Zunil, Guatemala).

5. *Reservoir interference, depletion, subsidence, and induced seismicity.* Long-term production of geothermal fluids can affect some production wells by drawing cooler water in from the margins of the system (Cerro Prieto). Thermal features such as hot springs, fumaroles, and geysers may cool down or cease as reservoir pressures and overlying water levels decrease and as cold groundwaters mix with reservoir fluids (Rotorua and Ohaki, NZ). Extensive removal of reservoir fluids may initiate ground subsidence (Wairakei and Ohaki). Usually the subsidence is differential and causes damage to roads and rare damage to wells and buildings. Major subsidence can eventually produce microseismicity and local faulting. Fluid injection often induces seismic activity within and near the margins of the reservoir.

6. *Earthquakes and volcanic hazards.* Most high-temperature geothermal systems are found in tectonically active regions where historic earthquakes and fault displacements have occurred (Dixie Valley). Buildings must be constructed to withstand reasonable levels of ground shaking in worst-case scenarios. Some geothermal fields are located on the flanks of historically active volcanoes (Kilauea, USA). Eruptive style and eruption frequency of nearby volcanoes must be evaluated before power plants and infrastructure are constructed in hazardous locations.

---

### VIII. SUMMARY

Geothermal systems occur wherever reservoirs of hot water and steam exist at comparatively shallow depths.

High-temperature systems most commonly exist near volcanic and tectonically active regions of the Earth. Although magma bodies may contain immense quantities of heat, convection of groundwater brings heat toward the surface much more effectively than conduction of heat through rock. Geothermal fluids are different from magmatic fluids because of their lower temperature, lower content of acid volatiles, equilibration in various near-surface rocks, and high content of meteoric water or other groundwater/seawater. Lifetimes of some geothermal systems exceed 1 million years and some systems are presently forming ore deposits. The geologic, hydrogeochemical, and geophysical characteristics of convecting geothermal fluids, their reservoirs, and their heat sources form the basis of geothermal exploration methods and development models. Commercial geothermal fields produce electricity by piping extracted hot fluids from wells to turbine-driven generators. Nonelectrical applications continue to increase, but spas, space heating, greenhousing, and aquaculture remain the prime uses. Like many other energy resources, geothermal systems are depletable and have a unique set of environmental and safety characteristics. Proactive measures to mitigate potential environmental problems are beneficial to the long-term health and financial well-being of commercial developments. Worldwide geothermal energy utilization increases yearly because it is an attractive alternative to burning imported and domestic fossil fuel resources.

## GLOSSARY

- advection** Subsurface movement of groundwater in permeable rocks under the influence of a lateral pressure gradient (from high terrain to a broad valley, for example).
- alteration** (or hydrothermal alteration) Change in the mineralogical composition of a rock, brought about by the action of hydrothermal fluids. The term includes direct deposition of secondary minerals as veins or vug fill.
- buoyancy** A vertical, upwardly directed force caused by the density difference between a hydrostatic column of hot fluid within a geothermal reservoir and an equal column

of colder fluid outside it. The resulting fluid movement is called “free convection” or “natural convection.” **conduction, convection** Modes of heat transfer. Conduction involves transmission of heat in a rock without mass transfer; heat transfer in a permeable rock by convection results from mass (fluid) transfer.

**fluids** A summary term that describes the phases of the medium convectively transferring heat, i.e., liquid, gas, and their combinations. Liquids may originate from infiltrated ground water (“meteoric” water) or from magma (“magmatic” water). The subsurface gas phase of water is “vapor,” but at the surface it is “steam,” containing condensate droplets. Gases in hydrothermal systems are usually less reactive (vapor, CO<sub>2</sub>, and H<sub>2</sub>S) than those in volcanic systems (vapor, HCl, SO<sub>2</sub>, HF, for example).

**geothermal system** A general term that describes natural heat transfer within a confined volume of the Earth’s crust where heat is transported from a “heat source” to a “heat sink,” usually the free surface.

**hydrothermal system** A type of geothermal system where heat transfers from a heat source (often a cooling pluton) to the surface by “free convection,” involving “meteoric” fluids with or without traces of magmatic fluids. Liquids discharged at or near the surface are replenished

by "meteoric" water derived from the outside ("recharge") that is drawn in by the rising fluids. A hydrothermal system consists of (1) a heat source, (2) a reservoir with thermal fluids, (3) a surrounding "recharge region," and (4) a (heat) discharge area at the surface with "manifestations."

**manifestations** A term that describes (1) features at ground surface where fluids discharge, mainly as single-phase fluids (e.g., hot springs, hot lakes and pools, fumaroles); (2) features resulting from fluid/rock interactions and hydrothermal mineral deposition, also at ground surface. The term, in its widest sense, refers to both active and inactive thermal features.

**volcanic system** A type of geothermal system where heat and mass transfers from an igneous body (usually a magma chamber) to the surface involving convection of magmatic fluids and sporadic discharge of magma (subsurface melts); meteoric fluids are not involved in the heat transfer process or are minor.

**volcanic-hydrothermal systems** A combination of a "hydrothermal" and a "volcanic" system, where ascending magmatic (primary) fluids commonly mix with meteoric (secondary) fluids (rarely sea water); also called a "magmatic-hydrothermal system."

## I. INTRODUCTION

In hydrothermal and volcanic systems heat and mass transfer in the upper crust from a deep source to a discharge region at the surface. The heat moves by both convection and conduction. In hydrothermal systems the convecting heat transfer medium is dominantly infiltrated surface water (i.e., of meteoric origin). The fluids that transfer most heat, albeit intermittently, in volcanic systems are magma and magmatic gases. However, ascending magmatic fluids may mix with mantling or descending meteoric fluids; convection of such a mixture is characteristic of volcanic-hydrothermal systems, which thus constitute a blending of volcanic and hydrothermal systems (Fig. 1). Active volcanic systems produce characteristic high-temperature ( $T \geq 150^{\circ}\text{C}$ ) surface discharge features described elsewhere in this Encyclopedia. In this chapter, the surface manifestations of volcanic-hydrothermal and hydrothermal systems are discussed.

Surface manifestations are the only directly observable expressions of geothermal systems. These manifestations vary widely in their appearance, often reflecting the type of geothermal reservoir from which their discharged fluids derive. Controlling parameters include

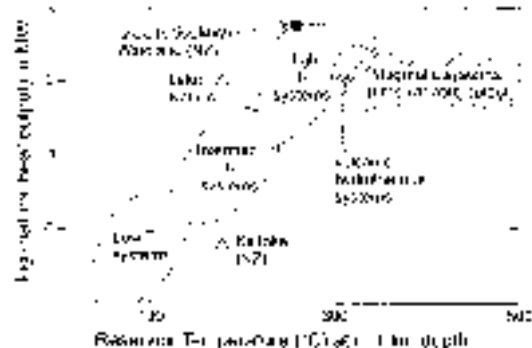

FIGURE 1 Subdivision of convective hydrothermal systems with their natural heat outputs and inferred reservoir temperatures ( $\sim 1$  km depth) as discriminants.

reservoir temperature, type of reservoir fluid, type of reservoir rocks, and the nature of the heat source. Indeed, the nature of the heat sources is of major importance. These can be grouped as follows:

1. Magmas within the crust (local or extensive)
2. Intracrustal nonmagmatic
3. Conductive heat flow within the upper crust

This grouping can be subdivided further by considering the plate-tectonic settings of each, since most of the anomalous heat transfer is via geothermal systems concentrated along active plate boundaries (active margins).

Geothermal systems can also be divided by using their reservoir temperatures at about 1 km depth (arbitrarily chosen) as a discriminating parameter. Here we distinguish among the following systems:

1. High ( $>225^{\circ}\text{C}$ ) temperature (high- $T$ )
2. Intermediate ( $125\text{--}225^{\circ}\text{C}$ ) temperature
3. Low ( $<125^{\circ}\text{C}$ ) temperature (low- $T$ ) systems

Hence, we use, for example, the phrase "manifestations associated with high-temperature systems" as a specific term. However, not all geothermal systems, especially those that are quasi-stagnant, have surface manifestations.

The amount of heat (unit: joule) transferred by a fluid can be assessed by measuring its mass flow rate at the surface and its enthalpy (heat content). These parameters define the heat discharge rate of surface manifestations,  $Q_s$ , in joules/second (J/s) or watts (W); a widely used unit is the megawatt (1 MW =  $10^6$  W).  $Q_s$  is an important parameter that can be used to classify geothermal systems since the extent of convection reflects the magnitude of their heat outputs. The natural output of typical low-temperature systems is commonly of the order of 0.1 to 3 MW, and that of high-temperature

systems between 30 and 300 MW. The types, numbers, and sizes of surface manifestations present at each reflect this.

The rate of heat discharge from volcanic systems,  $Q_v$ , can also be estimated from the mass of material erupted over a long but finite period, allowing for degassing. High-temperature hydrothermal systems hosted within volcanic regimes along many active plate margins (volcanic arcs, for example) have heat outputs ( $Q_s$ ) of about the same magnitude as  $Q_v$ .

Types of surface manifestation, listed in *italics*, are introduced in the following sections with reference to their occurrence over prominent types of geothermal systems. The links between various systems, using their inferred reservoir temperatures (c. 1 km depth) and their natural heat outputs as discriminants, are depicted in Fig. 1. Characteristic geothermal deposits and alteration are also introduced concurrently and underlined. The **locality** of individual manifestations is listed in bold font at its first mention. In the last two sections, all manifestations are grouped according to the modes of surface heat transfer, their characteristic surface alteration, and surficial deposits.

---

## II. MANIFESTATIONS OF VOLCANIC-HYDROTHERMAL AND AFFILIATED SYSTEMS

Ascending magmatic fluids in active volcanic systems commonly mix with mantling meteoric fluids. Such volcanic-hydrothermal systems have only been recognized recently as a separate type of geothermal system from the characteristic isotopic signatures of their fluids. It is possible that most volcanic systems have mantling hydrothermal fluids; for example, even the hot (>500°C) gases discharged from the **White Island** volcano (NZ) contain fluids with both magmatic and secondary (non-magmatic) components. A subdivision of volcanic-geothermal systems is warranted where the magmatic fluid component is no longer dominant by volume, e.g., in waning volcanic systems, which are here termed “quasi volcanic-hydrothermal systems.”

### A. Manifestations of Volcanic-Hydrothermal Systems

Volcanic-hydrothermal systems are mainly confined to stratovolcanoes or young calderas and exhibit character-

istic surface manifestations that are spatially zoned with respect to their volcanic center, namely *solfataras*, *fumaroles*, *hot acid lakes*, *acid hot springs* (discharging sulfate- and sulfate-chloride waters), and rare *acid streams*. At lower elevations, minor *thermal springs* may discharge neutral pH, chloride, or sometimes bicarbonate-chloride waters. The typical zonation of these discharge features is shown in Fig. 2.

The term *solfatara* derives from a local name, probably from the **Phleorean Fields** (S. Italy), an active volcanic-hydrothermal system (Forum Vulcani) within a caldera that was described by Pliny the Elder. Solfataras here deposit large amounts of sulfur around their vents and discharge steam, CO<sub>2</sub> and H<sub>2</sub>S (rarely SO<sub>2</sub>). Sometimes sulfur mounds develop, for example, at **Biliran** (Philippines), **Tatun** (Taiwan), and **Kawah Ijen** (Java). An accumulation of molten sulfur can occur at shallow depths. Active solfatara fields with a massive accumulation of sulfur have been mined at Tatun and Kawah Ijen.

In addition to sulfur, these manifestations also include deposits of sulfate minerals such as alunite, natroalunite, jarosite, gypsum, and a range of usually ephemeral hydrous sulfates. Kaolin group minerals such as dickite occur, and diaspore and pyrophyllite are also present in places. As the acid condensates become progressively neutralized by interacting with the host rocks, they may form smectites. However, the alteration process is dominantly destructive; amorphous silica that deposits as silica residue in this environment is dominantly derived from the surrounding rocks and remains at the surface as other constituents are leached.

The term *fumarole* has been used to describe vents that discharge vapor that turns into steam. It was used initially to describe and to classify features discharging volcanic gases, for example, by St. Claire Deville in the 1850s. It is not a specific term and has to be qualified with respect to discharge temperature, gas velocity, and gas composition. Fumaroles associated with volcanic-hydrothermal systems may discharge vapor at high speed (>150 m/s). The steam usually contains minor amounts of aggressive magmatic gases (such as HF, HCl, and SO<sub>2</sub>). If the magmatic component (with SO<sub>2</sub>) is dominant, fumarole temperatures may be >130°C (Kawah Ijen) but are usually <130°C where the hydrothermal component (with H<sub>2</sub>S) is dominant (Biliran).

Vents discharging steam over high-temperature systems without traces of magmatic gases were also described as “fumaroles”; the Italian naturalist Tozzetti applied this term in 1751 to the high-temperature fields of Tuscany, but he assumed that all the steam discharged was of magmatic origin. Isotope studies made in the 1950s showed that steam and hot water discharged by almost all high-temperature systems derives from mete-

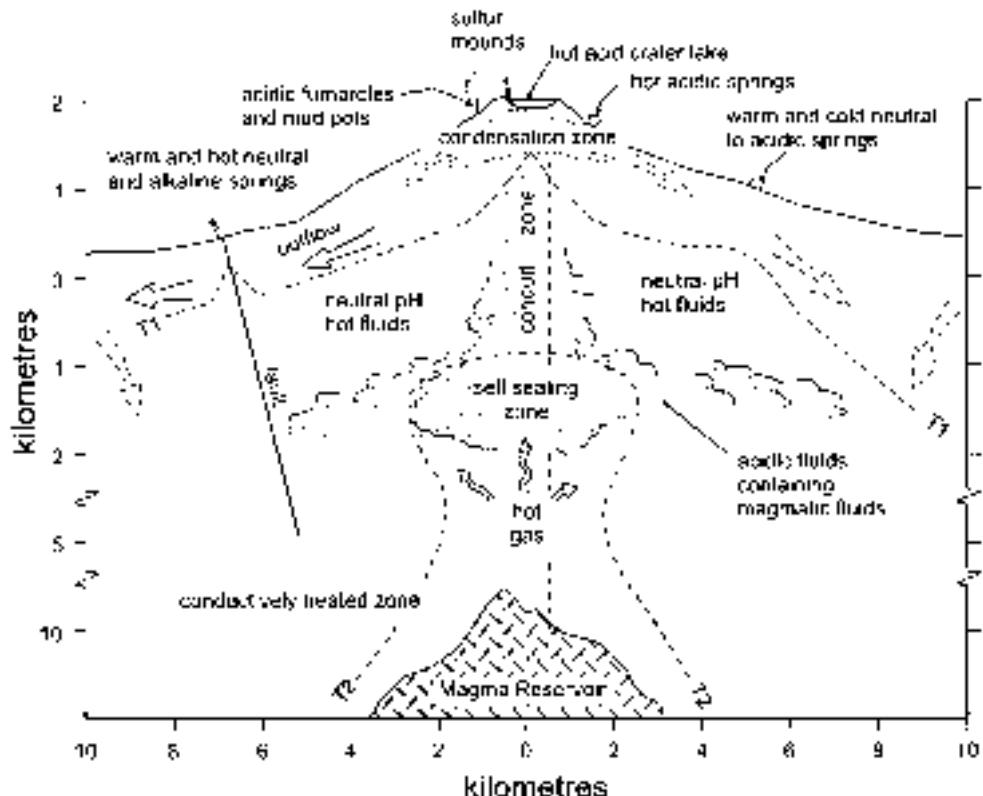

FIGURE 2 Conceptual model of a volcanic hydrothermal system with associated characteristic surface manifestations. The model is based on the Suretimeat system (Vanuatu) but shows features typical of other volcanic–hydrothermal systems (broken lines with T1 and T2 represent inferred isotherms for 150°C and ~350°C, respectively). (Modified from Hochstein and Sudarman, 1993.)

oric water, so the term “fumarole” appeared then to be a misnomer. However, more recent isotope studies have shown that a magmatic water component occurs in many high-temperature hydrothermal systems. The term now survives, therefore, to encompass all natural steam discharge features over hydrothermal systems.

Vapor and most magmatic gases condense at shallow depths (or dissolve in perched or descending meteoric waters), producing acid waters that may discharge in hot, *acid crater lakes* (Kawah Ijen) and as *hot acid springs* where vapor fluxes are high. The near-surface condensates can be channelled to discharge as *acid streams*; these are typical of volcanic–hydrothermal systems and occur, for example, on the outer flanks of **Sorik Marapi** (Sumatra). The pH of these waters is usually <2, and rock leaching is common. Discharge rates of up to 200 kg/s have been reported for a single acid stream at Sorik Marapi, but lower discharge rates (a few kg/s) are much more typical.

Acid condensates move downslope in the subsurface and mix with shallow groundwater, often within perched

aquifers, to become slowly neutralized by progressive fluid/rock interactions. Warm acid springs further downslope, therefore, have higher pH values, as demonstrated by the discharge from subsurface outflows of initially acidic condensates on the flanks of **Tangkuban-prahu** (Java) and **Nevado del Ruiz** (Colombia). Rapid neutralization occurs where the acid condensates pass through limestones (**Sibayak**, Sumatra).

Most volcanic–hydrothermal systems appear to be surrounded by a reservoir containing neutral pH waters (the reservoir can have a “toroid” structure, as indicated in Fig. 2). Such a structure, drilled at the **Biliran** (Philippines) and the **Sulphur Springs** (St. Lucia) prospects, have “acid cores” of small diameter (probably <1 km). A much larger diameter core (>7 km) is likely for Nevado del Ruiz, where a mantling buffer of two-phase fluids (hot water plus vapor) probably separates it from neutral pH chloride waters in the outer reservoir. The low permeability of the rocks hosting the reservoir explains the commonly low discharge rates of *chloride springs* on the lower flanks.

## B. Surface Manifestations of Quasi Volcanic–Hydrothermal Systems

These develop when the flux of magmatic gases decreases and a volcanic–hydrothermal system becomes a fully convecting high-temperature system. They also occur beneath older composite (andesitic and dacitic) volcanic complexes, calderas, and silicic (rhyolitic) domes. The heat they discharge derives mainly from deeply penetrating groundwater that taps a cooling pluton. *Acid condensates* are less common than in true volcanic–hydrothermal systems, but *acid altered ground* occurs. *Solfataras* produce only minor amounts of sulfur and fumaroles do not discharge corrosive volcanic gases, although the ratios of noncondensable volatiles (for example, CO<sub>2</sub>, He, Ar) are close to those in volcanic fumaroles. Minor, shallow *lateral outflows* of neutralized chloride–sulfate waters may discharge on the outer flanks.

Kaolin, cristobalite, hematite, and silica residue are common alteration products, but sulfate minerals are also common, including alunite and jarosite. However, diaspore and pyrophyllite are absent except where there has been considerable erosion (e.g., at **Matsukawa**, Honshu). Lead-rich barite (hokutolite) is precipitating from the highly acidic **Tamagawa Springs** (also in Honshu).

Relics of an earlier volcanic–hydrothermal phase, however, can persist as drillholes sometimes intersect saline, strongly acid, or neutral pH fluids. The **Alto Peak** system (Philippines), which contains a core of rocks saturated with vapor, is an example. There are many others of this type whose history can be inferred from the occurrences of deep acid alteration: for example, **Mahanagdong** (Philippines), **Dieng** (Java), **Kiris-hima** (Kyushu), and **Kakkonda** (Honshu). With prolonged convection in the main reservoir, steam-condensate and magmatic fluids become neutralized and diluted. Matured, quasi volcanic–hydrothermal systems can thus become indistinguishable from high-temperature systems beneath eroded volcanic centers.

---

## III. MANIFESTATIONS OF HIGH-TEMPERATURE SYSTEMS

The characteristic active and nonactive surface manifestations of high-temperature systems are discussed with respect to the topography of surrounding volcanic rocks

and their inferred heat sources. This allows recognition of three groups:

1. Manifestations of hydrothermal systems hosted by high standing volcanic centers (with an inferred local cooling pluton as their heat source)
2. Manifestations of hydrothermal systems in rather flat terrain transferring heat from inferred extensive hot crust or plutons
3. Manifestations associated with high-temperature systems over extensive hot crustal rocks in a plate collision regime

## A. Manifestations of Hydrothermal Systems Associated with High Standing Volcanic Centers

Many well-known high-temperature systems have this setting. Depending on the overall permeability of the reservoir rocks and their surroundings and the extent of recharge (infiltration of groundwater), three distinct types of reservoirs can be recognized. Here we use the terms “low,” “moderate,” and “high” permeability for rocks with average permeabilities,  $k$ , of the orders of  $<1$  to  $3$ ,  $3$  to  $10$ , and  $>10$  millidarcy ( $1$  millidarcy =  $1 \times 10^{-15} \text{ m}^2$ ), respectively. In each case almost all the heat reaching the surface is carried by deeply circulating meteoric waters that sweep heat from a source (usually a cooling pluton) and ascend under free convection.

If the  $k$  value of the reservoir rocks is high but that of rocks in the recharge area is moderate, then this results in the formation of a *liquid dominated system* (liquid saturation of the reservoir rocks,  $S_l$ , is between  $1$  and  $0.7$ ). If the  $k$  values of both the reservoir rocks and those in the recharge area are moderate, then a two-phase mixture can develop in parts of the reservoir (*natural two-phase system*) with  $0.7 < S_l < 0.4$ . Where  $k$  in the surrounding area is low (i.e., there is little recharge) but the  $k$  value of the reservoir rocks is high, then the dominant fluid in the reservoir will be vapor ( $0.4 < S_l < 0$ ), i.e., a *vapor dominated system*.

In all three cases, however, most hydrothermal minerals that form by replacement in the reservoir do so from interaction between the host rocks and a liquid phase. Further, rocks at the **Kawah Kamojang** and the **Darajat** fields (both in Java) contain vein calc-silicate minerals such as epidote, wairakite, and prehnite that clearly deposited directly from liquid even though boreholes in both fields discharge steam. This is because the permeability of the host rocks determines whether a field will

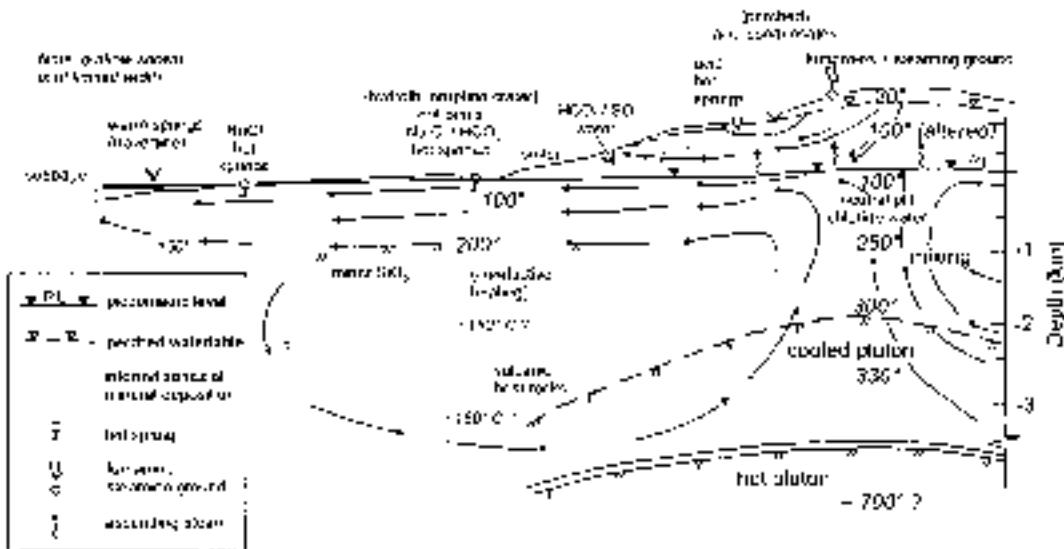

FIGURE 3 Conceptual model of a liquid dominated, high-temperature system beneath a partially eroded, high standing volcanic complex exhibiting lateral zonation (downstream) of surface manifestations. A large amount of heat is discharged by concealed outflows that are partly sealed through mineral deposition. The model is based, in part, on the Palinpinon system (Philippines); the heat source is a cooling pluton. (Modified from Hochstein, 1990.)

supply steam only or a two-phase mixture of steam and water to producing boreholes.

### 1. Manifestations of Liquid Dominated Systems

A schematic diagram of a liquid dominated system beneath an eroded volcanic complex (Fig. 3) shows that all manifestations over the central part of the reservoir derive from ascending steam that is discharged by *fumaroles* and from minor *steaming (hot) ground*. Condensed steam, with oxidised H<sub>2</sub>S gas, feeds minor *hot acid springs*. Steam and CO<sub>2</sub> can discharge together through *hot mud pools*, or separated CO<sub>2</sub> (rarely with H<sub>2</sub>S) can discharge at the surface producing characteristic *gas discharge features* that have local names: for example, *kaipohan* in the Philippines, *putizza* in Italy. Downslope, the ascending CO<sub>2</sub> dissolves in perched groundwaters to produce *warm springs* that discharge bicarbonate (HCO<sub>3</sub>) waters.

Many liquid dominated systems with the hydrological setting shown in Fig. 3 have *concealed* (subsurface) *outflows* of neutral pH chloride waters originating from the upper part of the reservoir. Silica deposition can partly seal the top of the outflows to descending surface water. Where these outflows discharge in valleys or at lower elevations, *hot springs* and *hot pools* occur (often boiling and occupying *hydrothermal eruption* or *dissolution craters*). Some manifestations here discharge a mixture of

hot water and steam (*spouting spring* or *geyser*). Further downstream, mixed chloride–bicarbonate waters may discharge as *warm springs* and *seepages*, some with travertine (mainly CaCO<sub>3</sub>) deposits. This lateral zonation of discharge features is a characteristic of these systems and was first described for the **Hakone** system (Japan).

Liquid dominated systems with the manifestations just described occur at **Palinpinon** and **Tongonan** (Philippines). At Tongonan, another characteristic discharge feature occurs near the toe of an outflow, a *hot ebullient pool*, whose ebullition is caused by ascending CO<sub>2</sub> gas. Manifestations over major outflows from a liquid dominated system occur also at **Berlin** (El Salvador) and **Momotombo** (Nicaragua). Elsewhere, the locations of reservoirs below steep and sometimes inaccessible terrain are not well known, and the existence of a liquid dominated system can only be inferred from discharge features along an outflow. This occurs, for example, at **El Tatio** (Chile), the “type system” for this hydrological setting. Other prospects, known only from manifestations at the toe of subsurface outflows, are **Cisolok** and **Cisukarame** (Java), whose outflows, based on geophysical evidence, extend for more than 10 km. The prospects at **Sipoholon** (Sumatra) and **Songwe** (Tanzania) are only known from their travertine depositing springs. Spouting springs (*spouters*) occur over an outflow of the **Ulebulu** system (Sumatra) and at El Tatio. A seasonal geyser occurs at the toe of

a small concealed outflow from the **Rajabasa** system (Sumatra).

## 2. Manifestations of Natural Two-Phase Systems

The fact that water in many liquid dominated systems beneath high standing volcanic complexes boils, thus creating a two-phase zone (Tongonan, for example), does not mean these are themselves two-phase systems; these can only be recognized where wells intersect a deep, coherent two-phase zone.

The **Olkaria** prospect (Kenya) was such a two-phase system prior to its exploitation. Extensive areas of *steaming ground* with minor *fumarolic activity* occur there. Practically all heat from this huge reservoir transfers to the surface by ascending steam that condenses at shallow depths, maintaining dominantly conductive heat transfer to the surface with only feeble *fumaroles*. There are no significant liquid discharges except for some *minor warm springs* that discharge small amounts of condensate (Fig. 4). Extensive steaming ground is also the dominant type of manifestation at the nearby **Eburru** prospect

and over many other high-temperature systems associated with young volcanic centers in the Kenya Rift Valley. None discharge appreciable amounts of hot water. In part, this is due to the semiarid conditions and the regionally deep water table. Fossil sinter occurs in this setting (shown in Fig. 4), at **Namarumu** (N. Kenya), for example, indicating that when infiltration rates were higher in the past some reservoirs were liquid dominated. Further north, in the Ethiopian Rift, another natural two-phase system, **Aluto**, discharges not only heat from steaming ground and fumaroles, but also neutral pH chloride water from *hot springs* and *seepages* that are located above an outflow at the foot of the young volcanic dome that hosts the reservoir.

## 3. Manifestations of Vapor-Dominated Systems

A characteristic spectrum of manifestations occurs over these rare systems, for example, on the broad volcanic massifs at **Kawah Kamojang** and **Darajat** (Java). Heat transfer is dominantly by steam ascending from the top of a thick concealed layer with condensates (*condensate*

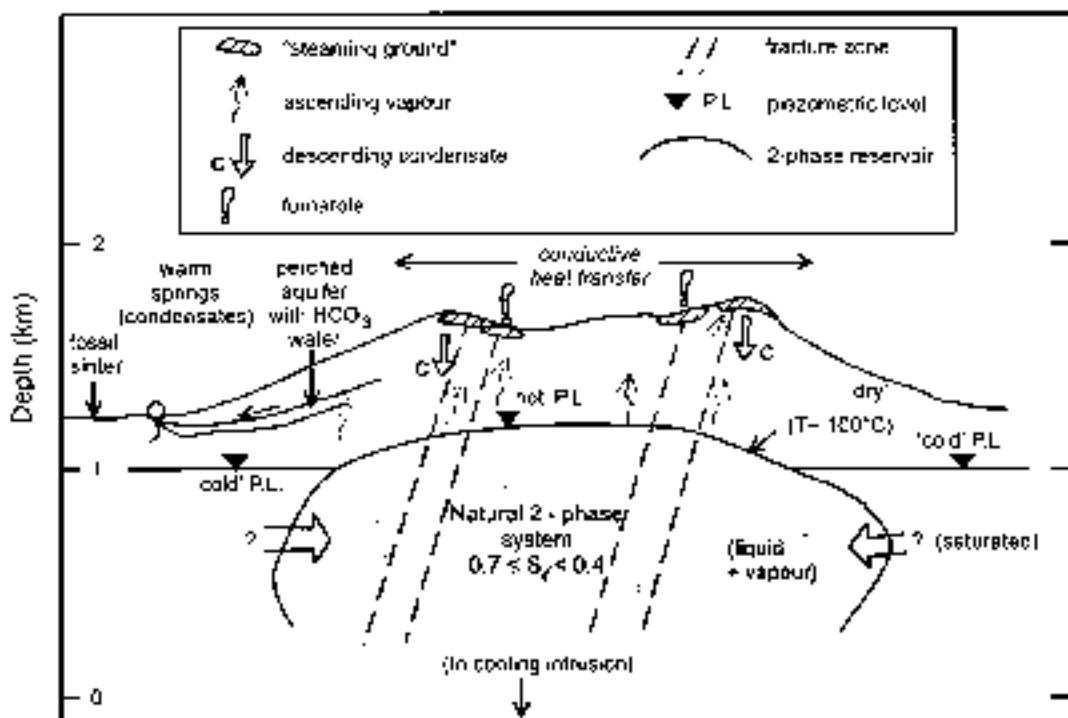

FIGURE 4 Simplified model of a high-temperature steaming ground system with a natural two-phase (coexisting liquid and vapor) reservoir beneath a broad volcanic center in a semiarid environment showing the restricted variety of surface manifestations in this setting. The model has some affinity to the Olkaria system (Kenya) and many other similar systems in the East African Rift Valley.

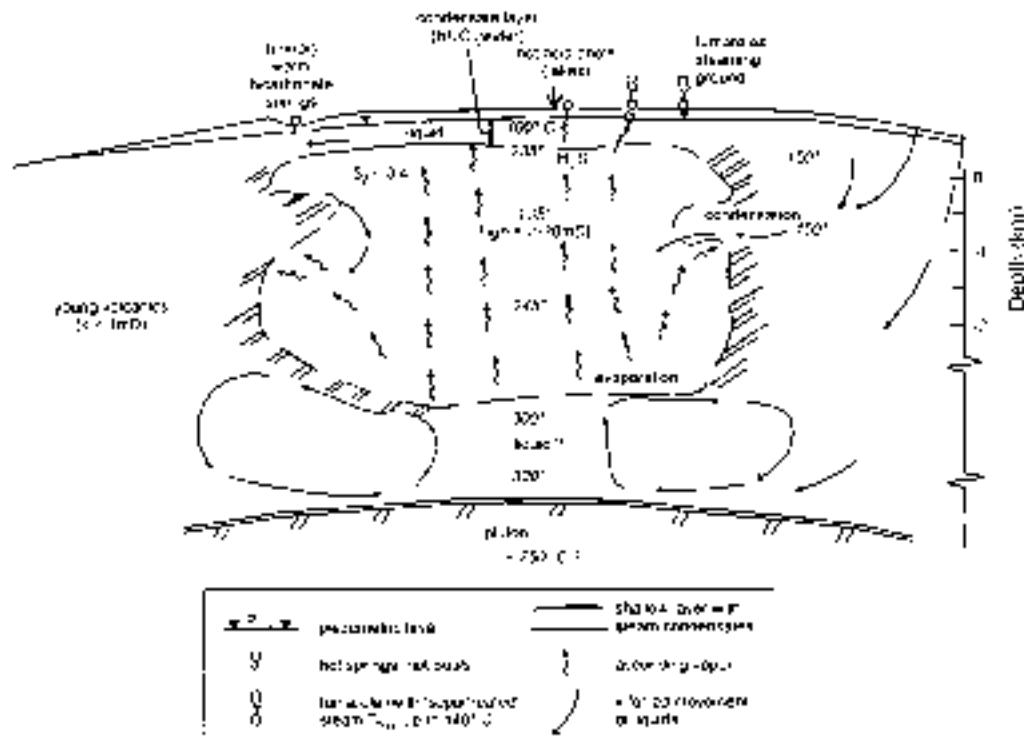

FIGURE 5 Conceptual model of a vapor dominated system beneath a broad, high standing volcanic complex. The reservoir has a condensate layer on its top. Heat transferred within the reservoir is discharged at the surface by steam and hot condensates (bicarbonate waters). The model has some similarity to the Kamojang system (Java); the heat source is a cooling pluton. (Modified from Hochstein, 1990.)

layer) of almost neutral pH bicarbonate waters (Fig. 5) that, together with intense alteration, may act as a confining cover. *Steaming ground* and *fumaroles* are common; in addition, minor acid condensates form “muddy” *hot pools* and small *acid lakes* with very low mass discharge. The low permeability of the rocks surrounding these reservoirs prevents any significant mass outflow, although shallow, minor bicarbonate–sulfate springs occur about 15 km outside Darajat. There are no neutral pH chloride springs on the lower flanks, and their absence is probably the most characteristic feature of these systems. The same types of surface manifestations also occur over **Ketetahi** (NZ), hosted by a young andesite volcano (Mt. Tongariro), although no drillholes have yet tested this tentative classification.

Surficial and shallow hydrothermal alteration is extensive above vapor dominated systems but does not, in itself, reveal whether or not the underlying reservoirs are occupied by vapor or a two-phase fluid: kaolin clays dominate (kaolinite, halloysite, and more rarely dickite), but sulfur and sulfates are also common (alunite, natro-alunite, gypsum, and a variety of hydrous phases, many ephemeral). Hematite and hydrinous iron oxides are also

typically present, as is silica residue, although fine-grained, black pyrite may persist near some thermal features. The alteration is usually pervasive and the overall process is dominantly destructive of the host rocks rather than depositional. The **Matsukawa** field (Honshu, Japan) has extensive alteration (7 × 1.5 km) comprising pyrophyllite and diaspore, alunite, kaolinite, and smectite zonally distributed around the main structural feature of the field. This alteration records former thermal activity as the present-day thermal manifestations consist of only a few areas of warm ground.

## B. Manifestations of High-Temperature Systems in Moderate Terrain

The heat sources for these systems appear to be extensive, hot crustal rocks whose thermal energy is maintained by the following:

1. Partial melting within the ductile upper crust (setting for the NZ systems hosted by young rhyolitic rocks and also for some at Yellowstone, Wyoming)

2. Deep, laterally aligned crustal and dyke intrusions in rift environments beneath systems hosted in basalts (e.g., systems over spreading centers such as Iceland) or sedimentary rocks (Baja California)
3. Deep cooling plutons (relics of an older subduction cycle?) now distant from an active subduction zone

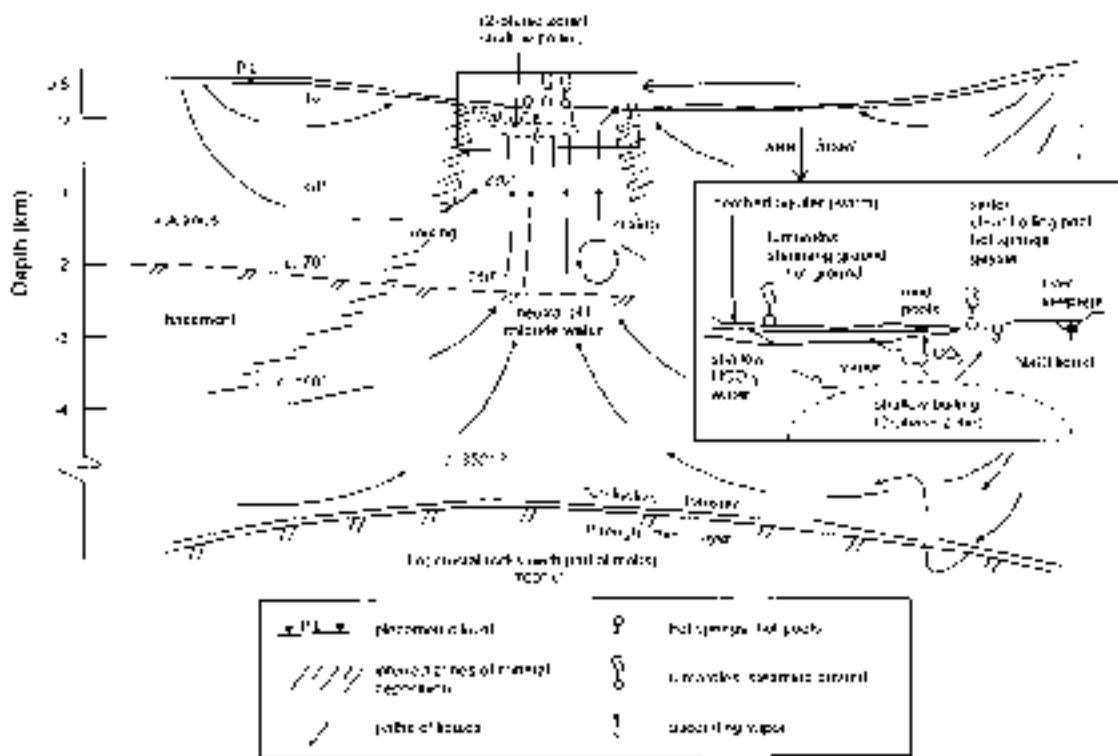

In all these settings there are systems with one of the three reservoir types mentioned in the previous paragraph. An additional reservoir type with the second setting listed is the *nonconvecting brine system*.

### **1. Manifestations of High-Temperature Systems in Moderately Steep Terrain Underlain by Extensive Hot Crustal Rocks**

The terrain surrounding these systems is not steep, and young volcanic cones are usually peripheral to the geothermal reservoirs. Because of their high recharge rate and the terrain, the hot fluids can ascend close to or reach the surface. Any *zonation of discharge features*, if it occurs, is not controlled by lateral pressure gradients created by differences in relief. Manifestations of discharging steam (*fumaroles* and *steaming ground*), conden-

sates and noncondensable gases (minor *acid springs* and *mudpools*) can, therefore, occur close to others that discharge neutral pH chloride waters (*clear hot pools*, *hot springs*). This thermal regime favors *hydrothermal eruptions*, if the liquid is very close to boiling in the shallow subsurface. The setting also favors the discharge of two-phase boiling fluids as *large geysers*. *Outflows* are rare because the horizontal pressure gradient is very small (flat terrain). Systems with the largest natural heat discharges (up to 500 MW at Waiotapu, NZ; see Fig. 1) occur in this setting with many prospects discharging >300 MW. An idealized section through a liquid dominated reservoir with its spectrum of manifestations is shown in Fig. 6.

The *silica sinter* that deposits from discharging waters shows a wide variety of forms. *Spouters* (spouting springs) or geysers deposit nodular silica called *geyserite*. Terracing is a common feature, with individual steps having heights ranging from a few millimeters to 2 meters (as at the **Rotomahana** system near Rotorua, New Zealand, destroyed by a volcanic eruption in 1886). The steps typically have lips to them and are usually closest together on the steepest slopes. The flow paths of the cooling waters change constantly through deposition of

**FIGURE 6** Conceptual model of a liquid dominated system standing in rather flat terrain; the heat source is an extensive layer of hot crustal rocks that contains some partial melts and host intrusions. The model has some similarity to the Wairakei system (NZ). (Modified from Hochstein, 1990.)

silica. Other silica varieties include banding, palisade structures, and wave forms. The last have the form of barchan sand dunes, but their crests grow toward the flow direction of thermal water. Silica sinter is usually hard and white, but it also may be porous, pale yellow, and friable. Microbiological activity plays a major part in silica deposition in some areas and bacteria and plants may be preserved as fossils.

Sinter covers several acres at **Norris Geyser Basin** (Yellowstone) and **Waiotapu** (New Zealand). When first deposited, silica sinter is opaline, but it transforms with time, first to cristobalite and finally to quartz, progressively losing water as it does so. Metal rich deposits precipitate with the silica from some springs: for example, ore grade gold and silver plus appreciable arsenic, antimony, and thallium, as are now precipitating at the Champagne Pool, Waiotapu. Sinter with locally 3 wt% tungsten is depositing at **Waimangu** (New Zealand).

The heat output ( $Q_s$ ) of all (~20) high-temperature hydrothermal systems in the Taupo Volcanic Zone (TVZ), over an active arc segment about 200 km long, is probably three times greater than the extrapolated cumulative heat discharged ( $Q_v$ ) from all its volcanic centers. The **Wairakei** system was liquid dominated prior to its exploitation and its manifestations included all those listed earlier. Impressive manifestations also occur over other liquid dominated systems nearby, such as at Waiotapu, which exhibits an apparent *reversed hydrological zonation* whereby the deep reservoir fluid discharges from a slightly higher *large hot pool* (an old hydrothermal eruption crater) that is surrounded by acid springs at lower elevations. Acid leaching of thick pumice has produced a number of steep sided or overhanging walled *dissolution pits*, some with acid condensates in them. A rare manifestation which occurs over the **Rotokawa** system is a *cold acid lake* into which a vigorous flux of  $H_2S$  dissolves. The **Whakarewarewa** system is well known for the occurrence of *large geysers*, *clear hot (near boiling) pools*, and widespread sinter deposits. Natural two-phase systems also occur (e.g., **Broadlands-Ohaaki**) but have few or no major discharge features. The rate of natural heat discharge ( $Q_s$ ) from Broadlands (before exploitation) was only ~75–100 MW compared with that from the other three prospects just cited (each with  $Q_s$  values between 300 and 500 MW).

A large number (up to eight) of probably liquid dominated high-temperature systems occur in the **Yellowstone National Park** (Wyoming, USA). The heat source here is a mantle plume extending into the base of the crust, which it has heated and partially melted. The total thermal output from all the systems at Yellowstone is therefore large, its magnitude being proba-

bly half that of the Taupo Zone systems. Many geothermal systems in Yellowstone show the characteristic thermal manifestations that occur over the liquid dominated systems, including *large geysers*, *clear boiling pools*, and extensive sinter deposits at the **Norris Geyser Basin**, for example.

Deposits of calcium carbonate occur in the outflow areas of high-temperature systems but are also associated with lower temperature systems. The carbonates deposit as a consequence of loss of  $CO_2$  from the discharging water in which it was formerly dissolved. Calcite is the dominant carbonate, but where loss of  $CO_2$  is very fast, aragonite occurs instead. The reason for this is not known. The calcium carbonate forms deposits that resemble those of silica sinter, e.g., bedded or layered, terraced or forming ridges and even columns up to 3 m high. Extensive and beautiful deposits of calcium carbonate occur at **Mammoth** (Yellowstone), but travertine very commonly surrounds many small springs or pools.

## 2. Manifestations of High-Temperature Systems in Crustal Spreading Environments

Many geothermal systems are hosted by young basaltic rocks in active rifts, such as Iceland. These high-temperature systems derive their heat from a set of dykes or sills. Generally, their manifestations are less vigorous than those listed in the previous paragraph. *Acid alteration* and sinter deposits are not extensive; the salinity of thermal water in prospects away from the ocean is low, generally <1 g/kg of total dissolved solids (TDS). A few liquid dominated systems have *geysers*, as at **Haukadalur**, including Great Geyser itself which gave its name to all similar intermittently discharging features; the term comes from the Viking verb “*gjose*” (to gush). Liquid and two-phase geothermal reservoirs occur together at **Krafla** and **Namafjall**, as indicated by the initial enthalpy of fluids discharged from wells there. Near the coast, infiltration of sea water is shown by the high mineral concentration (up to 20 g/kg) in hot water from the **Svartsengi** and the **Reykjanes** high- $T$  reservoirs (both liquid dominated). Several wells at **Krafla** discharged fluid with a magmatic signature as a result of an intrusion and eruption that occurred there in 1975.

The term “geothermal brine” has been used for liquids with high total dissolved solids (TDS). This term applies, in general, to liquids with TDS >20 g/kg (i.e., more saline than seawater); hot brines with TDS > 100 g/kg are called “hypersaline” brines.

Elongate, deep (>6 km) intrusions likely heat a number of the geothermal systems in Baja California (Mex-

ico) and the Imperial Valley (California); these are liquid dominated and mainly high-temperature systems. The fluvialite sediments host reservoirs that contain a brine or “hypersaline” brine that arguably derives its high salinity by dissolving surrounding evaporites. Because of their high density, the brines have little surface discharge, so the dominant mode of heat transfer is by conduction. An example is **Cerro Prieto** (Mexico) where, prior to exploitation, some heat reached the surface via small patches of hot, steaming ground and conductive losses were about 30 MW. Other brine systems in the Imperial Valley (USA), such as **Brawley**, have no surface manifestations whatsoever. Minor steaming ground and small mud pots occur over the “hypersaline,” stagnant high-temperature reservoir of the **Salton Sea** (also Imperial Valley). This is similar to the “hypersaline” system with a similar geological setting, the **Cesano** prospect, in Central Italy.

Hypersaline brines derived from the lateral infiltration of seawater occur in the **Lake Assal** system (Djibouti), hosted by basalts, over an incipient rift with extensive evaporites at its surface. At **Dallol** (Danakil Depression, N. Ethiopia) meteoric water enters a salt dome by advection and dissolves salt almost to the limit of NaCl solubility. The hypersaline brine is heated by conduction from a cooling intrusion. This produces hot, hypersaline brine pools ( $T = 110^{\circ}\text{C}$ ); the TDS of the brine can be up to 420 g/kg, high in Na, K, Mg, and Cl. Here an overflow of hot brine causes the formation of salt mounds.

### *3. Manifestations of High-Temperature Reservoirs Hosted by Sedimentary Rocks*

Another group of high-temperature systems occur in sedimentary to low grade metamorphic rocks in a setting with deep cooling plutons (perhaps the product of an older subduction cycle). A hot water- $\text{CO}_2$  gas dominated reservoir occurs, for example, at **Ngawha** (NZ), which is several hundred kilometers distant from the presently active subduction zone, but lies above a subduction zone that was active more than 10 Myr ago. Quaternary basalts occur nearby but are not part of the high-temperature reservoir, which comprises Mesozoic greywackes covered by about 600 m of almost impermeable (to water) sediments. Vigorous upflow of  $\text{CO}_2$  with mercury occurs throughout the entire area and through several cold lakes, but most heat ( $\sim 50$  MW) transfers to the surface by conduction.

The two largest systems known have similar settings and are both vapor-dominated, namely **Larderello** (Italy) and **The Geysers** (California). There is circumstan-

tial evidence that steam, which ascended to the surface prior to the exploitation of both reservoirs, came from an extensive condensate carapace similar to that shown in Fig. 5. At Larderello, large amounts of boron were mobilized by vapor from marine sediments and deposited at the surface in borax ponds, the *laguni* that were once mined. Fumaroles discharging B-rich steam have been described as *soffioni*. The magnitude of natural heat transfer and that by steam was unfortunately not assessed at either place before exploitation began.

### **C. Manifestations of Systems over extensive Hot Crustal Rocks in a Plate Collision Environment**

The heat sources for all the high-temperature systems mentioned so far involve mobilization of upper mantle melts and fluids. A characteristic trace component which reveals the involvement of subcrustal melts is the  ${}^3\text{He}$  isotope. Its role can be assessed from the  ${}^3\text{He}/{}^4\text{He}$  ratios,  $R$ , of gases, normalized with respect to its atmospheric ratio. Geothermal gases from all high-temperature systems described so far have  $R$  values that are 1 to 2 orders of magnitude greater than typical values ( $<0.15$ ) of gases discharged by low-temperature systems far distant from active margins, e.g., over a “cold” continental crust (with no volcanic history).

However, a number of high-temperature systems, hosted by metamorphic or sedimentary rocks, occur in Tibet and Kashmir that discharge steam and gases with anomalously low  ${}^3\text{He}/{}^4\text{He}$  ratios ( $R < 0.15$ ). These systems transfer heat derived from young granites, probably generated by shear-heating from plate collision. At one, **Yangbajing** (Tibet), temperatures  $>250^{\circ}\text{C}$  have been measured in drillholes. Hot geothermal fluids here ascend beneath the flanks of a high mountain range (Inner Himalayas) and discharge as a concealed outflow within a wide valley. The zonation of manifestations is again controlled by the relief of the terrain. Traces of acid condensates and extensive acid steam alteration (alunite, residual silica) occur over the flanks near the inferred upflow. There is no significant discharge of liquid over the outflow, whose top is sealed by extensive deposits of silica and carbonates. Only at the toe of the outflow is there a spectrum of manifestations that discharge neutral pH chloride waters, namely; *boiling pools*, *hot springs*, *spouting (two-phase) boiling springs*, and some *steaming ground*. A number of *large hydrothermal eruption craters* occur further down the valley, where there are also massive deposits of travertine. A similar,

although less obvious, zonation of manifestations occurs at the nearby **Yangyi** prospect, another system with temperatures  $>200^{\circ}\text{C}$  in 500-m deep wells. From descriptions of their discharge features and chemical geothermometry, it is inferred that at least another dozen such high-temperature systems occur in Tibet. These appear to be associated with 30 to 50 km wide, elongate bands of hot, upper crustal rocks ("heat bands") produced by shear heating resulting from lateral movements of large crustal blocks. Also impressive are the intermediate-temperature systems within the same *heat bands* that occur at more than 100 places (see later discussion).

---

#### IV. MANIFESTATIONS OF INTERMEDIATE- AND LOW-TEMPERATURE SYSTEMS

Intermediate- and low-temperature systems occur in many different geological and hydrological settings, both along and outside active plate margins. It is often difficult to distinguish them from high-temperature systems, since standard chemical and isotopic geothermometers, based on slow equilibration processes (i.e., Na/K and most gas geothermometers), give temperatures reflecting conditions much deeper than, say, 1 km depth. However, faster equilibrating fluid/rock interactions allow application of the silica (assuming equilibration with chalcedony) and the Mg/K geothermometers. These, and the lack of significant shifts in the  $^{18}\text{O}$  isotope values, can be used to predict likely temperatures in the upper few kilometers of such reservoirs. Because of their lower temperatures and less buoyant fluids, their natural heat outputs are also lower. They thus have fewer surface manifestations. All intermediate temperature prospects have *liquid dominated reservoirs* that can extend to great depths ( $>5$  km). *Fumaroles* and *steaming ground* are absent, although *boiling springs* occur in some; however, the maximum fluid discharge temperatures are usually below boiling.

Although a few intermediate-temperature systems are located in active and inactive volcanic arcs, where they are heated by convecting plumes of hot water, the majority derive their energy from deeply penetrating meteoric water that "sweeps" heat from the hot but brittle upper crust into a discharge area ("sink"), often via fractures ("fracture zone" systems). According to their geological

and hydrological settings, most intermediate-temperature systems can be grouped as follows:

1. Systems over active and inactive volcanic arcs, i.e., hosted by volcanic rocks
2. "Heat-sweep" systems in active rifts and at plate collision boundaries
3. Fracture zone systems hosted by sedimentary or metamorphic rocks

##### A. Intermediate-Temperature Systems over Volcanic Arcs

A few intermediate-temperature systems have this setting but they are everywhere outnumbered by the high-temperature systems ( $\sim 1 : 10$  in New Zealand and Sumatra). Some intermediate-temperature systems are probably decaying high-temperature systems over a waning heat source. A few dead systems host epithermal mineral deposits, but most of these were likely once high-temperature systems. A well-studied dead reservoir is at **Ohakuri** (NZ), which was probably a high-temperature system about 100 kyr ago. Still active intermediate-temperature systems occur at **Horohoro** and **Atiamuri** (NZ). Their surface manifestations are not impressive. Minor silica sinter and a boiling spring occurs at Atiamuri, where drilling shows that the temperature at a depth of about 1 km is only  $175^{\circ}\text{C}$ . At Horohoro, there is *minor hot spring activity* and *cold altered ground*. The chemical composition of these thermal waters points to their being appreciably diluted with ground waters.

Hot crustal rocks beneath an extinct arc segment can take several million years to cool conductively. In such a setting, a few intermediate-temperature systems may survive, for example, at **Te Aroha** (Coromandel, NZ), which is hosted by andesites along an arc segment that became extinct  $\sim 5$  million years ago. Here little heat ( $\sim 1$  MW; see Fig. 1) is transferred by a few hot springs and CO<sub>2</sub>-rich fluids that deposit aragonite. Over the same extinct arc segment occurs the **Kaitoke** hot springs (Great Barrier Island, NZ), which are similar to those at Te Aroha.

##### B. "Heat-Sweep" Systems

The reservoirs of "heat-sweep" systems may be of volcanic or sedimentary rocks. Fracture zone systems can develop in a part of the crust with anomalously high

heat flow but not associated with volcanism, and in continental rifts. Intermediate-temperature systems have not been described in detail, but some, however, have been explored by drillholes in the hope that they were high-temperature systems. The number of examples that follow is therefore small and restricted to a few of the better known prospects.

### 1. Heat-Sweep Systems in Active Rifts

The East African Rift Valley is underlain along its entire length by hot crustal rocks heated mainly by intrusions. Rain infiltrating over its higher standing rift shoulders favors the development of large heat-sweep systems which discharge hot fluids along the axis of the arid rift valley (see Fig. 7). The large hydraulic head sets up its own convection pattern, that is, a pattern of "forced convection." If hot fluids ascend through evaporites they discharge hot saline water in springs at 40 to 80°C, for example, along the margins of **Lake Natron** (Tanzania), **Lake Magadi** (Kenya), **Lake Afrera**, and **Lake Asale** (both in northern Ethiopia). Evaporation produces large surface deposits of crystalline carbonates of sodium (trona) at the first two lakes. The compositions of brines of shallow origin is not governed by temperature-dependent equilibria; however, silica and isotope data indicate that the deep fluid temperatures are most likely <170°C. The area affected by such heat sweeps is large (>100 km<sup>2</sup>), which explains the high heat outputs (of the order of 100 MW) of the first two examples cited; the anomalous position of the Lake Natron heat output is shown

in Fig. 1. They are the largest intermediate-temperature systems known.

Elsewhere along the East African Rift, where evaporites are thin or absent, less saline hot water discharges into lakes and sinks. **Lake Bogoria** (Kenya) has a heat output from several *boiling springs* and *ebullient pools* of the order of 100 MW. Cation geothermometers clearly point to the mean reservoir temperature of this sweep system as being <180°C. The surface discharge features could be mistakenly interpreted as being manifestations of a high-temperature system. Manifestations of intermediate-temperature sweep systems occur also in northern Kenya and the Southern Lakes District of Ethiopia.

Several systems in the Basin and Range Province of the United States are probably heat-sweep systems (**Soda Lake**, **Beowawe**, and **Stillwater** in Nevada, for example). Their manifestations are mostly minor.

### 2. Heat-Sweep Systems in a Plate Collision Setting

In Tibet, Kashmir, and west Yunnan, there are several intermediate-temperature systems, as indicated by the chemical geothermometry of their discharge fluids. The topography, high infiltration (some from snow melt), and large hydraulic heads over recharge areas favor the development of a heat-sweep hydrology over crustal strips heated by shear deformation ("heat bands"). A good example is the **Naqu** prospect in Central Tibet characterized by *hot springs* ( $T_{\text{max}} = 60^{\circ}\text{C}$ ), which deposit travertine from waters that the K/Mg geothermometer indicates to be ~130°C at depth. **Laduogang** (near Yangbajing) is another intermediate-temperature system explored by drilling. Ebullient pools discharging bicarbonate waters here locally deposit carbonate nodules (pseudo-geyserite). In the foothills of the Himalayas, similar systems occur (**Manikaran** in northern India, for example). Subsurface temperatures as hot as 150°C are indicated by the K/Mg geothermometer for most systems in Tibet depositing travertine. This is also a characteristic product of many extinct systems there.

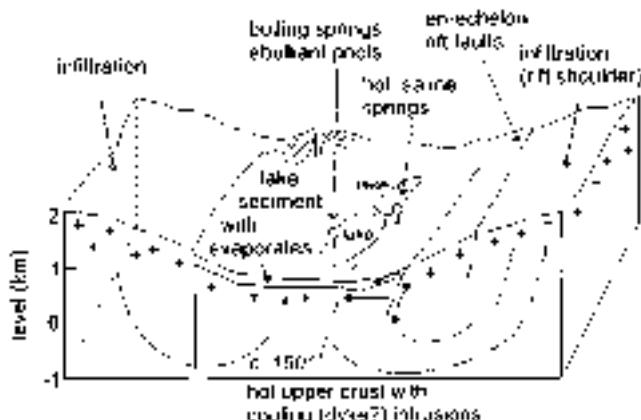

FIGURE 7 Conceptual model of a heat-sweep system (forced convection) producing intermediate-T reservoirs within an active continental rift. The model is based on lake systems such as those in northern Tanzania, Kenya, and Ethiopia.

### C. Fracture Zone Systems

Deep-reaching heat-sweep systems can also develop in terrain with rather flat topography if fluids ascend via a deep, highly permeable (>100 millidarcy) fracture zone in a brittle crust of high heat flux (>70 mW/m<sup>2</sup>). Such high fluxes often occur where thick gran-

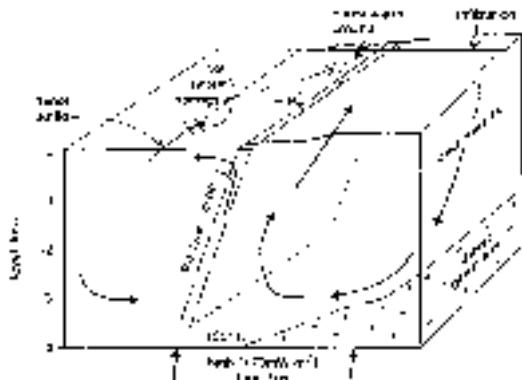

FIGURE 8 Conceptual model of a heat sweep system (free convection) discharging hot fluids through a deep reaching fracture zone (fracture zone system). The heat source gives a higher than normal terrestrial heat flow; this setting can occur far away from active margins and volcanism. The model is based on the Fuzhou system in South China.

ites provide radiogenic heat (see Fig. 8). Fracture zones near the surface may be “narrow” (<100 m) or “wide” (>200 m). A good example of the former is the **Fuzhou** prospect in southern China; the **San Kamphaeng** prospect in northern Thailand is an example of a wide fracture system. Another dozen or so fracture zone-sweep systems occur in northern Thailand (e.g., **Fang**) and a few within the coastal strip of southern China (e.g., **Zhangzhou**).

The dominant manifestations of all these systems are hot springs, and occasional hot pools, both with minor encrustations of sinter and travertine; alteration of the surrounding rocks is rare. Conduction contributes to the heat transfer, which commonly lies between 3 and 10 MW. Prospects with indicated high Na/K equilibrium temperatures (some greater than 225°C) can also be misinterpreted as being “high-temperature systems,” although their low heat outputs and isotopic signatures (no significant  $^{18}\text{O}$  shift) show them to have intermediate-temperature reservoirs.

#### D. Manifestations of Low-Temperature Systems

A large number of convective low-temperature systems occur in geological settings that favor the development of structurally controlled, smaller heat sweep systems. Most discharge warm (i.e., <40°C) water from a network of fractures that constitute their reservoir. Stratigraphically controlled systems in sedimentary rocks, discharging

over an anticline, for example, are rare. Since temperatures in their upper reservoirs are low (i.e., <125°C), buoyancy forces, and hence the heat output of these systems, are also low (typically between 0.1 and 3 MW). Rock/fluid interactions occur at a much slower rate and mineral–fluid equilibrium is seldom attained;  $^{18}\text{O}$  shifts do not occur. The “true” low-temperature systems are rare in volcanic arc settings, whereas they are common where topography and tectonics allow small heat-sweep systems to develop, for example, along the margin of large rift valley lakes, such as **Lake Malawi** (East Africa). Low-temperature systems can form even in brittle crust with an average terrestrial heat flux ( $\sim 60 \text{ mW/m}^2$ ), corresponding to temperature gradients of only  $\sim 25$  to 30°C/km, although they are more common where fluxes are higher. In the Basin and Range Province and Colorado Plateau in the western United States, there are at least 900 low-temperature systems, which thus outnumber the intermediate and high-temperature systems by  $\sim 20:3$  and  $20:1$ , respectively. In the Himalayan area there are  $\sim 500$  low-temperature systems that discharge fluids hotter than 40°C; they outnumber the intermediate and high-temperature systems by  $\sim 20:6$  and  $\sim 20:1$ , respectively.

Despite the worldwide occurrence of low-temperature systems, their surface manifestations differ little, consisting usually of *warm* ( $T < 40^\circ\text{C}$ ) and sometimes *hot springs* ( $T > 40^\circ\text{C}$ ) without any surface alteration or deposits other than travertine. The compositions of the discharge fluids reflect the sweep depth and mixing contribution from saline pore fluids in the sedimentary host rocks. Numerical modeling shows that these systems are longer-lived than all others. The development of free convection in a fracture network of a low-temperature system, for example, can take a million years, whereas full convection within permeable high-temperature reservoirs may develop in only 10,000 years. Because of their low temperatures, mineral deposition is so slow that it does not block the fluid-flow channels, and they are likely to be long-lived systems.

Manifestations of a few low-temperature systems differ, but include warm, often tepid springs that deposit travertine, for example at **Acque Albule** near Rome (Lacus Albulus), which was the main quarry for ancient Rome, and distant from active volcanoes. In western Turkey, **Bursa** and **Pamukkale** have a similar setting. However, CO<sub>2</sub> gas also discharges close to low-temperature systems depositing travertine, and these could be described as “moffete.” Because of the high solubility of CO<sub>2</sub> in cold water, carbon dioxide rising from the mantle, as recognized by its typically high  $^3\text{He}/^4\text{He}$  ratio, can dissolve at the bottom of cold lakes, such as at **Lake**

**Nyos** (Cameroon) and the **Laacher See** (Germany), which thus act as “gas” traps.

---

## V. CLASSIFICATION OF MANIFESTATIONS (MODE OF HEAT TRANSFER)

Based upon the various types of manifestations in their settings, some provisional classifications and groupings are attempted. Since the same types of manifestations associated with heat discharge occur over a large number of convective systems, this classification is only tentative. We can distinguish between manifestations associated with the following modes of heat discharge: (1) diffusive; (2) direct and continuous; (3) intermittent; (4) catastrophic; and (5) concealed. The various manifestations associated with these modes have been ranked in Table I according to their role in surface heat transfer.

### 1. Diffusive Heat Discharge

Diffusive heat transfer by thermal conduction results in *warm ground*; it is not obvious at the surface and can only be recognized by temperature surveys in shallow (say, 1-m deep) holes. It may be the dominant mode of heat transfer of some intermediate- and low-temperature systems. At Fuzhou (South China) almost half of the total heat transfer of ~10 MW is by warm ground. It is also the dominant mode where high-temperature systems are covered by almost impermeable sediments. More than 80% (~40 MW) of the heat transferred from the Ngawha (NZ) system is by conduction through warm ground. Since near-surface conductive heat transfer does not raise the surface temperature, warm ground cannot be detected by infrared sensing; however, under suitable conditions warm ground with stunted vegetation produces *reflective infrared anomalies* (due to small differences in leaf chlorophyll condition). Such plants constitute, therefore, in the widest sense, a surface manifestation, albeit a surrogate one.

Diffusive heat transfer by thermal conduction is also dominant in *steaming ground*, where vapor rises to shallow depths but does not discharge because of an almost impermeable surface layer, produced by intense alteration (e.g., clays are widespread in this setting). Vapor condenses and the condensates drain away. This produces steep thermal gradients, above 100°C/m in the top 15 cm, thus raising the surface temperature well above ambient. Conductive heating of moist air pro-

duces a thin diffuse layer of steam that explains the name (although it is strictly a misnomer, since no steam is visible if the air is dry). Steaming ground can always be recognized from the air by infrared anomalies. This manifestation occurs over many high-temperature systems. Steaming ground is the most important signature of heat transfer over high-temperature systems (with two-phase zones) in the arid parts of the African Rift Valley and contributes at least, together with minor steam vents, about 50% (~200 MW) of the amount of heat discharged from the Olkaria system (Kenya).

Evaporation from the surface of *hot pools* also constitutes a diffusive heat discharge. These pools can be subdivided as *calm*, *boiling*, or *ebullient* (*effervescent*). They are widespread and occur mainly over liquid dominated, high-temperature reservoirs in flat terrain (where they usually occupy hydrothermal eruption or dissolution craters), but also over outflows from reservoirs beneath steep terrain, over vapor-dominated reservoirs (often over quenched fumaroles), and occasionally over intermediate-temperature fracture zone systems. The amount of heat transferred is proportional to the pool area, its temperature, and other parameters that enhance evaporation. Hot pools may be fed by ascending hot water, by steam-heated groundwater, or by steam. In the first case the water has almost neutral pH; in the last case it is acid. Ebullition and effervescence are usually the result of discharge of CO<sub>2</sub>. The largest hot pool at Waiotapu (NZ), for example, discharges ~20 MW. Hot pools discharging neutral pH chloride water from high-temperature reservoirs are characterized by a rim of thick silica sinter. A type of hot pool is the *mud pool*, whose mud is kept liquid by the condensation of steam and rainwater and the upwelling is caused by the discharge of gas from below. A *mud volcano* is a feature at the margin of a mud pool produced where gas discharges from a vent and builds a cone of mud as high as 2 m. The mud usually comprises cristobalite and kaolin clays, but smectites may also occur.

### 2. Direct and Continuous Heat Discharge

The most common manifestations over all types of geothermal systems are *warm* or *hot springs*. *Boiling springs* are present over many high-temperature systems but rarely over intermediate-temperature ones. Artesian discharge of hot water produces *spouting hot springs* (spouters), which sometimes occur in a valley that drains a liquid dominated system. A spouter may also discharge a mixture of steam and boiling water, thus acting like a continuous geyser (Steady Geyser at Yellowstone Park, for example). *Acid hot springs* are typical discharge fea-

TABLE I Ranking of Surface Manifestations (Discharge Features) According to Their Role in Transferring Heat in Geothermal Systems

	A1	A2	B3	B4	B5	C3	C4	C5	C6	D7	D8	D9	D10

Symbols for Ranking:

- Not known
- (x) Occasionally present
- x Usually present (minor heat transfer)
- xx Usually present (major heat transfer)
- xx In some prospects manifestation may transfer > 50% of all heat discharged.

Other Symbols:

- ac\* dominantly 'acidic' pH of liquids in pool or lake
- n\* dominantly 'neutral' pH of liquids in pool or lake

Types of Geothermal Systems:

- A1 Volcanic - Hydrothermal
- A2 Quasi Volcano - Hydrothermal

Systems associated with High standing Volcanic Centres:

- B3 High T, Liquid dominant
- B4 High T, Natural 2-Phase
- B5 High T, Vapor dominant

Systems associated with flatter terrain:

- C3 High T, Liquid dominant
- C4 High T, Natural 2-Phase
- C5 High T, Vapor dominant
- C6 High T, Plate Collision
- D7 Inferior T, Volcanic Arc Setting
- D8 Inferior T, Heat Sweep Setting
- D9 Fracture Zone Types
- D10 Low T

tures associated with volcanic-hydrothermal systems, but also occur over high-temperature systems beneath high standing volcanic centers. Heat discharge rates of most single hot springs rarely exceed a few megawatts, although this is higher where springs occur in clusters or are aligned over a fracture. Large discharge rates from a single spring are unusual. However, if thermal fluids collect in a large confined aquifer and then funnel beneath a stream, large discharges may occur. The Hippo Pool hot spring in Ethiopia occurs in such a setting and constitutes the largest single discharge of

thermal water (~1000 kg/s, transferring ~105 MW) in the East African Rift.

"Wet" steam, that is, steam at the saturation temperature containing condensation droplets, is discharged by most fumaroles over almost all types of high-temperature systems and volcanic-hydrothermal systems. "Dry" steam, hotter than saturation temperature, is discharged by a few fumaroles at high flow rates. The terms *wet* and *dry fumarole* have been used to describe these features. Fumaroles that discharge at speeds >20 m/s are noisy; vents with a quiet discharge (i.e., <20 m/s) have been

called *steam vents*. Temperatures up to 145°C were measured in a dry fumarole at Darajat (Java) whose vapor derives from the top of the reservoir. Heat discharge rates of fumaroles are usually low despite the impressive appearance of their large steam cloud; the largest fumarole in the Ketetahi fumarole field (NZ) discharges only ~5 MW. Steam vents that deposit significant amounts of sulfur are called *solfataras*; those with high boric acid are *soffioni*.

Noncondensable gases, such as CO<sub>2</sub> and H<sub>2</sub>S, sometimes discharge without any steam component; they transfer little heat since gas temperatures are usually low. Minor, cool CO<sub>2</sub> discharges, called *moffete*, occur both over volcanic–hydrothermal systems and nonvolcanic (usually travertine depositing) low-temperature systems. Vents and ground discharging a mixture of CO<sub>2</sub> and H<sub>2</sub>S gases are called *kaipoban* in the Philippines, where they occur over high-temperature systems with an “acid core” (Palinpinon, for example). Peripheral CO<sub>2</sub> discharges at many other systems may have large gas fluxes (Sibayak in Sumatra, for example), or the gas can diffuse through the ground (lack of vegetation and dead birds in depressions are signs of such diffuse discharges).

### 3. Intermittent Heat Discharge

*Geysers* are spectacular manifestations discharging intermittently a mixture of boiling water, gas, and steam; they are, therefore, apart from some spouters, the only natural two-phase discharge feature of hydrothermal systems. Geysers occur over liquid dominated high-temperature systems, usually in rather flat terrain, and rarely at the toe of outflows. The average heat output, even of the largest geysers, is moderate, rarely exceeding 5 MW. They are the best-known of all thermal manifestations, and more has been written about them than about all other manifestations, although they are very rare. Geysers require fractured rocks filled with hot water at boiling temperature at shallow depth. Filling and flashing then causes a sudden discharge from a shallow cavity. This occurs regularly, but that from a complex fracture/cavity network may result in irregular discharges. Since they discharge deep water that is oversaturated with silica, geysers are always associated with wide sinter aprons. The discharge characteristics of geysers are very sensitive to pressure changes in the supply water. Effer- vescence of dissolved CO<sub>2</sub> can also trigger intermittent geyser-like discharges.

Thermal discharge features may show seasonal variations, especially in countries with a pronounced rainy season that raises the groundwater level. A famous sea-

sonal discharge feature is the geyser at Rajabasa (Sumatra), which only discharges during the rainy season. Springs with intermittent discharge of hot water occurring in a geyserlike cycle in Iceland have been referred to as *pulsating springs*. A similar feature is the lake in Inferno Crater at Waimangu (New Zealand), which usually overflows every 5 weeks.

### 4. Catastrophic Discharges

In a setting that favours geyser activity and also over some vapor-dominated systems, there may be *hydrothermal eruptions*. These eruptions are triggered by an instability in a hydrostatic liquid column very close to boiling temperature. A slight pressure drop, for example, is sufficient to initiate an eruption. Once the upper portion of the vent has been uplifted by steam expansion, the resulting drop in pressure within the liquid column beneath induces further flashing discharges at progressively greater depth. The ejected debris forms a characteristic ring of hydrothermal eruption breccia. Hot water often later fills the crater, thus forming a large hot pool, as occurs at Waiotapu (NZ), which is surrounded by its eruption breccia. Some hot lakes can widen by marginal, smaller hydrothermal eruptions, which occurred, for example, in an acid lake over the vapor-dominated Kawah Kamojang field (Java).

Hydrothermal eruptions have also been triggered by engineering activity such as at Yangbajing (Tibet), where the pressure of drilling fluid was not sufficient to balance the pressure of shallow (<50 m) reservoir fluids. Naturally induced hydrothermal eruption craters surround the drill site.

### 5. Heat Discharge Associated with Seepage

*Seepage* is an ill-defined term, used to describe any type of subsurface discharge of thermal fluids, at both shallow and deep levels. Shallow seepage occurs if hot water from a geothermal reservoir discharges by concealed springs at the bottom of a river, a lake, or into shallow groundwater. If a river seepage is fed by an outflow from a nearby high-temperature system, almost no surface manifestations associated with it may be visible. This is the situation at **Mokai** (NZ), where ~300 MW of heat is discharged by hot chloride water into a large river at the toe of an 8-km long concealed outflow. Seepage into rivers and streams can be recognized from the different mass fluxes of nonreactive constituents, such as Cl and B, measured up- and downstream of the place where such an inflow is likely.

## VI. SURFACE ALTERATION AND DEPOSITS

The thermal activity that is the surficial surface expression of a geothermal system is usually much smaller in its extent than is the surficial hydrothermal alteration. For this reason the hydrothermal minerals and their distribution provide useful clues about a geothermal system. For example, the surface alteration at **Matsukawa** in northern Honshu (Japan) was the single most important exploration guide for deducing the extent and potential of this important field.

The intensity of surface alteration at a particular site reflects a variety of parameters, including the shallow hydrology of the field, its near surface plumbing, the reactivity of the host rocks and the fluids, and the duration of fluid/rock interactions or mineral deposition. The extent of surficial hydrothermal alteration ranges from zero, for fields such as **Brawley** and **Heber** (Imperial Valley, California), to several hectares, as in the Yellowstone fields and at Waiotapu (NZ).

More than 100 minerals are known to occur in active geothermal fields. Some are rare (e.g., gold) and unexpected (e.g., lepidolite), but there are about 20 that are common and widespread in a large number of thermal fields hosted by a wide variety of rock types. Typical assemblages of surface alteration minerals associated

with different types of geothermal systems are listed in Table II.

The identities of the hydrothermal minerals that form at a specific location depend upon a variety of factors, but the main ones are temperature and the composition of the reacting fluid, especially its pH and the amount of gases it has dissolved in it. In addition, the duration of fluid/rock interactions is reflected in the intensity of alteration, together with hydrological factors such as rock permeability.

Alteration produced by steam, or strictly steam condensate and gases, is dominantly destructive of the host rocks, but that associated with thermal waters of near neutral pH is mainly constructive. Thus, silica residue occurs as a product of steam alteration and silica sinter occurs where alkali waters discharge. The former derives its silica from the surficial rocks as most other cations are removed, but the silica in sinter is transported to the surface from the reservoir itself by the ascending alkali chloride waters.

Despite the corrosive behavior of steam condensate and acid gases, they produce a wide variety of hydrothermal minerals, including sulfur and many sulfates, of which alunite, gypsum and jarosite are usually the most common. Kaolin clays are also typical of this type of alteration and are usually either kaolinite, halloysite or, more rarely, dickite. Fine-grained hematite and hydrous iron oxides are also common products of oxidation, and

TABLE II Typical Assemblages of Surface Alteration Minerals Associated with Different Types of Geothermal Systems

Assemblage	Type of Geothermal System (as in Table I A)
Silica sinter, metal-rich precipitates silification of surface deposits, geyserite	B31, C6, C6
Travertine (calcite), aragonite, pseudo-geyserite	A2(d) <sup>a</sup> , B3(d) <sup>a</sup> , B4(d) <sup>a</sup> C6(d) <sup>a</sup> , D7, D8, D9, D10
Kaolin, silica residue, cristobalite alunite, ulvö sulfates, cinereous pyrite, sulfur	A(alt), B(alt) C(alt), D7
Silica residue, diaspore, pyrophyllite, sulfur, alunite other sulfates	A1, A2
Jarosite, more soluble sulfates, sulfur	A1, A2, B3, B1, B5 C3, C4, C5, C6, D7, D8, D9

(d)<sup>a</sup> = distal or perched above main reservoir

cristobalite is fairly widespread. This type of alteration is common above vapor dominated reservoirs, but also is present in those that have reservoirs with water only or else two phases. They are thus not diagnostic of reservoir type. Silica sinter and travertine have a variety of morphologies, many of which are similar, e.g., banding, terraces, geyserite (and pseudo-geyserite), overhangs, palisade structures, and postdepositionally formed features such as pressure ridges and fragmentation textures. Both also commonly record extensive microbiological activity, and many contain plant material. However, travertine (calcite or aragonite) and silica sinter have a quite different genesis and significance. Silica sinter deposits as thermal waters that are oversaturated with respect to quartz, chalcedony, or cristobalite cool at the free surface, whereas travertine forms as the depositing waters lose CO<sub>2</sub> formerly dissolved in them.

The presence of silica sinter is thus usually a reliable indication that the depositing fluids are derived from a reservoir hotter than about 180°C, but travertine has little geothermometric significance and the waters from which it deposits could have traveled several kilometers laterally.

---

## VII. PERSPECTIVES

### A. Heat Transfer and Classification

The magnitude of heat discharged by the thermal manifestations of hydrothermal systems has not been studied in detail, but some estimates are available. Comparison of these estimates with inferred, average, long-term heat discharge rates based on accumulated volume discharge rates of lava and tephra (say, 50 km<sup>3</sup> per 10 kyr) from highly active volcanoes indicates that many high-temperature hydrothermal systems can deliver as much energy, at a steady rate, as large volcanoes through their intermittent discharges, namely of the order of 100 × 10<sup>18</sup> joule per 10 kyr (e.g., accumulated and extrapolated natural output of the Wairakei hydrothermal system versus that of the nearby Taupo caldera in New Zealand). Some of the energy throughput of hydrothermal systems replenishes their reservoirs, which may store between 10 and 30 × 10<sup>18</sup> joule in the upper few kilometers, that is, about equal to the energy stored in the largest hydrocarbon reservoirs.

For appropriate and applicable temperature ranges, the dynamic viscosity of magma ( $T > 1000^\circ\text{C}$ ) is more than six orders of magnitude greater than that of hot

water and vapor ( $T > 250^\circ\text{C}$ ); the heat energy transferred per unit mass by various magma types can be half that of mixtures of hot water and vapor. It appears, therefore, that in the longer term, hydrothermal systems are more effective in transferring heat energy than are volcanic systems, although details of the settings that favor the development of hydrothermal systems are not well understood.

Identification and ranking of high-temperature systems needs more attention. Ranking, in turn, requires assessment of the natural heat output and the likely reservoir temperatures in the same way as eruption characteristics have been used to assess and to classify volcanic systems. In this respect, geothermal research lags volcanological research, where several catalogues listing the worldwide distribution of volcanoes have been published. These catalogues list a volcano as “active” if it erupted at least once during historic times or during the last 2000 yr. The listed “active” volcanoes usually comprise both centers that discharge or have discharged magmatic fluids and volcanic–hydrothermal systems. The catalogues also list a number of high-temperature systems that have had historic hydrothermal eruptions as being “active” volcanoes, where such eruptions have been misclassified as “phreato-magmatic eruptions.” In addition, hydrothermal systems that discharge only steam (i.e., steaming ground) are sometimes misidentified as “active” volcanoes. When the spatial distribution of volcanic versus hydrothermal systems is assessed, these problems have to be considered.

Although no comprehensive lists of high-temperature hydrothermal systems exist, most of them have been identified over active plate margins, often showing a clear alignment of both active volcanoes and high-temperature geothermal systems. There are probably 12 such centers in Sumatra that can be classified as “active volcanoes”; there are also at least 30 high-temperature systems, each discharging between 30 and 300 MW. Thus, the high-temperature hydrothermal systems of Sumatra outnumber the active volcanic systems by 2.5 : 1.

### B. Thermal Alteration and Mineral Deposition

Ore-grade concentrations of some minerals occur at the surface of several active hydrothermal systems where they have deposited from ascending thermal waters. For example, the Champagne Pool at Waiotapu (NZ) is now depositing a precipitate rich in gold (up to 80 mg/kg)

and silver (up to 200 mg/kg). At the Waimangu field nearby, silica sinter is precipitating that locally contains 3% elemental tungsten. The surface and near-surface parts (down to about 300 m) of many fields are thus analogues of typical low sulfidation epithermal ore deposits. The hydrological processes, such as boiling and fluid mixing, that occur in active hydrothermal systems leave mineralogical signatures (such as vein adularia and bladed calcite) that persist after the activity has ceased. For example, silica sinter of similar appearance to that at Waiotapu, but of Carboniferous age, occurs at the Wobegong epithermal mineral prospect in Queensland. The famous Devonian Rhynie cherts of northeast Scotland show unequivocal evidence that they deposited from hot chloride waters that once discharged at the surface.

In the deeper subsurface (>300 m, i.e., where boiling temperatures are >230°C in saturated reservoir rocks), the hydrological conditions in active hydrothermal systems more closely match those that once prevailed in some mesothermal ore deposits hosted by volcanic rocks. Here base metal sulfides sometimes deposit in concentrations locally up to ore grade, usually as a result of boiling, cooling, or fluid mixing. These sulfides most likely deposit where temperature gradients within the reservoir are steepest (near reservoir boundaries, for example). Little is known about the thermal regimes that occur below 3 km depth in active geothermal fields. Near the magma–host rock interface the conditions and processes that occur are likely to be the same as those that occurred when some of the large porphyry copper deposits formed in the western United States, such as Bisbee (Arizona) and Bingham (Utah).

Thermal and hydrological conditions can change during the lifetime of a hydrothermal system, as is evident from cores (with cross-cutting veins and mineral overprints) recovered from deep drillholes. The lifespans of geothermal systems are still poorly known, although this is an important research problem. At present we know that some hydrothermal systems, such as Ohaaki-Broadlands (NZ), have lasted for at least 300,000 yr and the Kawerau Field (NZ) has been active, in some form or other, for at least 280,000 yr. Icelandic geothermal systems do not usually live longer than 250,000 yr, but systems transferring heat from huge plutons, such as that beneath the greater Larderello Region (Italy), can have geothermal surface activity for >3 million years.

### C. Outlook

In the past the lessons learned from studying active geothermal systems and the processes that occur within

them have been applied to interpreting and understanding hydrothermal ore deposits. However, the opposite direction in research outlook could be equally revealing. Thus, rocks exposed through mining or erosion, which once reacted with thermal fluids deep in the bowels of an active geothermal system record, through their mineralogy and textures, evidence about the fluid characteristics and the thermal evolution of the system. There are many valuable insights waiting to be learned from studies of these rocks.

Geothermal systems are dynamic phenomena. Their surface manifestations are often beautiful and fascinating and have attracted admiration or fear since ancient times. They are, however, visible expressions of heat energy that has been transferred from great depth to the surface and so they are analogous to volcanoes. In the same way that the products of individual volcanoes differ widely, depending on their structural settings and the composition of their magmas, so do geothermal systems have a great variety of characteristics. Each system seems to be unique, although we have here tried to group them into broad but distinguishable categories.

The energy that geothermal systems hold has barely been tapped. Only about 9000 MW of electrical energy is now produced worldwide from geothermal fluids with ~90,000 MW thermal energy. Almost the same amount is utilized in myriad other ways (domestic and industrial heating, air conditioning, production of industrial bulk heat). Improvement in technology and plain need will lead to their being exploited more fully in future. However, geothermal systems are also, literally, wonderful natural laboratories worthy of study for their own sakes.

## GLOSSARY

- black smoker** A hot (generally  $> 330^{\circ}\text{C}$ ) hydrothermal vent that produces fine, dark mineral precipitates upon mixing with cold, ambient seawater. As the temperature and metal content of the vent fluid source decreases, the "smoke" grades from black to gray to white.
- chimney** A steep-sided hydrothermal mineral formation on the seafloor, formed by precipitation of primarily metal sulfides and sulfates when hot hydrothermal fluids mix with seawater.
- dike** A bladelike, tabular injection of magma that cuts through country rock.
- fluid inclusion** A fluid trapped within a rock. Small droplets of hydrothermal fluid may become trapped within secondary minerals, thus recording information about the kind of fluids present during mineral formation.

**hydrosphere** The layer of water existing within and between the lithosphere and atmosphere.

**hydrothermal plume** Hydrothermal effluent diluted with seawater after venting. Analogous to a smoke plume rising through the atmosphere from a smokestack, hydrothermal effluent rises from seafloor vents, entraining cold seawater until it reaches a level of neutral buoyancy, then spreads laterally. The thermal and chemical signal of hydrothermal plumes can be used to measure the output of a hydrothermal system, to help locate vents on the seafloor, and to assess the chemistry of the vented fluids.

**lithosphere** The rigid, rocky, outer crust of Earth or any planet.

**major elements** The most abundant chemical elements in a material. In seawater, for example, those elements present at millimolar levels (Na, Cl, K, Mg, Ca, SO<sub>4</sub>).

**magnesium metasomatism** Uptake of Mg from seawater into secondary minerals.

**MORB** Mid-ocean ridge basalt; the dominant rock type along mid-ocean ridge spreading centers, derived from partial melting of the mantle and containing on average 50% by weight SiO<sub>2</sub>.

**ophiolite** Ocean crust that has been tectonically placed on a continent. Ophiolites often host hydrothermal metal sulfide minerals.

**phase separation** Generally, the formation of immiscible vapor and liquid phases by heating or decompressing a fluid. For a pure liquid, phase separation is synonymous

with boiling, or the formation of vapor bubbles from a bulk liquid. In multicomponent aqueous fluids such as seawater, phase separation may also occur as condensation of dense brine from a bulk, vaporlike fluid.

**stockwork** A network, within a host rock, of cracks and veins filled by minerals precipitated from hydrothermal fluids.

**upflow zone** Region in the crust through which buoyant fluids rise in a network of cracks.

**water/rock ratio** A measure of the intensity or extent of water–rock reaction, that is, how much rock has reacted with a given quantity of water. Low water/rock ratios indicate intense reaction, analogous to making strong coffee. To calculate water/rock ratio requires a specific chemical or isotopic exchange reaction.

## I. DEFINITION AND SIGNIFICANCE OF SUBMARINE HYDROTHERMAL VENTS

Submarine hydrothermal vents are the exit points on the sea floor for thermally driven convection of seawater within the ocean crust and are the result of interaction between seawater and submarine volcanoes. Vents are located in volcanic environments where seawater penetrates into permeable ocean crust, is heated by volcanic heat sources, reacts with ocean crustal rocks, and rises back to the seafloor. Hydrothermal circulation is a fundamental part of the production of new oceanic crust and transports a significant amount of the heat that escapes from the interior of the Earth. The associated chemical exchange between the hydrosphere and lithosphere has important impacts on the chemical balance of the oceans, the alteration of oceanic crust, and the reincorporation of altered oceanic lithosphere into the mantle at subduction zones.

Hydrothermal fluids transport high concentrations of metals through the ocean crust and deposit them as sulfide, sulfate, oxide, and silicate mineral deposits in stockwork feeder zones, in seafloor chimneys and mounds, and in metalliferous sediments. Through tectonic motion at convergent plate boundaries, some ancient submarine mineral deposits have been emplaced on continents and are mined for copper, zinc, and other metals. Hydrothermal fluids also transport gases produced by water–rock interaction or exsolved from magmas. The chemical energy available when hot, reduced hydrothermal fluids react with cold, oxygenated seawater can be harnessed by microbes at and below the

seafloor. Similar volcanically powered life forms may exist on other planetary bodies where a hydrosphere interacts with volcanoes.

---

## II. OVERVIEW

### A. History

As the theory of plate tectonics and seafloor spreading was developed in the 1960s, it became clear that global-scale volcanism on the ocean floor has been a fundamental and dominating aspect of the Earth's geology, though eruptions remain hidden under thousands of meters of water. The theory of hydrothermal circulation of seawater through the ocean crust, which developed alongside the plate tectonic theory, had power to explain many different oceanographic observations, including (1) anomalous accumulation of metals in sediments and concentrated mineral deposits along midocean ridges; (2) excess of the primordial, mantle-derived isotope  $^3\text{He}$  in seawater above midocean ridge depths; and (3) measured heat flow much lower than predicted by theoretical conductive cooling models for ocean crust less than  $\sim 65$  million years old. Although hydrographic work revealed the presence of  $60^\circ\text{C}$  brines in the Atlantis II Deep in the Red Sea in the mid-1960s, the first seafloor vents directly observed and sampled took the form of warm ( $17^\circ\text{C}$ ) water discharging through dense animal communities at the Galapagos spreading center in 1977. This was followed in 1979 by the discovery of  $350^\circ\text{C}$  water discharging from metal sulfide chimneys at  $21^\circ\text{N}$  on the East Pacific Rise, a dramatic confirmation of the prediction of hot springs along submarine volcanic centers. The incredible density of previously undescribed fauna at hydrothermal vents was a scientific revelation. In the succeeding years, a great deal of exploration and sampling has been done along seafloor spreading centers, revealing tremendous variety in the form of hydrothermal venting and how it changes through time and space. This chapter will review some of what is known about seafloor hydrothermal venting, with emphasis on the chemistry of midocean ridge (MOR) hydrothermal fluids, the evolution of venting through time, and the effects of volcanic activity on hydrothermal systems.

### B. Setting of Submarine Hydrothermal Systems

More than 35 active submarine hydrothermal vent fields have been located and sampled for vent fluids, minerals,

and fauna. Table I and Fig. 1 include most of the known hydrothermal sites in deep water that have been thoroughly sampled. Table II contains some fluid chemistry data for a range of different deep ocean hydrothermal environments. More than 100 instances of hydrothermal mineral occurrences have been documented at seafloor volcanic sites, and comprehensive lists of these are found in references in Further Reading. Most active hydrothermal sites have been located by oceanographic water column studies of hydrothermal plumes, followed by seafloor submersible studies to conduct detailed sampling. Both diffuse low-temperature and focused high-temperature vents (Fig. 2) have been found across the range of tectonic environments from the slow-spreading Mid-Atlantic Ridge to the fastest-spreading portions of the East Pacific Rise, as well as in intraplate hot-spot, island arc, and backarc basin environments. In some cases, as at Guaymas Basin, Escanaba Trough, or Middle Valley (Table I), submarine volcanoes erupt beneath or within a thick layer of terrigenous sediment, giving rise to sediment-hosted sulfide mineral deposits and unique hydrothermal fluid chemistry (Table II). Wherever there is submarine volcanism, there is also hydrothermal activity due to the active role that circulating seawater plays in cooling and cracking newly emplaced magma. This chapter deals with midocean ridge and other deep-ocean hydrothermal systems; it does not include the many shallow hydrothermal systems around volcanic islands.

Although MOR volcanism is generally restricted to the <1 km-wide zone around the ridge axis, global heat flow studies have clearly shown that about 80% of the hydrothermal heat loss occurs in older (1 to ~65 Myr) crust away from the ridge. It is hypothesized that warm water circulation on volcanically inactive MOR flanks results in larger water and geochemical fluxes, but, as of this writing, Baby Bare Seamount on the eastern flank on the Juan de Fuca ridge on 3.5 Myr crust is the only clear example of a ridge flank warm-water vent. Ridge flank vents are difficult to locate because of the minuscule thermal signal they create in the water column, and because they may have little visual impact in the vast areas of older ocean floor. The exact nature and chemical composition of ridge flank fluids escaping to the ocean are poorly known. As search strategies improve, more ridge flank hydrothermal vents are likely to be found.

The location and form of seafloor vents is a complex function of heat source location, crustal permeability, and physical and chemical feedbacks. Only a few generalizations will be made here. On MOR segments that are volcanically robust, vents are often located within the narrow axial graben or aligned along eruptive fissures

(Fig. 2a). In more tectonic regimes, where a well-developed graben exists, vents are often associated with normal faults on the graben walls (Fig. 2b). Long-lived, mature vent fields with large sulfide structures are often associated with faults and fault intersections. For example, persistent high-temperature venting is found near the caldera-bounding fault in Axial Volcano on the Juan de Fuca ridge. Within the well-mapped Main Endeavour vent field, dozens of hot smoker vents describe a curved line extending over 100 m and joining several large sulfide structures. In these and many other areas, it is likely that active fault zones maintain high permeability between a hot reaction zone and the seafloor.

### C. Structure of Hydrothermal Systems

All hydrothermal systems have three essential features: (1) water, (2) a heat source, and (3) a permeable medium through which the water flows. In the case of submarine hydrothermal systems (Fig. 3), water is derived from seawater which saturates the brittle upper layer of oceanic crust. The heat is ultimately derived from radioactive decay and other sources within the earth, which is transferred to magmatic systems, predominantly along volcanically active, midocean-ridge spreading centers in the oceanic crust. Magma chambers are discontinuous beneath the midocean-ridge axis and vary in depth from several kilometers below the seafloor up to 1 km or less in areas of very high magma supply. Heat may be conducted through the roof of a magma chamber (Fig. 4a) to circulating seawater in the overlying crust, or heat may be actively mined from a magma chamber (Fig. 4b) as it solidifies and cracks. In the case of an active seafloor eruption (Fig. 4c), heat is transferred from the erupting lava, from the feeder dike, and deeper in the system from the magma source region. The structure and dynamics of hydrothermal systems are determined by the physics of water flowing through a permeable medium driven by density gradients induced by volcanic heating. Perturbations due to ocean and earth tides, chemical exchange and mineral precipitation, microbial activity, and feedback between the physical and chemical processes occurring in hydrothermal systems add many layers of complexity to the essential equation involving water, heat, and a permeable medium. There are still many gaps in our knowledge of the structure of hydrothermal systems and what controls their evolution through time.

Hydrothermal systems can be viewed as having three parts: a *recharge zone* where seawater percolates down

TABLE I Confirmed Active Submarine Hydrothermal Vent Sites

**FIGURE 1** Map of global spreading centers and subduction zones. Numbers correspond to the descriptions in Table I and indicate hydrothermally active sites where fluids have been collected. There are many additional sites of known submarine mineral deposits of volcanic origin. Large portions of the midocean ridge system remain unexplored, including most of the high-latitude ridges and the mid-Atlantic ridge south of the equator.

**FIGURE 2** Photographs of submarine hydrothermal vents. (A) Diffuse vent environment photographed in 1994 from the submersible *Shinkai 6500* on the southern East Pacific Rise at 17°25'S, with Zoarcid fish, Bythograeid crabs, amphipods, tube worms (possibly *Tevnia*), serpulid worms, and other fauna. Warm water is venting from the small fissure in the lower center of the photo, and also around the edges of basalt lobes in upper half. The fissure is associated with hydrothermal activity over a distance of >500 m. (B) 370°C black smoker vent at 18°26'S on the EPR. Crabs cling to the tube of a *Riftia* tubeworm in lower right. The spindly black smoker in upper center may well be the mineral-encrusted remains of a large tubeworm that has been incorporated into the growing sulfide edifice. It is not unusual for vent fauna to become part of seafloor mineral deposits. This is one of a series of vents growing in lines perpendicular to a normal fault within a 90 m-deep axial graben. (C) Top of the 300°C, 4-m high "Monolith" sulfide chimney on the Juan de Fuca ridge near 44°59'N. Science gear in the *Alvin* basket in foreground includes the handle and intake to the manifold fluid sampler at left and the SUAVE *in situ* chemical analyzer at right.

through the crust and is slowly heated and chemically modified by low-temperature reactions; a high-temperature *reaction zone* near the heat source where fluid equilibrates with hot rock; and an *upflow zone* where heated, buoyant fluids ascend rapidly to the seafloor. The location of the heat source and the permeability structure of the crust are extremely important factors in any hydrothermal system.

Very little can be said with certainty about the recharge zone. It is not known whether recharge (Fig. 3) is predominantly along near-vertical faults and fissures along the ridge axis, through inclined, ridge-parallel

faults near the ridge axis, from cross-cutting faults perpendicular to the ridge axis, or through a crack network distributed over a very broad region. It is likely that different combinations of these recharge pathways are involved in particular hydrothermal systems depending on their tectonic and volcanic history.

Convection fluids reach their maximum temperatures in the high-temperature reaction zone. In midocean ridge systems, the reaction zone is generally believed to be over a magmatic heat source near the base of the sheeted dike complex (a set of ridge-parallel volcanic dikes through which magma is delivered from the

magma source to the upper extrusive layer; Fig. 3). Once fluids penetrate close enough to the heat source, they reach temperatures of at least 300–450°C at 250–500 bar pressure, and reaction rates greatly increase. Based on (1) thermodynamic calculations applied to some hydrothermal fluid compositions and (2) relatively stable compositions in some time series studies of vent fluids, it is believed that MOR hydrothermal fluids may reach a steady-state composition or approach equilibrium with a greenschist alteration mineral assemblage. Hydrothermally altered seawater at 350–450°C and 250–500 bar pressure is quite buoyant and will rise quickly from the reaction zone near the heat source into the upflow zone.

The upflow zone is in many ways an extension of the

reaction zone up to the sea floor, because hot, buoyant fluids may continue to react with wall rocks and secondary minerals as they rapidly rise to seafloor vents. However, although the reaction zone is characterized by heating to maximum temperature and extensive water–rock exchange, the upflow zone is characterized by cooling and mineral precipitation. The rising fluids cool in the upflow zone by adiabatic decompression, conductive heat loss, and mixing with cooler fluids surrounding the upflow conduits. The residence time of hydrothermal fluid in the reaction zone (at temperatures >150°C) is poorly constrained and is estimated to be of the order of 2 yr or less based on radium isotopes measured in hot fluids. Based on the observed exit velocities of hot

vents and on recent time series measurements, the residence time of fluids in the upflow zone must be of the order of days. In a well-established hydrothermal plumbing system, the upflow zone should be thoroughly altered and the conduits lined with secondary minerals, so that passage of the hot fluid should have relatively little effect on the fluid composition. The primary imprint of high-temperature water–rock reaction is established at the base of the upflow zone.

### III. CHEMISTRY IN THE THREE ZONES OF A HYDROTHERMAL SYSTEM

The three zones of hydrothermal systems on the mid-ocean ridge can each be characterized by a set of dominant chemical reactions. In the recharge zone, the exact nature of fluids remains unknown because they have not been sampled. The general picture of recharge zone fluids is based on thermodynamic calculations, studies of oceanic rocks altered at low temperature, and experimental water–rock reaction studies at low temperature. Seawater in contact with basalt at low temperatures (0–

100°C) gradually becomes more reduced, losing first oxygen, then nitrate and sulfate. Magnesium, which makes up about 10% of the cations in seawater on a molar basis, is removed from seawater into secondary minerals. This process of magnesium metasomatism generates acid that promotes further attack on the basalt, releasing calcium, iron, and other cations into the hydrothermal fluid. At temperatures below about 50°C, boron and alkali metal ions (K, Li, Rb, and Cs) are taken up from the fluid into the rock, but as temperatures increase, the reactions reverse and the rocks become a source of these elements to the hydrothermal solutions. The net effect of recharge zone reactions on the fluid depends primarily on the residence time and the rate of temperature increase.

Direct sampling of crustal fluids in a MOR recharge zone is a difficult proposition and has not been done. However, fluid samples have been recovered recently on the sediment-covered east flank of the Juan de Fuca ridge from natural warm springs on “Baby Bare,” a basaltic outcrop, and from a man-made Ocean Drilling Program (ODP) hole penetrating a 60–70°C fluid reservoir in the basaltic crust beneath 250 m of sediment. These off-axis fluids are important for two reasons: (1) They provide a direct measure of fluid compositions

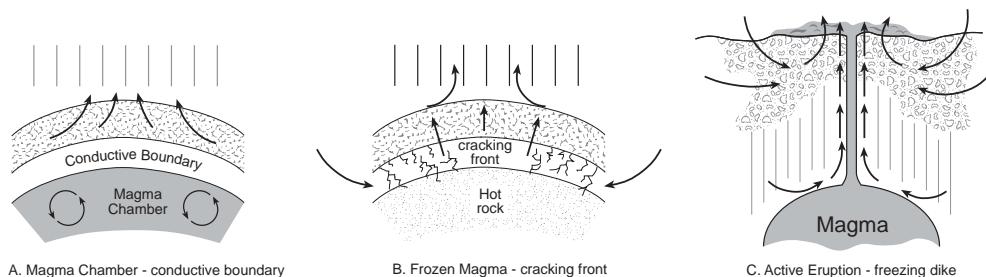

**FIGURE 3** Cutaway view of essential structure of midocean ridge hydrothermal systems. This idealized structure is derived from drilling and seismic studies of the ocean crust and from studies of ophiolites. The uppermost layer of extrusive volcanics is the most permeable and has a thickness from several hundred meters to over a kilometer. The extrusive layer transitions into sheeted dikes, which are the feeder system between the magma source and upper extrusives. Below the sheeted dikes are gabbros, which have crystallized out of the magma source percolating up from the mantle. Arrows denote flow of hydrothermal seawater, with the dashed arrows denoting flow along the ridge axis behind the cutaway plane of the figure.

from off-axis hydrothermal venting, where approximately 80% of the total hydrothermal heat flux to the deep ocean occurs, and (2) they are an analogue for recharge zone fluids on the MOR axis because they are the result of prolonged, low-temperature reaction of seawater with basaltic crust.

The fluids venting at Baby Bare seamount and the fluids recovered from nearby ODP Hole 1026B reveal a great deal about conditions in relatively warm basaltic ocean crust and generally confirm the theoretical and experimental predictions. More than 90% of the seawater Mg has been removed from solution, confirming that Mg uptake by hydrothermal circulation on ridge flanks is important and has a major impact on the balance of Mg in the oceans. Alkalies are depleted, as inferred from altered basalts. The fluid redox state is still dominated by seawater: Significant seawater sulfate is present, and hydrogen sulfide concentrations are very low (less than 0.5 micromol/kg). Metal concentrations are generally limited by oxide or oxyhydroxide solubility rather than by sulfide mineral solubility. Total CO<sub>2</sub> and alkalinity are lower than in seawater, indicating that precipitation of calcium carbonate has taken place. The general character of the off-axis fluids, an analogue for recharge zone fluids, is in agreement with thermodynamic predictions and inferences from studies of altered basalts.

As fluids move through the transition from the recharge zone to the reaction zone, they pass through an important temperature horizon of ~150°C, above which anhydrite (CaSO<sub>4</sub>) becomes saturated and precipitates from solution. As sulfate is the second most abundant anion in seawater, this has a major impact on the fluid chemistry and can produce substantial volumes of anhydrite in pore spaces. The sulfur isotope signature of hydrogen sulfide in hot vent fluids requires contributions both from basaltic sulfur and from reduced seawater sulfate, and there is evidence that anhydrite may be present in some high-temperature reaction zones.

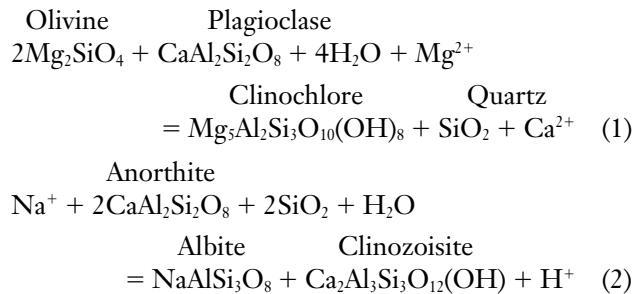

By the time fluids reach the high-temperature reac-

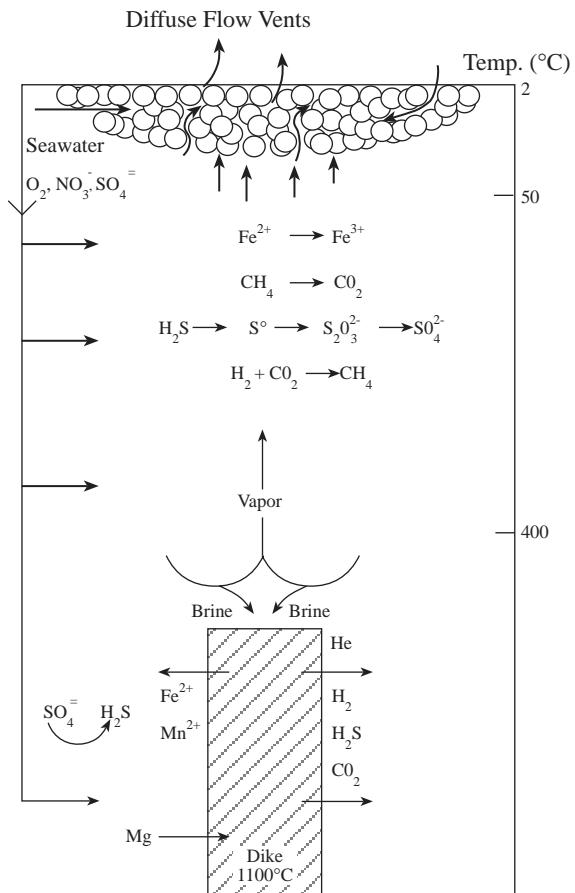

**FIGURE 4** Hydrothermal heat transfer and reaction zones. Arrows denote flow of hydrothermal fluids. (A) Fluids circulate below the base of the sheeted dike section, extracting heat through a relatively thin conductive boundary layer over a convecting magma chamber. In this case the reaction zone remains relatively stationary as long as there is a strong supply of magma. (B) Circulating fluids mine heat from a solidified magma body by advancing downward along a cracking front, continuously exposing fresh rock in the reaction zone. (C) Flow of fluids around a dike and over and through erupted lavas during an active seafloor eruption. Putting the heat source at the seafloor and within highly permeable volcanics may result in rapid extraction of heat and formation of "event plumes" in the overlying water column.

tion zone, most of their Mg has been taken up into secondary minerals, and what remains is quickly removed as Mg metasomatism accelerates with increasing temperature. As temperatures approach 400°C, the solubility of many species that are trace elements in seawater greatly increases. Many transition metals are extracted from basalt and increase in concentration over their seawater concentration by 3 to 7 orders of magnitude. Dissolved silica reaches concentrations at or near quartz saturation (~15 to 25 mmol/kg depending on temperature, pressure, and salinity). Hydrogen sulfide reaches millimolar levels as metal sulfides are leached from the host rock and as seawater sulfate is reduced (Fig. 5). Other volatile compounds (e.g., CO<sub>2</sub> and He) are extracted from the host rock, acquired from magmatic degassing or generated from water/rock reactions (e.g., H<sub>2</sub>). The isotopic ratios of hydrogen and oxygen in water and of many of the dissolved elements in solution are changed by isotopic exchange with the ocean crust. Hydrothermal fluids emerge from the reaction zone highly altered from the original seawater composition.

In MORB-hosted hydrothermal systems, it is thought that the overall reactions governing fluid–mineral equilibrium are the alteration of primary olivine and plagioclase to form secondary plagioclase, chlorite, epidote, and quartz (i.e., a greenschist assemblage). Although greatly simplified, the process can be represented in part by these reactions:

It is thought that hydrothermal fluids approach equilibrium with a greenschist mineral assemblage in the reaction zone, and that the redox state of hot fluids is buffered near the pyrite–pyrrhotite–magnetite triple point. If the mineral assemblage and the major element composition (Cl, Na, Ca, K) of the fluid are specified, then the concentrations of other metals and hydrogen sulfide in the hydrothermal solution are determined by the major variables of the system: temperature, pressure, pH, and redox potential. A change in any one of these variables changes the position of equilibrium and can result in redistribution of chemical species in solution (i.e., shifts in acid dissociation or ionic complexation) or in precipitation or dissolution of minerals. As hot,

**FIGURE 5** Chemical and microbial processes in hydrothermal reaction and upflow zones. Hydrothermal fluid circulating around a magmatic heat source picks up volatiles and metals through outgassing and water–rock interaction. Phase separation partitions volatiles and some metals into the vapor phase, and metal-rich brines accumulate around the heat source. A thermal and redox gradient is produced as hot, reduced fluids mix with cold seawater in the upflow zone. Some important energy-yielding redox reactions are shown in the sequence in which they might occur as mixing proceeds (methanogenesis, oxidation of sulfur compounds, oxidation of methane and iron). Diffuse vent fluids on the seafloor bear the imprint of these chemical and microbially mediated reactions occurring in hotter zones below. [From Butterfield et al., 1997.]

buoyant fluids rise from the reaction zone, the extent of cooling they undergo depends upon the pathway to the seafloor (i.e., how well insulated is the pathway, and how much mixing with cold “groundwater” takes place). The result of cooling a solution saturated with respect to metal sulfide solubility is an oversaturated solution that will precipitate if the reaction kinetics are fast enough. Metal sulfide precipitation releases acid, so if

substantial cooling and precipitation take place, the resulting fluid will become more acidic, which in turn can cause dissolution of other minerals further along the flow path. For example, cooling a 400°C fluid to below 350°C results in precipitation of much of the copper as chalcopyrite and lowers the pH, and if the resulting fluid is in contact with sphalerite or other zinc sulfides, they may dissolve and greatly increase the zinc concentration in the fluid. This process of zone refining is reflected in mineral deposits and in the global data for vent fluids (Fig. 6, Table II).

The permeability structure of the upflow zone will have a major influence on the chemistry of the vented fluids, and on the potential for microbial growth and mineral precipitation below the seafloor. If hot fluids are effectively flowing up through a system of sealed pipes lined with sulfide minerals, then mineral precipitation will be limited to the relatively minor effects of adiabatic expansion and conductive cooling. Real hydrothermal systems are much more complex than this. For example, it is estimated that as little as 10% of the heat flux on the MOR axis occurs as focused, hot vents. The remaining 90% of axial heat loss is through diffuse venting, which is in large part a result of high-temperature fluids mixing with cold crustal seawater below the seafloor. This requires a high degree of mixing and cooling below the seafloor, which leads to substantial

precipitation of metal sulfides and sulfates (anhydrite, barite, etc.).

The existence of microbes and their metabolic activity in hydrothermal systems is a function of the major environmental parameters (temperature, pressure, salinity) and chemical processes in the three hydrothermal zones. Microbial metabolism in the low-temperature recharge (or off-axis) zone must be based on degradation of detrital organic matter and slow reactions between crustal rocks and seawater as the reducing power of the rocks consumes the oxidants in seawater. Aerobic iron oxidizers, followed by sulfate-, iron-, and manganese-reducing microbes (among others), are likely to be found in the recharge zone. The high-temperature reaction zone is most probably abiotic, as no known organisms can grow at temperatures of 300–450°C (and certainly not at magmatic temperatures). The upflow zone is the focus of intense thermal and chemical energy. Mixing of hot and cold fluids below the seafloor creates a thermal and chemical gradient that provides tremendous energy flow through highly porous rock, a prime habitat for microbial growth. When the electron donors in hot, reduced hydrothermal fluid ( $H_2S$ ,  $H_2$ ,  $CH_4$ ,  $Fe^{2+}$ , etc.) meet the electron acceptors in cold seawater ( $O_2$ ,  $SO_4^{2-}$ ,  $NO_3^-$ , etc.), many energy-yielding reactions occur that can be catalyzed by microbes. Many different species of microbes, both Archaea and Eubacteria, have been isolated from hydrothermal vent environments, but they represent only a small fraction of the organisms that are likely to exist there. Microbes clearly play a role in catalyzing reactions, and in so doing they effect geochemical transformations that might otherwise be kinetically impeded. For example, the reaction

proceeds very slowly even at 300–400°C in the absence of a suitable catalyst, but methanogenic microbes carry out this reaction at temperatures up to 110°C in the sub-seafloor mixing zone. Low-temperature vents sampled in several MOR sites have millimolar levels of methane, presumably due to the activity of methanogens. Seafloor sampling continues to unveil novel microbes from vent environments, and it appears likely that microbes are involved in catalyzing many geochemical transformations in portions of hydrothermal systems that are below the upper temperature limit for life.

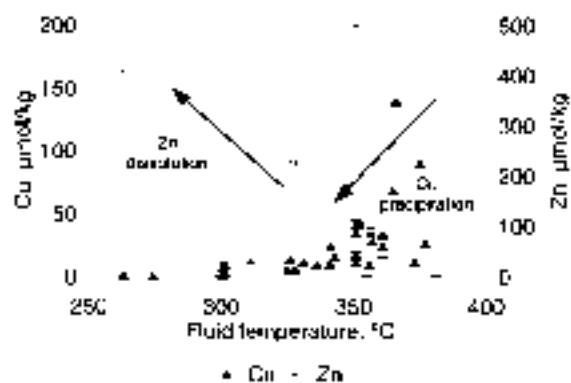

FIGURE 6 Concentration of copper (triangles) and zinc (rectangles) in hydrothermal fluids from various MOR sites as a function of vent fluid temperature. Copper and zinc have nearly the same concentration in the MORB source rock, but copper requires higher temperatures for transport in aqueous fluids. Copper concentrations fall as temperature decreases because of the temperature control on solubility. The cooling-induced precipitation produces acidity that can redissolve zinc sulfide minerals, resulting in higher zinc concentrations at lower temperatures. High Cu/Zn ratios in the hottest fluids are probably the result of dissolution of chalcopyrite linings in fluid conduits.

#### IV. ROLE OF PHASE SEPARATION

The chemical composition and the transfer of heat by hydrothermal vent fluids cannot be understood unless

one considers the important process of fluid phase separation. Hydrothermal fluids circulating through the ocean crust reach temperatures high enough (370–450°C) to separate into vapor and liquid phases at the hydrostatic pressures (200–400 bar) encountered beneath midocean ridges (Fig. 7). If fluids encounter the two-phase curve at temperatures less than the critical point (point A in Fig. 7), then normal boiling occurs and produces a low-salinity vapor phase from a bulk seawater-like liquid. As the critical point is approached, the properties of vapor and liquid phases become more and more similar and are identical at the critical point. If fluids encounter the two-phase curve at temperatures higher than the critical point (point B in Fig. 7), then a dense high-salinity brine condenses out of a bulk fluid of near seawater salinity. The vapors and brines produced by phase separation span a range of salinity from near zero for subcritical vapors to several times seawater in supercritical brines.

Phase separation produces a vapor and brine that are chemically very different from each other and from their parent fluid. Every chemical species in the fluid at the time of phase separation is distributed between vapor and liquid phases according to its physical and chemical properties. Dissolved species that are primarily ionic (e.g.,  $\text{Na}^+$ ,  $\text{Cl}^-$ ) have a very strong affinity for the liquid phase, and there is little change in the ratios of these species (e.g.,  $\text{Na}/\text{Cl}$ ,  $\text{K}/\text{Na}$ ) in the liquid phase as a

result of phase separation. Neutral species, including neutrally charged acids or bases (e.g., silicic acid, boric acid, ammonia), neutral ionic complexes (e.g., aqueous  $\text{NaCl}^0$ ), and gaseous species (e.g., carbon dioxide, methane, helium), have a stronger affinity for the vapor phase. The distribution of neutral species between liquid and vapor can be calculated from Henry's law:

$$K_H^p = \frac{f_g}{m_g}, \quad (4)$$

where  $K_H$  is the Henry's law constant at pressure  $p$ ,  $f$  is the fugacity of the volatile component  $g$ , and  $m$  is the molality of the volatile component in the liquid phase.

The net result when phase separation occurs and the liquid and vapor phases become physically segregated, is the creation of low-chlorinity, vapor-dominated fluids enriched in gases, and residual liquids depleted in gases. (Chlorinity is essentially a measure of the chloride concentration in a fluid and is used in preference to salinity for fluids where chloride is the only major anion in solution.) Subcritical boiling produces residual liquids that are only marginally above seawater chlorinity. Supercritical phase separation is required to produce high-chlorinity, brine-dominated fluids depleted in gases. If phase separation did not occur in submarine hydrothermal systems, then all vent fluids would have chloride concentrations within about 10% of the seawater concentration, because chloride has no major source within the oceanic crust, and chloride-bearing minerals are not a major hydrothermal alteration phase. In fact, the chlorinity of vent fluids ranges from less than 10% of that of seawater to more than twice that of seawater (Fig. 8a). All of the major cations are strongly correlated with chloride (Fig. 8b) because they all partition heavily into the liquid or brine phase. Gases are more enriched in the vapor-dominated phase (Fig. 8c). Thus, phase separation has a first-order effect on the chemistry of hydrothermal fluids, and this must be taken into account before other second-order effects (such as depth of reaction zone or minor differences in rock composition) can be discerned.

The range of fluid chlorinities at seafloor vents is much smaller than the range of chlorinities that can be produced by phase separation in hydrothermal systems. The maximum chlorinity observed in any MOR vent fluids sampled to date is slightly more than twice the chlorinity of seawater (Fig. 8a). A brine produced by condensation from seawater-derived fluid at 450°C would have a salinity five times greater than that of seawater. Brines produced by exsolution of an aqueous phase from a magma at temperatures in excess of 700°C have salinities more than 10 times that of seawater. The

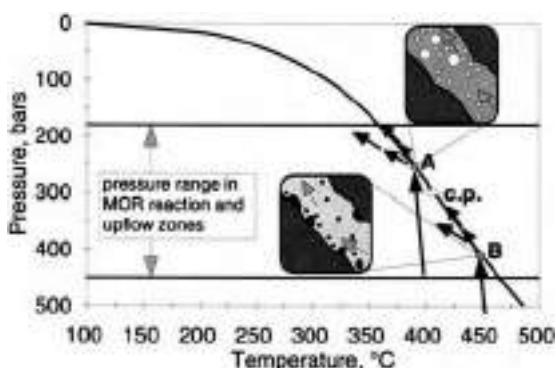

FIGURE 7 Two-phase boundary for seawater. The oval marked c.p. is the critical point for seawater. Solid black arrows denote adiabatic fluid flow. Arrows with stippled heads denote fluid flow with heat loss. Inset figures attached to A and B illustrate flow of two-phase fluids through a hydrothermal conduit. If fluids ascending from a deep reaction zone cross the two-phase curve at label B, temperature and pressure higher than the critical point, the result is condensation of dense brine (dark drops in inset B) from a vaporlike liquid. If the fluid crosses the two-phase curve at label A, below the critical temperature, the result is formation of vapor bubbles (light circles in inset A).

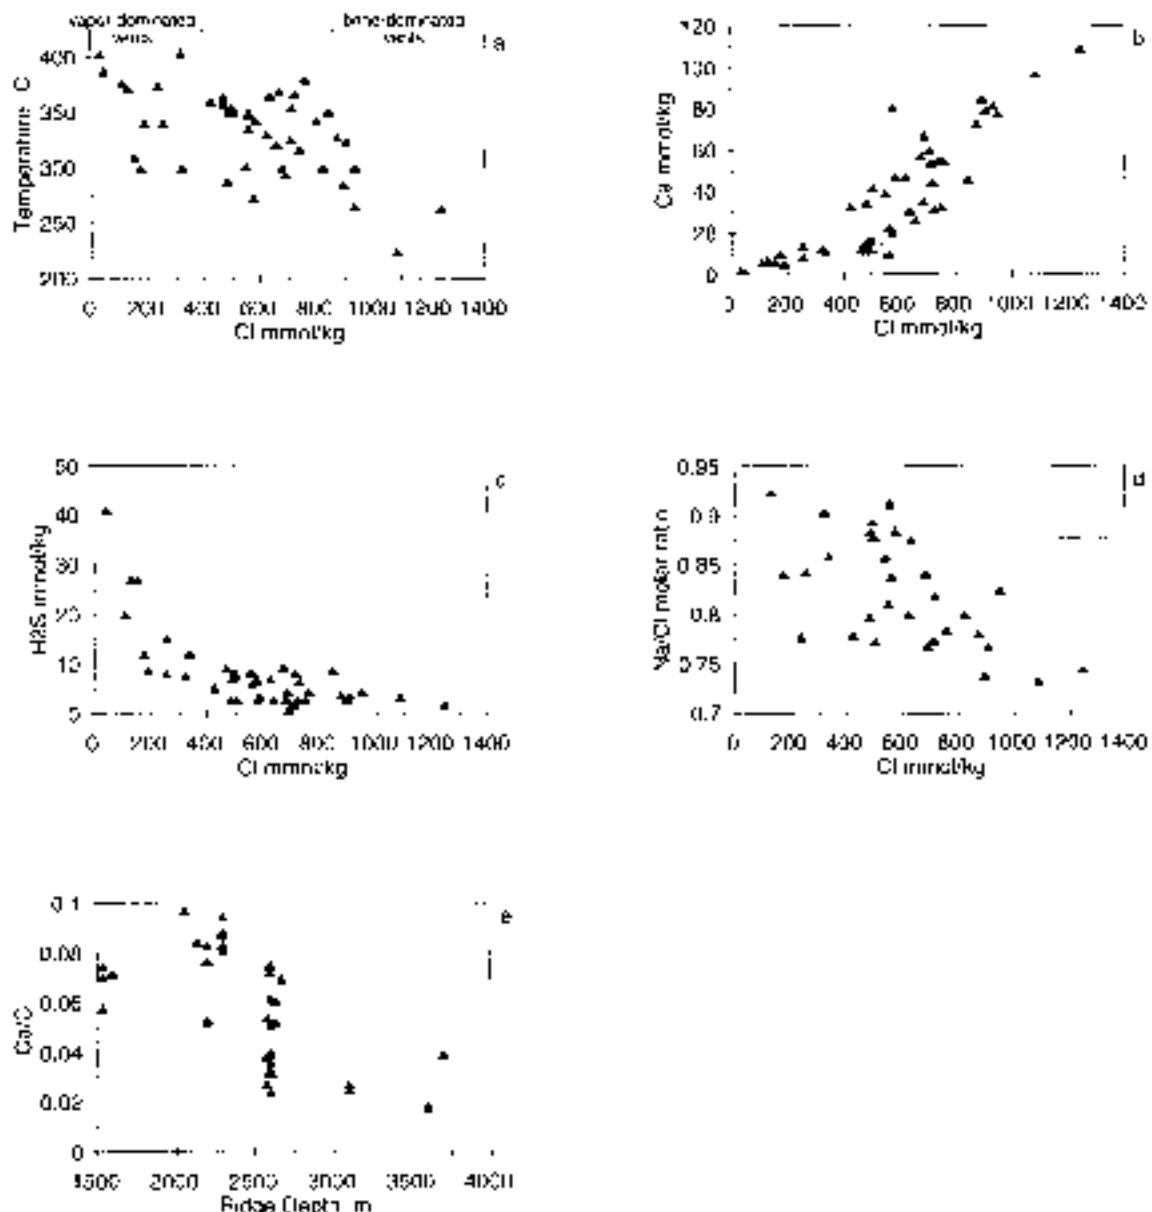

FIGURE 8 Vent fluid properties reflecting sub-seafloor processes. (a) Concentration of chloride in vent fluids as a function of measured vent fluid temperature. Vapor dominated fluids are found only in the hottest systems where active phase separation (boiling) takes place. (b) Calcium vs chloride concentration in fluids from MOR vents. All major cations have a strong positive correlation with chloride because of partitioning during phase separation. (c) Hydrogen sulfide concentration vs chloride in fluids from MOR vents. Volatile components in MOR fluids are highest in low-chloride vent fluids. (d) Na/Cl ratio vs chloride concentration in MOR vent fluids. Na uptake by minerals is most pronounced in brine-dominated fluids, probably because of longer residence times and the effect of chloride complexing on the activity of  $\text{Na}^+$  and  $\text{Ca}^{2+}$ . (e) Ca/Cl ratio in MOR vent fluids vs seafloor depth. The trend of decreasing Ca/Cl ratio with ridge depth may be due to the effect of increasing reaction zone pressure on fluid-mineral reactions involving calcium.

full range of fluid salinities and temperatures is recorded in fluid inclusions trapped over a range of depths within the ocean crust, with the highest salinities and temperatures found in the deepest plutonic rocks. Although high-salinity brines definitely occur within the oceanic crust, they either are too dense to ascend to the seafloor or are highly diluted by circulating seawater-derived hydrothermal fluids prior to venting at the seafloor.

If a fluid has approached equilibrium with a mineral assemblage before phase separation occurs, then the resulting brine and vapor phases produced will almost certainly be moved away from that equilibrium. If there is sufficient time, the fluids produced by phase separation will reequilibrate through water–rock reactions. Vapor-dominated fluids are more buoyant than their parent fluid or the conjugate brines, so we expect them to have a shorter residence time, and less time to react with the surrounding rock. If that is the case, then their cation ratios should not depart significantly from the ratios of near-seawater chlorinity fluids that have not undergone phase separation and segregation. Denser, high-chlorinity brines, however, may reside longer in the crust and have sufficient time to approach a new equilibrium. For this reason, their cation ratios may depart from those of fluids with chlorinity near or below that of seawater.

It is possible to see second-order effects in the existing global hydrothermal fluid chemistry data. A simple way to see through the effects of phase separation on fluid chemistry is to compare the ratios of selected elements to chloride. For major ions, these ratios are not changed substantially by vapor–brine partitioning, so differences are due to other processes. For example, the Na/Cl ratio of vent fluids varies around the seawater value, and high-chlorinity fluids have the lowest Na/Cl ratios (Fig. 8d), as well as the highest Ca/Cl ratios. The conclusion is that reactions that remove sodium from solution (e.g., albitionization) have progressed farther in the brines, which may be due to the higher chloride concentration favoring exchange of Na for Ca in the rock, combined with a longer residence (reaction) time. Another second-order effect suggested by the global MOR vent fluid data is the correlation of Ca/Cl ratio with ridge depth (Fig. 8e). Although there is considerable range in Ca/Cl at any depth, there is a clear trend to lower Ca/Cl at deeper sites. Because the thermodynamic driving force is toward increasing Ca fixation at higher pressure and temperature, the global trend in vent fluid Ca/Cl may be due to deeper reaction zones at deeper ridges, although the details of the rock composition at each site may also play a role. An example of how variations in MORB composition can have a subtle effect on the

major element composition of vent fluids is seen at the Endeavour segment of the Juan de Fuca Ridge. The K content of Endeavour basalts is nearly three times higher than that of average MORB from the rest of the Juan de Fuca ridge, and likewise the K/Cl ratio of fluids from Endeavour ( $0.057 \pm 0.003$ ) is significantly higher than for the rest of the Juan de Fuca ridge ( $0.047 \pm 0.003$ ) and other MORB-hosted sites. As databases for hydrothermal fluid chemistry and host rock petrology are compared and analyzed, it is expected that more relationships between the two will become apparent. This, in turn, will allow the effects of other geological parameters (e.g., spreading rate, ridge depth) to be better understood so that models of global hydrothermal fluxes over time can be developed.

---

## V. HYDROTHERMAL CHEMISTRY OF SEAMOUNTS AND NON-MORB ENVIRONMENTS

Seamounts located on divergent plate boundaries or at intraplate hotspots are characterized by high magma supply to shallow crustal depths. The most striking effect on the fluid chemistry in this environment is due to magmatic degassing of carbon dioxide. The CO<sub>2</sub> content of stable MOR hydrothermal fluids ranges from near-seawater levels (~2 mmol/kg) up to about 25 mmol/kg. The CO<sub>2</sub> content (Table II) exceeds 250 mmol/kg at Axial Volcano on the Juan de Fuca ridge and the intraplate Loihi seamount, both basaltic volcanoes. The helium content of these fluids is also a factor of 10 higher than that of typical MOR fluids. The decompression associated with transporting basaltic magma higher up into the crust at seamounts clearly results in significant transfer of gases from the magma to hydrothermal fluids. In vapor-dominated fluids at Axial Volcano, where active boiling occurs in the upflow zone, the concentration of carbon dioxide exceeds the concentration of chloride, making it the most abundant species in the fluid. Although Axial Volcano fluids have exceptionally high volatile content and a wide range of chlorinity, the ratios of major elements to chloride are typical of other MORB-hosted vents of similar temperature. Input of high levels of carbon dioxide from magmatic degassing in this case has little effect on the primary fluid characteristics; high-temperature reactions similar to other MOR environments govern the bulk fluid major element composition. At Loihi seamount and at Teahitia seamount, however, the fluid tem-

pertures are much lower, and the high levels of magmatic carbon dioxide and sulfur dioxide appear to provide acidity that drives the dissolution of basalt glass at low temperatures within the volcanic edifice. The result is warm fluid of relatively low pH with high levels of iron and other metals.

A small percentage of the global seafloor volcanic spreading centers are covered with sediment due to their position near continental runoff sources (e.g., Middle Valley, Escanaba Trough, Guaymas Basin—Fig. 1, Table I). The presence of sediment cover has a striking impact on the chemistry of hydrothermal fluids. Relative to sediment-starved MOR vent fluids (Table II), they are generally depleted in ore-forming metals and enriched in boron, ammonia, bromide, iodide, alkalis, and organic-derived hydrocarbons, and have higher pH and alkalinity. However, the effects of sediment cover vary considerably because there is such a large range in sediment composition in different environments (percentage and type of carbonate, organic, and terrigenous components) and in the location of the heat source (below or within the sediments) and the structure of the recharge and upflow zones.

MORB composition occupies a narrow band in the spectrum of submarine volcanic rock types. Although most of the ocean basins are of MORB composition, and most of the hydrothermal systems sampled to date are MORB-hosted, a range of more silicic rocks (basaltic andesites, andesites, rhyodacites) are common in island arc and backarc environments (e.g., Manus basin, Lau basin, North Fiji basin, Okinawa trough), and ultramafic rocks are exposed on portions of slow spreading ridges (e.g., Rainbow hydrothermal site on the MAR). Differences in rock type can lead to large differences in hydrothermal fluid composition. Because the bulk composition and primary minerals of the source rock are different, the reaction sequence and the position of equilibrium that governs the master chemical variables, pH and redox state, are changed. For example, when seawater reacts with more silicic rocks, the fluids are more enriched in K and other alkalis and less enriched in Ca than in MORB-hosted fluids. Under some conditions, uptake of Mg by minerals can be reversed, so the working assumption of near-zero Mg in high-temperature end-member hydrothermal fluid that is universally applied in MORB-hosted systems is no longer valid. Reaction of hydrothermal seawater with ultramafic rocks produces much higher levels of methane than does reaction with MORB. The incompatible and trace element concentrations vary considerably from ultramafic to acidic rocks, which can be directly reflected in the fluid trace element chemistry, especially for highly soluble

trace alkalis. Consideration of hydrothermal fluxes and how they affect the chemistry of the oceans must include the full range of submarine environments.

Because of the subduction of hydrated ocean crust beneath volcanic arcs and the potential involvement of a wider range of magma sources, the volatile content ( $H_2O$ ,  $CO_2$ , and  $SO_2$ ) of magmas near convergent plate boundaries can be much higher than in MORBs. In the JADE hydrothermal field at ~1500 m depth in the Okinawa trough, the flux of  $CO_2$  is so great that  $CO_2$  gas hydrates form and bubble up out of the volcanoclastic sediments. In the DESMOS caldera in the Manus backarc basin, input of magmatic  $SO_2$  to the hydrothermal system followed by disproportionation results in vent fluids with both high  $H_2S$  and sulfate concentrations higher than in seawater. There is a very wide range in both the fluid chemistry and types of mineralization in non-MORB hydrothermal systems.

---

## VI. EFFECT OF VOLCANIC ACTIVITY ON HYDROTHERMAL SYSTEMS

Submarine volcanic eruptions illustrate clearly that geological, chemical, and microbiological processes are intimately linked in hydrothermal systems. Intense physical, thermal, and chemical energy is focused near the seafloor during an eruption, significantly perturbing the preexisting flow of energy through the ocean crust. Recent research has begun to unveil the hydrothermal response to a seafloor volcanic event.

Basaltic eruptions on the midocean ridge can range from small pillow lava mounds to extensive sheet flows, depending on the eruption rate and volume. It is thought that dikes generated from axis-parallel, elongated magma chambers feed seafloor eruptions. MOR eruptions have been detected remotely from seismic t-waves traveling through the ocean sound channel, and *Alvin* submersible dives encountered the immediate aftermath of an eruption at 9° N on the East Pacific Rise in 1991, but an eruption in progress has yet to be observed and studied in real time. What is known in general about the hydrothermal response to seafloor eruptions is based on a composite of posteruption observations on the seafloor and in the overlying water column on time scales from days to years.

A submarine dike injection and eruption places a large quantity of heat suddenly in the upper, most permeable, volcanic layer of the ocean crust (Figs. 4c and 6). The immediate response is rapid heat loss at the seafloor

directly from erupted lavas to bottom seawater, and below the seafloor from the molten dike to the rock and water saturating the porous upper crust. Whether the local crust is hydrothermally active or not prior to the eruption, the dike-induced convection will flush out the "groundwater" and eject it into the deep sea to form a hydrothermal plume. Although the exact mechanism is not known, it is clear that seafloor eruptions are associated with hydrothermal "event plumes": very large quantities of heat (equivalent to a year or more of black smoker output) transported in a matter of days high up into the water column (of the order 1000 m vertical rise compared to 100–300 m for typical 350°C smoker effluent).

The properties of event plumes are different from "normal" or "steady" plumes resulting from black smoker output. The event plumes for which data is available have in common a helium-to-heat ratio near the low end of the range for smoker fluids, while the contemporaneous deeper "steady" plumes in the same locations have high helium-to-heat ratios that decay over time back toward lower values. A simple physical mechanism can account for the pattern of helium-to-heat ratios. If event plumes form during the period immediately after eruption, they are driven by heat conducted out of the dike and erupted lavas into the surrounding seawater, and because conduction of heat through rock is orders of magnitude faster than diffusion of helium, the event plumes will have low helium-to-heat ratios. As the heat transfer rates decline and event plume formation dies out, the cooling dike and lavas crack and the helium is extracted by circulating fluids, generating high helium-to-heat ratios (because the large heat loss preceded the helium extraction). As both helium and heat are exhausted from the dike, the ratio returns to the steady-state value.

There are direct seafloor observations of hydrothermal systems at eruptive sites after event plume formation is over. The observations have included extensive diffuse venting along what is believed to be the eruptive fissure or the seafloor trace of a dike injection. The initial posteruptive vent fluids are volatile-rich and vapor-dominated as the heat flux is high enough to drive active phase separation. Over a period of months to years, the heat flux declines, widespread diffuse venting contracts to more limited areas, and the chlorinity of vented fluids increases as brine dominated fluids replace vapor dominated fluids (Fig. 9). The observations require that brines accumulate below the seafloor during the high heat flux period of active phase separation and are later flushed from the system. Volcanic eruptions cause a transient perturbation in hydrothermal systems, charac-

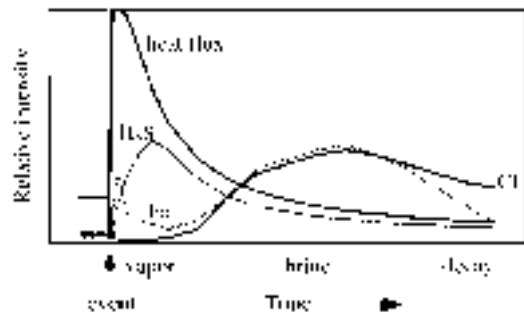

FIGURE 9 Evolution of hydrothermal heat flux and selected fluid properties (Cl, Fe, and H<sub>2</sub>S concentrations relative to initial levels) following a seafloor volcanic eruption. Initial chloride concentration is the same as in seawater. Systems evolve from vapor dominated, high heat flux stage, through a transition to brine dominated discharge, and eventually decay back toward zero heat flux and seawater composition. Both the magnitude of the heat flux and the length of the time scale depend on the size of the volcanic event. The transition from vapor to brine may take several months to a few years. [From Butterfield et al., 1997.]

terized by a cycle from low-chloride fluids during high heat flux periods to high-chloride fluids during low heat flux periods. The reaction zone moves downward from very near the seafloor during the eruption toward the base of the dike as the dike is cooled. The water/rock ratio is high during vigorous circulation through the highly permeable volcanic layer, and decreases toward normal black smoker values (~1) as the reaction zone moves into the sheeted dike layer where permeability is lower.

Just as subaerial volcanic eruptions can have devastating effects on plant and animal life, seafloor eruptions cause major disruptions in the submarine ecosystem. Observations show that lava flows have paved over existing communities of hydrothermal vent fauna. The boundary between life and death for vent animals is remarkably sharp; live tube worms have been observed within centimeters of newly erupted pillow basalts at Axial Volcano on the Juan de Fuca ridge, attesting to the very rapid quenching of seafloor lavas by ambient seawater. Time series observations indicate that recolonization of newly created hydrothermal habitat following seafloor eruptions begins within the first year.

A dramatic and rapid microbial response to the sudden increase in energy flow associated with volcanic events has been repeatedly observed. In the first weeks or months following an eruption, microbial production below the seafloor appears to bloom, resulting in the emission of fluids loaded with white, flocculent particulate material. There is some laboratory and field evidence

that this material is rich in elemental sulfur generated from sulfide-oxidizing microbes. This phenomenon has only been observed in areas affected by recent volcanic activity.

The pattern of evolving heat flow and fluid chemistry that is set up as a transient effect of individual volcanic eruptions may also be reflected in the evolution of entire vent fields or ridge segments as they experience changes in magma supply rate and tectonic stretching that control the rate of heat output over time. When volcanic and tectonic processes allow highly efficient mining of heat from the deep reaction zone, the brine generated from supercritical phase separation at depth will remain in the crust while vapor-enriched fluids transport large quantities of heat and volatiles out of the system. When the conditions evolve to lower the heat output, the brine that has accumulated begins to be flushed from the system. Along the Endeavour segment of the Juan de Fuca ridge, there are four vent fields spread over 10 km along axis. The central Main Endeavour field is the hottest (360–380°C) and most vigorous and is vapor dominated, while the two distal vent fields have much lower heat output and brinelike fluids. Further south on the Cleft segment, brine-enriched fluids have vented for more than a decade, illustrating the longevity of hydrothermal cycles and the remarkable storage capacity of the ocean crust. To truly understand the dynamics of hydrothermal systems in submarine volcanic centers will require continued exploration, real-time observations and sampling during seafloor eruptions, sub-seafloor sampling capability, accurate measurement of the heat flux from vent fields and ridge segments, and active imaging of the three-dimensional thermal and permeability structure of the ocean crust.

#### ACKNOWLEDGMENT

This article draws on the work of scientists too numerous to include in a short bibliography, but the seven book compilations cited below contain an excellent cross-section of work on hydrothermal systems. Thanks to Mark Hannington, Ian Jonasson, and an anonymous reviewer for their helpful and constructive comments on the first draft. Thanks also to Aries Galindo and Jim Anderson for graphics support. This publication was supported by the University of Washington Joint Institute for the Study of the Atmosphere and Ocean (JISAO) under NOAA Cooperative Agreement No. NA67RJ0155, contribution number 683, and by the NOAA VENTS Program, PMEL contribution number 2042.

## GLOSSARY

**caldera** Volcanic crater formed by collapse during an eruption.

**fumarole** Vent from which volcanic gases are emitted.

**geothermal system** Any regionally localized geological setting where portions of the Earth's internal heat flow are transported close enough to the Earth's surface by circulating steam or hot water to be readily harnessed for use.

**hydrothermal eruption** Explosion that follows transformation of groundwater into steam. No incandescent or juvenile material is erupted. Synonym for phreatic eruption.

**hydrothermal system** A groundwater system that has a source (or area) of recharge, a source (or area) of discharge, and a heat source. Hydrothermal systems associated with volcanoes are termed volcanic hydrothermal systems. When a magma supplies the heat source and volatiles, the hydrothermal system qualifies as a magmatic hydrothermal system.

**hydrovolcanic eruption** Eruption that results from the interaction between magma and groundwater or surface water. Synonym for phreatomagmatic eruption.

**isotope** Atoms with the same number of electrons and protons, but a different number of neutrons and therefore different masses. Most chemical elements occur in nature as two or more isotopes. The relative abundances of isotopes of a given chemical element are not constant in all natural materials. Hydrogen, carbon, oxygen and sulfur, which are prominent elements in volcanic fluids, all have stable isotopes. As opposed to radionuclides, stable isotopes do not undergo spontaneous decomposition.

**maar** Small volcano characterized by a crater that is wide (several hundreds meters to several kilometers in diameter) relative to its height and whose floor commonly lies below the general level of surrounding topography. Maar volcanoes can form during hydrovolcanic eruptions or very energetic gas eruptions.

**meteoric water** Waters of any age that originate from precipitation: rain, snow, ice, river, lake, and most low-temperature groundwaters. They are derived from ocean water through the atmospheric circulation process.

---

## I. INTRODUCTION

The Catalog of Active Volcanoes of the World (CAVW) reports that about 16% of the 714 Holocene (~10,000 years old) or younger terrestrial volcanoes contain a lake (Table I), but the exact number varies with time because of their ephemeral nature. Volcanic lakes occur all over

TABLE I Volcanic Lakes Hosted by Holocene or Younger Volcanoes<sup>a</sup>

Volcano name	Lake name	Location	Crater type	Status
<b>Europe to Caucasus</b>				
West Eifel volcanic field		Germany	Maars	
Chaine des Puys	Pavin	France	Cinder cone

the world, with a higher percentage in volcanic arcs. These lakes may look like other natural reservoirs that accumulate meteoric water from precipitation, runoff, and inflowing streams. Yet, many volcanic lakes are hot and contain large amounts of dissolved solids in their waters. In fact, a few of these lakes consist of concentrated mixtures of sulfuric and hydrochloric acids that represent the most acidic and mineralized natural waters on Earth. Some also host long-lived molten sulfur bodies, a spectacular phenomenon shared only with Io, a moon of Jupiter. Lastly, a few volcanic lakes can store large amounts of potentially lethal gas in their bottom waters.

Such distinctive characteristics reflect the influence of volcanic inputs on the lake physical and chemical conditions. These inputs consist of hot gas and liquids that ultimately result from the interactions between groundwater and fluids released by a magma body at depth. To some extent, volcanic lakes can be viewed as the uppermost manifestation of a hydrothermal reservoir between the surface and an underlying magma. As such, they constitute unique windows for better understanding the processes that dictate how ascending magmatic fluids are transported toward the surface and react with their surrounding environment within the volcanic edifice. By studying volcanic lakes, scientists have ac-

quired a general knowledge of the physical and chemical signatures of eruptible magma and of the thermal and/or chemical changes that may precede an eruption. Some researchers aim to use volcanic lakes to provide insight into the magnitude of terrestrial degassing; others consider volcanic lakes as the shallow part of ore-depositing magmatic/hydrothermal systems. Volcanologists also study volcanic lakes because of their highly hazardous nature. Once released, the large volumes of water that they hold may generate devastating debris flows (lahars) and floods. Since 1500 A.D., debris flows from crater lakes have killed many people (Table II). Another danger is related to the sudden escape of carbon dioxide ( $\text{CO}_2$ ) from gas-rich lakes. Such an event occurred twice in Cameroon in the mid-1980s, killing nearly 1800 people.

Historically, visual accounts of volcanic lakes go back to the Spanish conquest era. Dutch, Japanese, and Russian geologists reported the first water analyses of a few crater lakes early in this century. After the Second World War, comprehensive research on volcanic lakes was begun. Rapid progress was accomplished where the proximity of a volcano observatory allows for repeated sampling of the lake. The lake of Mt. Ruapehu volcano (New Zealand), Yugama Lake at Kusatsu-Shirane volcano (Japan), and Laguna Caliente at Poás volcano (Costa Rica) are the best examples for which long-term

TABLE II Hazards at Volcanic Lakes since 1500 A.D. Associated with More Than 100 Fatalities

Volcano lake	Country	Year	Hazard type	Deaths	Damage to constructions
Agua	Guatemala	1541	Debris flows	?	Former capital destroyed
Kelut	Indonesia	1586	Debris flows	10,000?	
Raung	Indonesia	1638	Debris flows	>1,000	
Awu	Indonesia	1711	Debris flows	3,200

Kelut	Indonesia	1966	Debris flows	282	12,000 hectares of land destroyed
Nyos	Cameroon	1986	Gas burst	1,746	Almost no damage

studies are available. The presence of a lake in a crater during or immediately after an eruption also has drawn the attention of volcanologists, for example at Soufrière volcano, St. Vincent, in 1971–1972 and El Chichón in 1982. In 1984 and 1986, the unforeseen gas bursts of Lake Monoun and Lake Nyos in Cameroon put volcanic lakes into the spotlight among the scientific community.

In this chapter, we explain the principal processes occurring in volcanic lakes and show how these can be linked with the monitoring and mitigation of their hazards. We also devote a short section to the mineralization associated with some volcanic lakes. Lakes on top of active craters have received most attention from volcanologists. However, we shall see that lakes in dormant craters also feature striking characteristics, among which gas accumulation is of particular importance.

## II. PROCESSES IN VOLCANIC LAKES

Volcanic lakes on Earth do not display the same physical, chemical, and biological conditions. Physical and chemical differences reflect the complex interplay of volcanic and nonvolcanic phenomena. The volcanic phenomena relate to the nature and amount of volcanic–hydrothermal fluids entering the lake as well as to the crater morphology and permeability, whereas the nonvolcanic phenomena depend primarily on atmospheric conditions (e.g., precipitation). Volcanologists collect and analyze a wide variety of geophysical and geochemical data to understand how volcanic lakes work. These data are also used to constraint box models that quantify heat, water, and chemical fluxes into and out of volcanic lakes.

### A. Physical, Chemical, and Biological Variability

#### 1. Volcanic Setting

Volcanic lakes occur chiefly along continental margins (e.g., Central America) or island arcs (e.g., Indonesia), but some also sit astride the Mid-Atlantic Ridge (e.g., Iceland). They lie in craters formed by hydrothermal, hydrovolcanic, or magmatic eruptions and more rarely occupy valleys blocked by lava or debris flows. Lakes in hydrothermal depressions are usually small (e.g., Oyunuma), those in maar craters ordinarily are bigger and deeper (e.g., Nyos), and those on top of degassing active craters typically have intermediate dimensions. The

most voluminous systems fill vast calderas. Volcanic lakes occasionally form unusual settings. For example, three adjacent lakes occupy the summit craters of Kelut volcano in Indonesia. At Taal, a renowned volcano in the Philippines, a large caldera lake hosts a volcanic island that also contains a comparatively smaller crater lake. Buried under the 250-m thick ice shelf of Vatnajökull glacier is the warm lake of Grimsvötn, the most active volcano in Iceland.

#### 2. Water Composition

Volcanic lakes display a wide range of water compositions. The data reported in Table III illustrate this diversity. There are systems with neutral pH ( $\sim 7$ ), dilute (total dissolved solids or TDS  $< 100$  mg/kg) waters (e.g., Crater Lake at Mt. Mazama, United States) or, conversely, with highly acidic ( $\text{pH} < 1$ ) and strongly mineralized (TDS  $> 100,000$  mg/kg) waters (e.g., Kawah Ijen, Indonesia). In between, many volcanic lakes such as Kelut in Indonesia, Oyunuma in Japan, and Lake Nyos in Cameroon have intermediate acidity ( $\text{pH} \sim 2\text{--}6$ ) and lower TDS ( $< 2000$  mg/kg). In addition to these differences in acidity and mineralization, volcanic lakes also can differ from each other by the type of dissolved chemical constituent(s) that they contain. For example, the lake of Kelut is sodium- and chloride-rich, that of Oyunuma is chloride- and sulfate-rich, and that of Nyos is carbon dioxide-rich (Table III). Lastly, volcanic lakes can be chemically well mixed to their bases (e.g., Kawah Ijen) or stratified (e.g., Nyos).

Unlike other terrestrial water reservoirs, the chemical composition of a volcanic lake may be altered with no apparent relation to seasonal variations. This may happen when the host volcano changes its activity suddenly. A good illustration of this was observed at Karimsky volcano, Russia. Following the 1995 eruption from a nearby cone, the initially dilute neutral caldera lake rapidly acquired acidic pH ( $\sim 3$ ) and high TDS ( $\sim 800$  mg/kg) values. In other cases, the chemical evolution of a volcanic lake is more progressive. Posteruption monitoring of El Chichón's crater lake indicates gradual decrease in acidity and dissolved solids concentrations, suggesting inputs of more dilute volcanic fluids or reduction of their fluxes.

#### 3. Thermal Regime

Approximately 40 lakes are reportedly hot with temperatures above that of the ambient air. The majority of these lakes are perched atop degassing summit craters, whereas some fill hydrothermal depressions in geothermal areas. Interestingly, only a few systems sustain tem-

peratures above ~45–50°C for prolonged periods of time (e.g., Kawah Ijen). Hot lakes are thermally homogeneous, whereas cool lakes may be stratified (e.g., Oyuna, Nyos).

#### 4. Color

Volcanic lakes display a variety of colors. Crater Lake in Oregon is a splendid blue water body, Kawah Ijen is turquoise-green, Maly Semiachik, Russia, is whitish-blue, and Oyunuma is black (Fig. 1). Surface coloring

of a lake may also fluctuate temporarily, as shown at Keli Mutu, where one of the lakes sometime switches from dark green to blood red at the onset of the wet season. Hue changes at Ruapehu and Poás appear to be associated with increasing subsurface volcanic activity.

#### 5. Biotic Diversity

Algae, diatoms, fungi, and bacteria are the only organisms that may survive under moderately to highly acidic conditions. Diatoms may partly control silica geochem-

FIGURE 1 (Top) Photograph of Kawah Ijen volcanic lake (Indonesia, June 1995). Note variations in lake shading, steaming from the lake surface, and the light streaks of sulfur slicks toward the center of the lake. (From Oppenheimer, 1997, Taylor & Francis.) istry in acidic volcanic lakes with pH as low as  $\sim 1.5$  (e.g., Katanuma, Japan). Recently, Japanese scientists confirmed that sulfur-oxidizing bacteria (*Thiobacillus thiooxidans*) participate in the sulfur cycle in Yugama Lake and Maly Semiachik, two strongly acidic crater lakes ( $\text{pH} < 1.5$ ). The discovery of organic markers such as branched alkanoic acids in Yugama Lake suggests that other unidentified bacteria also may grow in these harsh environments.

## B. Volcanic Lakes on Top of Active Craters

### 1. Calorimeters and Condensers for Volcanic Heat and Fluids

Assuming that persistent volcanic lakes represent the surface expression of a hydrothermal system that transports heat, water, and chemical constituents upward from a cooling and degassing magma body situated at depth, one can estimate these fluxes by heat and mass balance analysis. To do this, volcanologists use a “box model” to equate volume and temperature changes in a crater lake with fluxes of water and heat into and out of the lake. Inputs of water to the lake consists of volcanic–hydrothermal fluids (i.e., steam plus ascending brines) and meteoric water (i.e., precipitation, runoff, streamflow, and groundwater seepage). Outputs are due to evaporation, lake water seepage, and overflow. Heat is derived from the enthalpy of the hot fluids entering the lake and from solar and atmospheric radiation; it is lost by evaporative and radiative fluxes from the lake surface, by seepage and overflow, and by heating precipitation and runoff into the lake. Evaporation is the most important energy sink, and its magnitude depends primarily on the wind velocity and on the difference between the lake surface temperature and that of the ambient air temperature. Figure 2 illustrates the influxes and outfluxes used in the box model, and Table IV summarizes results obtained by applying this method to different volcanic lakes.

The box model has been used to infer the main dynamic processes that dictate the existence and physical properties of volcanic lakes. The authors concluded that the ratio between volcanic heat input and heat dissipation of a lake determines the persistence and the temperature of a lake in a crater. Since most heat loss occurs at the lake surface through evaporation, small lakes have only a small capacity for heat dissipation and their temperature rises quickly with small heat inputs; large lakes are better buffered against variations in heat input. The flux of meteoric water into a lake is also an important

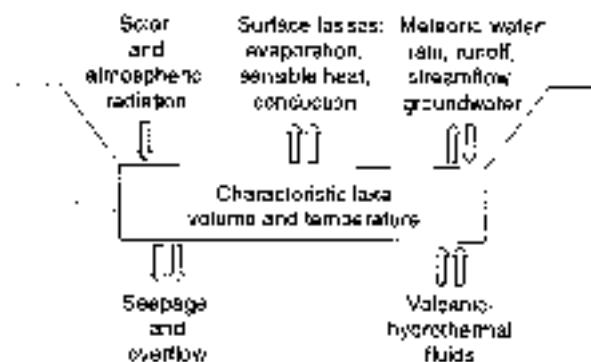

FIGURE 2. Cartoon showing fluxes of water (white arrows) and heat (shaded arrows) into and out of a volcanic lake as used in the “box model.”

parameter in the lake’s heat and mass budget, and this depends on the surface area. On a local scale, each lake size will have a limiting gas input for a given rainfall and an upper temperature limit at which it starts to lose mass. Calculations suggest that steady-state lakes have temperatures less than  $45^{\circ}\text{C}$ . Field observations confirm this deduction.

Knowledge of magmatic heat and volatile fluxes serves in monitoring programs, as well as to help assess the volcanic contributions to the atmospheric budget of carbon, sulfur, chlorine, and fluorine. Using time-series data on the level (i.e., lake volume) and temperature of lakes along with the box model, we have been able to deduce release rates of magmatic heat and volatiles (in particular sulfur) during passive degassing of magmas underlying volcanic lakes. The incentive is that these calculations provide long-term estimates, whereas most other estimates for volcanoes that degas freely into the atmosphere rely on short-term measurements that are extrapolated to longer time scales. Degassing volcanoes that host hot lakes typically deliver heat outputs ranging from  $\sim 20$  to  $1000$  megawatts ( $10^6 \text{ W}$ ) and sulfur fluxes ranging from  $\sim 50$  to  $400$  tons per day, comparable to estimates for other volcanoes that do not contain a lake. Researchers have noticed that some crater lakes may retain significant amounts of native sulfur, as part of the volcanic sulfur input is precipitated in the lake or just below.

By analogy with shallow geothermal systems, and using results from the box model, volcanologists have proposed a model for transferring heat and water from a degassing magma to a lake above it (Fig. 3). Below the lake, a two-phase vapor–liquid zone is formed as high temperature magmatic gases condense into groundwater. Heat pipes or vapor–liquid counterflows may play

an important role during heat transfer in the two-phase zone. Beyond this zone is a comparatively cool liquid envelope. The hot gas–water mixture is injected into the lake as a buoyant jet that powers wholesale convection of the water column, thus allowing for both thermal and chemical homogeneity. Seepage of the lake water through the crater floor and recirculation within the subsurface gas condensation zone probably complicate this picture and can be important components of the lake's hydrologic budget.

## 2. Chemical and Isotopic Characteristics

Escape of steam and other gases from a shallow magma can provide the raw material for the chemistry of volcanic lakes on top of degassing craters. Absorption of ascending magmatic vapors containing the acidic gases sulfur dioxide ( $\text{SO}_2$ ), hydrochloric acid (HCl), and minor hydrofluoric acid (HF) into the hydrothermal vapor–liquid zone beneath the crater produces low-pH solutions that subsequently discharge into the lake.  $\text{SO}_2$  reacts with water ( $\text{H}_2\text{O}$ ) to form sulfuric acid ( $\text{H}_2\text{SO}_4$ ) plus native sulfur ( $\text{S}^\circ$ ),

or  $\text{H}_2\text{SO}_4$  plus hydrogen sulfide ( $\text{H}_2\text{S}$ ),

Both reactions refer to the disproportionation of  $\text{SO}_2$  and can be simultaneous. The acidity of the waters originates principally from proton ( $\text{H}^+$ ) release due to the dissociation of HCl and  $\text{H}_2\text{SO}_4$  at temperatures below  $\sim 300^\circ\text{C}$ . The resulting sulfate- and chloride-rich waters acquire low pHs and are capable of completely dissolving silicate rock. Although this reaction consumes protons (therefore reducing water acidity), it may be a non-buffered, simple rock-dissolution process, because condensation of magmatic acidic gases continuously replenishes the system with  $\text{H}^+$ . As a result, the low-pH hydrothermal fluids that reach the lake also become enriched in chemical components (e.g., silica, aluminum, iron, magnesium, sodium) leached from the rock. In the lake, dilution by meteoric inputs and evaporation somewhat alter the composition of these hydrothermal fluids. However, the lake may retain very low pH values that prevent precipitation of secondary minerals. Only silica (cristobalite or opal) and occasionally gypsum tend to precipitate in these volcanic lakes. Kawah Ijen and Poás are good examples of lakes containing waters formed by these processes (Table III).

<sup>a</sup> Modified from Pasternack and Varekamp (1997).

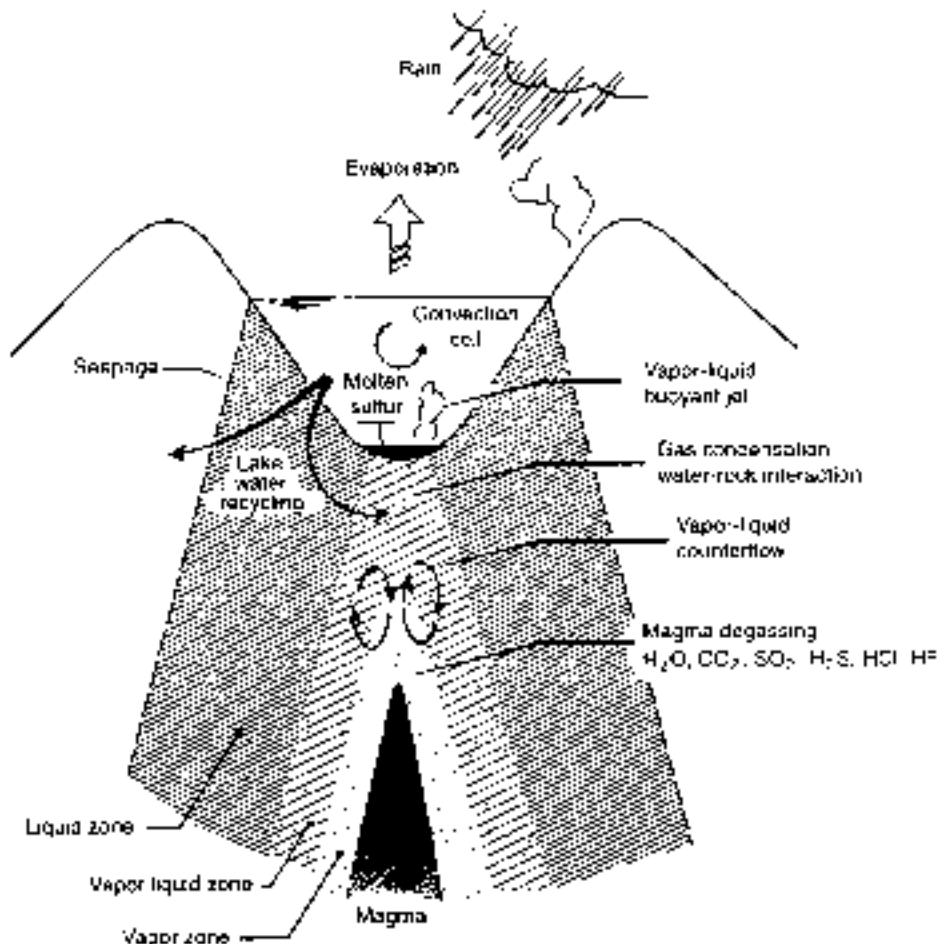

FIGURE 3 Illustration showing processes that may occur in and below hot acidic volcanic lakes on top of active degassing craters.

The occurrence of carbon dioxide ( $CO_2$ ) in hot acidic crater lakes remains puzzling. Like other magmatic volatiles, this gas should be released into the subsurface acidic two-phase hydrothermal zone connected to the lake. Owing to its very low solubility in hot, low-pH solutions,  $CO_2$  gas bubbles should rise through the lake-hydrothermal system and escape at the lake surface. However, we generally do not see  $CO_2$  bubbling at the surface of hot acidic lakes. This could indicate that  $CO_2$  leaves the hot, acidic hydrothermal vapor-liquid zone at depth and dissolves into the comparatively less acidic, cooler liquid envelope that surrounds it. This process would eventually lead to the formation of the carbonate-rich springs typically found at lower elevations on the volcano's flanks.

In contrast to the highly acidic and mineralized lakes found in degassing craters, there are also lakes that exhibit dilute to intermediate water compositions although hosted by active volcanoes that recently erupted fresh

magma. This situation occurs at Kelut volcano, where the lake has near-neutral pH values (~5.5–6.5) and moderate dissolved solids concentrations (TDS ~ 3400 mg/kg) (Table III). Yet, heat and mass budget calculations as well as geochemical data clearly show that Kelut's hot crater lake is fed mostly by magmatic-hydrothermal inputs. The case of Galunggung in Indonesia, the last violent explosion of which occurred only in 1982, is similar; local inhabitants catch fish in the cool lake that fills the summit crater. The waters are neutral (pH ~ 7) but show an anomaly in dissolved sulfate (Table III). These examples reveal that the structure of the magmatic-hydrothermal system below the lake is likely to play an important role in controlling the ability of hot, acidic fluids to reach the summit crater lake. In this respect, the host edifice's hydrology and permeability may be key characteristics.

Together with chemical data, stable isotopes are used by geochemists to assess the volcanic and nonvolcanic

contributions to a crater lake. Volcanic lake waters that receive inputs of hot magma–hydrothermal fluids from below may be significantly enriched in “heavy” isotopes such as deuterium (D) and oxygen-18 ( $^{18}\text{O}$ ) with respect to local meteoric water. This results from the combined effects of hydrothermal condensation of hot magmatic steam, with characteristic high D and  $^{18}\text{O}$  contents, and continuous evaporation from the lake surface; evaporation fractionates the heavy isotopes into the liquid phase. In addition, enrichment in  $^{18}\text{O}$  may also partly be due to high-temperature water–rock interactions in the magmatic hydrothermal system beneath the lake.

In a similar fashion, the sulfur isotopic ratios in a volcanic lake may be indicative of the origin and formation process of its sulfur compounds (i.e.,  $\text{SO}_4$ ,  $\text{H}_2\text{S}$  and/or  $\text{S}^\circ$ ). For example, a large fractionation of the heavy sulfur isotope ( $^{34}\text{S}$ ) into  $\text{H}_2\text{SO}_4$  typically accompanies the  $\text{SO}_2$  disproportionation reaction [Eqs. (1) and (2)]. Accordingly, the isotopic difference ( $\Delta$  in ‰) between  $\text{H}_2\text{SO}_4$  and  $\text{H}_2\text{S}/\text{S}^\circ$  measured for several acidic sulfate–chloride lakes in degassing craters tends to be larger ( $\Delta_{\text{H}_2\text{SO}_4-\text{S}^\circ}$  up to 26‰) than that found in systems lacking this sulfate formation process ( $\Delta_{\text{H}_2\text{SO}_4-\text{S}^\circ} < 15\text{‰}$ ). Assuming isotopic equilibrium is reached between dissolved  $\text{SO}_4$  and  $\text{S}^\circ$ , these values suggest that the  $\text{SO}_2$  disproportionation reaction occurs at hydrothermal temperatures between ~200 and 350°C.

Generally, sulfate dissolved in hot acid lake waters also has a high  $^{18}\text{O}$  concentration. Some workers have suggested that this results from equilibration with lake water at relatively high temperature (~100–170°C) in the hydrothermal vent feeding the lake. However, partial or complete equilibration with other fluids of unknown isotopic compositions that exist in the subsurface magmatic–hydrothermal system may also lead to the  $^{18}\text{O}$  compositions observed in the lake sulfate.

### C. Volcanic Lakes in Dormant Craters

#### *1. Freshwater-like Reservoirs in Large Calderas*

There are many large dormant calderas on Earth that are partly or wholly filled by voluminous lakes whose compositions are close to meteoric (e.g., Crater Lake and Batur, Indonesia, Table III). Yet, these waters may still exhibit a dilute volcanic hydrothermal signature. For example, Crater Lake in the 6800-year-old caldera of Mt. Mazama shows near-neutral to slightly alkaline pH and dissolved solids contents quite typical for fresh water reservoirs (TDS ~ 80–100 mg/kg). However,

the lake is well mixed to total depth (589 m) and its concentrations of dissolved chloride, sulfate, boron, lithium, and silica are higher than expected, suggesting existence of an active hydrothermal system associated with some remnant of a magma body at depths greater than 7.5 km. Indeed, warm bicarbonate-, sodium-, and sulfate-rich springs are discharged on the crater floor. The estimated volcanic heat input is in the range ~15–30  $10^6$  W.

#### *2. Volcanic Lakes in Geothermal Areas*

Low-relief hydrothermal fields associated with active, or inactive but still hot, volcanic systems classically feature various surface manifestations, including steaming grounds, boiling springs, and low-temperature fumaroles. Small crater lakes are also common. These can receive volcanic inputs from below, but unlike lakes on top of active craters, they condense only a fraction of the total heat and chemical fluxes associated with the subsurface hydrothermal activity. The thermal energy output of Noboribetsu geothermal area in Japan is ~40 MW; a quarter is apparently directed to the hot lake ( $T \sim 50^\circ\text{C}$ ) in Oyunuma crater. Typically, volcanic inputs consist of hot water and low-temperature ( $T < 100^\circ\text{C}$ ) steam discharges that are vented as small buoyant jets into the lake or as diffuse emissions through the lake sediment pile.

Not surprisingly, the water compositions of volcanic lakes in hydrothermal areas are similar to those of nearby sodium-chloride boiling and steam-heated acid sulfate spring discharges. The NaCl waters are derived from prolonged water–rock interactions and dilution of magmatic fluids at depth followed by near-surface boiling. Acid sulfate waters originate from the oxidation of  $\text{H}_2\text{S}$ -rich steam phase separated from the rising sodium chloride as it mixes with cool oxygenated groundwater. These sulfate waters, with minor, if any, amounts of chloride are moderately acidic ( $2.5 \leq \text{pH} < 5$ ) and can leach the rock from its chemical constituents. Acid sulfate waters usually have high total dissolved solids concentrations. Oyunuma lake displays a mixed thermal water composition, whereas Bannoe lake, Russia, is dominated by a steam-heated sulfate composition (Table III). From an isotopic viewpoint, the D and  $^{18}\text{O}$  contents of sodium-chloride waters show the influence of extensive water–rock interaction, whereas the isotopic compositions of steam-heated sulfate waters reflect a meteoric origin. In the same way as active volcanic lakes behave, evaporation at the hot lake surface may concentrate the “heavy” isotopes in the lake waters. Dissolved sulfate in hydrothermal lakes have a distinct

sulfur isotopic composition; they retain the low  $^{34}\text{S}$ -content of  $\text{H}_2\text{S}$  from which they derive. This results from the fact that oxidation of  $\text{H}_2\text{S}$  by oxygen at shallow levels does not involve significant fractionation of the "light" and "heavy" sulfur isotopes between the sulfur species.

### 3. Gas-Rich Volcanic Lakes

Monoun and Nyos, two lakes in maar craters along the Cameroon Volcanic Line, suddenly expelled massive amounts of  $\text{CO}_2$  in 1984 and 1986, respectively. Following these events, geochemical surveys revealed that both lakes are unusual environments, because their bottom waters store "free"  $\text{CO}_2$  gas dissolved by the pressure. Together with their basin topography, the Nyos and Monoun water columns thus have a chemically and thermally stratified structure and the capacity to accumulate tremendous amounts of  $\text{CO}_2$  gas. It is believed that  $\text{CO}_2$ -rich soda thermal springs ( $T < 30^\circ\text{C}$ ) discharge as diffuse emissions into these lakes. Geochemical evidence suggests that the Cameroon Volcanic Line is a zone of enhanced mantle degassing. Apparently, the mantle may ultimately be the source of  $\text{CO}_2$  at Nyos, judging from the isotopic composition of its carbon and from that of helium in the waters. Recent calculations indicate that Lake Nyos contains about  $0.5 \times 10^6$  tons of  $\text{CO}_2$  in its waters. From 1987 to March 1995, the estimated  $\text{CO}_2$  flux to the lake decreased from 11,000 to 6600 tons per year. By comparison, the long-term  $\text{CO}_2$  release rate deduced for Grimsvötn is  $\sim 3.5$  to 7 times higher, but the gas does not accumulate in this lake.

Lake Nyos has a maximum depth of 209 m, and vertical profiles of dissolved solids indicate that "free"  $\text{CO}_2$  gas is overwhelmingly the most abundant chemical species in the lake. Carbonic acid ( $\text{H}_2\text{CO}_3$ ) is also present in the lake waters. Concentration builds up with increasing depth because of the pressure-dependent solubility of  $\text{CO}_2$  (Fig. 4). From a depth of 48 m, a gradual and temperature gradient is observed that corresponds to the position of the surface mixing layer with meteoric water (chemocline). Below this, as the total  $\text{CO}_2$  concentration increases, the pH decreases as a result of the dissociation of  $\text{H}_2\text{CO}_3$ . At Nyos, the pH of the waters change from 8.0 at the surface to a minimum of 5.1 at the bottom (Table III). Iron is highly soluble under the slightly acidic conditions found below the chemocline, making the lake strongly enriched in this element. The presence of iron in its reduced redox state (ferrous iron) indicates that the water is anoxic below the surface mixing layer. Together with the high  $\text{CO}_2$  gas concentration of the bottom waters, this leads to precipitation and

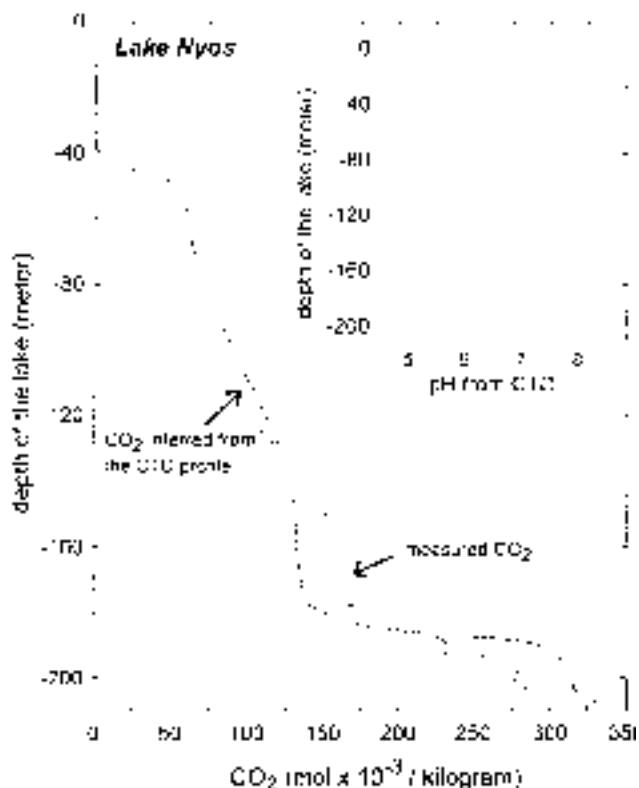

FIGURE 4 "Free" carbon dioxide ( $\text{CO}_2$ ) gas concentrations in the water column of Lake Nyos measured *in situ* in November 1993 and calculated from conductivity-temperature-depth (CTD) profile obtained in April 1996. Inset: pH values in the water calculated from the CTD profile.

deposition of small amounts of siderite ( $\text{FeCO}_3$ ), a rather rare mineral in a freshwater lake environment. After the 1986 catastrophe, the surface of Lake Nyos turned reddish brown, because of the formation of iron hydroxide as the ferrous bottom waters were carried up to oxidizing shallow levels.

The occurrence of density-stratified gas-charged lakes is not very common. An example, on a much larger scale, is Lake Kivu, East African Rift, where the predominant gas is also  $\text{CO}_2$ , but accompanied by large quantities of methane ( $\text{CH}_4$ ). Of the 37 systems inspected along the Cameroon Volcanic Line, only Lake Nyos and Lake Monoun exhibit the  $\text{CO}_2$  anomaly. Existence of a  $\text{CO}_2$ -recharge similar in size to that of Lake Nyos has been reported for Lake Mashu, a 1000-year old caldera lake on Hokkaido, Japan. Fortunately, there is insufficient time for  $\text{CO}_2$  gas to accumulate in the bottom waters, since the seasonal overturns of the lake expel the gas into the atmosphere twice a year. Anomalies of  $\text{CH}_4$  and  $\text{CO}_2$  gases have been detected in the bottom

waters from Lake Piccolo on Mt. Vulture, Italy. The origin of these gases is likely organic, but an inorganic contribution for CH<sub>4</sub> cannot be ruled out.

## D. Mineralization in Volcanic Lakes

### 1. Liquid Sulfur on Earth

Early in this century, Japanese observers inferred the presence of molten sulfur on the lake bed of Yugama Lake. They based their interpretation on the morphology of S° spherules that are continuously conveyed to the surface of the lake. Later, scientists recognized the presence of similar S° material floating on the surface of other hot volcanic lakes in both active craters and geothermal areas. Although less frequent, the ejection of sulfur tephra during mild eruptions through a lake (e.g., Poás in 1989, Kawah Ijen in 1993, and Copahue, Argentina, in 1995) is also suggestive of the presence of subaqueous molten S°. Such bodies of liquid S° have been probed successfully at Ruapehu, Maly Semiachik, Kusatsu-Shirane, Poás, and Bannoe lakes, revealing temperatures between ~120 and 170°C. Apparently, the heat flow through the crater floor can be sufficiently high to melt S° trapped within sediments lying on the lake bed. The color of quenched liquid S° samples collected from different lakes varies from yellow to black and may be controlled by the type and amount of impurities present in S°.

We do not have a precise idea of the size of these subaqueous molten S° bodies. There is strong evidence that substantial deposits of S° form in certain lake environments. Such deposits can be sizeable, for example,  $2.6 \times 10^6$  tons of S° accumulated over 1420 years at Rotokawa, New Zealand. The sediments of Poás crater lake may host  $0.5 \times 10^6$  tons of S°, whereas El Chichón crater had stored  $4 \times 10^3$  tons of S° in the space of less than 1 year after a lake had formed. In volcanic lakes, S° can be produced directly through the disproportionation reaction of SO<sub>2</sub> [reaction (1)], produced during oxidation of H<sub>2</sub>S derived from reaction (2), or transported to shallow levels by steam boiled off from a hydrothermal system.

### 2. Acidic Crater Lakes as Potential Ore Forming Environments?

From the mineralogy and stable isotopic compositions of the alteration assemblage associated with certain base metal deposits found at shallow levels and containing a high proportion of sulfide minerals (the “high-sulfida-

tion” deposits), economic geologists have deduced that circulation of low pH, oxidizing, sulfur-rich fluids occurred at early stages of ore deposition in this class of ore deposits. Seepage of acidic mineralized brines formed by condensation of hot magma–hydrothermal mixtures in crater lakes may be one mechanism by which this type of alteration signature is produced at depth. Tops of some ore deposits contain breccias and sedimentary structures that are interpreted to be the roots of acidic crater lakes.

Geochemical modeling indicates that subsurface circulation of strongly acidic waters within a magmatic hydrothermal system underlying a crater lake only dissolves the rock to produce the silica-rich core that invariably constitutes the most altered parts of high-sulfidation ore deposits. However, seepage of acidic lake waters away from the central zone of acid gas condensation may also permit precipitation of an alteration mineral assemblage similar to that observed in association with the high sulfidation deposits. Indeed, infiltration through permeable stratigraphic units and/or flank fractures of the host edifice allows for prolonged water–rock interactions and mixing with groundwater. Both processes will gradually decrease the acidity of the circulating lake fluids, leading to saturation of secondary minerals such as alunite, clays, and pyrite and eventually to that of sulfides such as covellite and enargite.

---

## III. HAZARDS OF VOLCANIC LAKES, THEIR MONITORING AND MITIGATION

The compilation “Volcanoes of the World” lists 55 volcanoes with a record of at least one eruption through a lake. Water and hot magma make an explosive combination, and a summit crater lake on an active volcano places these two components in dangerous proximity. Lake water adds to the danger by contributing, in an eruption or in a crater rim failure, to debris flows and floods that can devastate the volcano’s flanks and beyond. This kind of activity has caused a great number of deaths (Table II). Toxic water releases, sector collapses, and gas bursts constitute additional hazards associated with volcanic lakes. Yet, very few lakes are monitored on a regular basis. Changes in a lake’s appearance and thermal and/or chemical output are the diagnostic symptoms that are watched for. Manual collection of data is the most widely used technique, but volcanic lake surveillance by means of automated instrumentation and satellite remote sensing is being developed. At Kelut,

extensive efforts to drain the lake have successfully reduced the danger posed by overflow of the lake, causing lahars. A new challenge for volcanologists and engineers is to artificially degas the CO<sub>2</sub>-rich Nyos and Monoun lakes in order to prevent another sudden CO<sub>2</sub> release.

## A. Hazards

### 1. Hydrovolcanic Eruptions, Base Surges, and Tsunamis

Hydrovolcanic eruptions result from the mixing of water and hot rock. Active edifices hosting a lake present a high potential for this type of interaction, leading to hydrovolcanic eruptions that are more destructive than equivalent size eruptions that lack a lake. This phenomenon was first documented at Taal during a series of eruptions that involved the caldera lake in 1965–1966. Base surges swept over the landscape like hot hurricanes, tearing trees from the ground and destroying houses, then flowed across Lake Taal and engulfed fleeing boats before hitting the shores. As huge masses of water were suddenly displaced, a tsunami formed in the large lake. Damage extended up to 6 kilometers from the vent, and more than 200 people died. It was later recognized that more violent base surges accompanied by tsunamis also occurred during the 1911 eruption through the lake-hosted Main Crater.

### 2. Debris Flows (Lahars) and Floods

The Indonesian word “lahar” refers to a debris flow that contains mostly fragments of volcanic origin mixed with water. Crater lakes on active volcanoes with steep slopes can release water to form lahars that, in the case of acidic lakes, can be caustic. The volcanic lakes are often situated in densely populated areas, and some of the worst lahars in history are associated with crater lakes (Table III). Indonesia has suffered dreadfully from crater lake-related lahars, the most devastating of which have occurred at Kelut. In 1919, an eruption expelled the lake and generated lahars that traveled as far as 37 km, destroying 100 villages over a 130-km<sup>2</sup> area and killing 5000 persons. Lahars from the 1586 eruption reportedly took the lives of 10,000 people. Sudden drainage of a volcanic lake due to crater collapse or crater rim failure/breaching, without precursor activity, is another source of debris flows and floods. This happened in 1953 at Ruapehu when a breach in the crater walls caused the lake waters to gush out, forming a debris flow that swept away the Tangwai bridge just before

the arrival of an express train. The carriages plunged into the valley, and 151 people perished. Catastrophic draining of a crater lake at Agua volcano, Guatemala, created lahars that totally destroyed the former capital of Ciudad Vieja in 1541.

### 3. Toxic Water Releases and Flank Collapses

Highly acidic and mineralized waters in summit crater lakes sometime seep into flank watersheds, profoundly affecting the water quality. At Kawah Ijen, the Banyupahit River continuously receives toxic discharges from the acidic crater lake. Seven kilometers from its source, the river waters display pH values < 1 and TDS contents > 20,000 mg/kg. Over most of its length, the river is totally devoid of life. When it reaches a vast irrigation system about 30 km from the summit, it carries ~1500 tons of sulfate, 28 tons of fluoride, 500 tons of chloride, 100 tons of aluminum, and 0.03 ton of copper daily. When the lake overflows and sometimes during the rainy season, the villagers are forced to divert the toxic flow from the rice fields directly into the sea, causing the near-shore fauna to perish. Contamination of the river watershed by the lake water also occurs at Poás and Copahue.

In addition to contaminating local water supplies, the low-pH crater lake waters that seep and circulate within the host edifice alter and dissolve the rock, in some instances significantly. For example, over a 100-year period the bulk dissolution rates at Poás and Kawah Ijen volcanoes have removed  $\sim 6 \times 10^5$  and  $1.4 \times 10^6$  m<sup>3</sup> of rock, respectively. Although the edifice volumes ( $\sim 100$  km<sup>3</sup>) are much larger than these values, the process may result in an increase in the permeability of flank aquifers over the lifetime of the hydrothermal system (hundreds to thousands of years). In turn, this may weaken the volcano along preferential fluid pathways (i.e., fractures and faults) and eventually promote sector collapse of these volcanoes.

### 4. Gas Bursts

Some crater lakes can rapidly release free CO<sub>2</sub> amassed in their bottom waters. The tragedies of Monoun and Nyos are the only two historical examples of this type of crater lake hazard. The exact triggering mechanism for releasing the CO<sub>2</sub> remains controversial. Complete overturn of the lakes induced by sinking of cool and denser water from heavy rainfall is not regarded as a viable mechanism, because a well-developed stratified structure persisted immediately after the catastrophe. Gas exsolution may have been initiated quietly at shallow levels, although the possibility remains that the process

began from the lake bottom. A plausible hypothesis is that sudden upward displacement of the chemocline initiated the saturation of CO<sub>2</sub> gas and formation of bubbles by reducing the pressure exerted on the water column. Once upwelling started, the process escalated as more CO<sub>2</sub> was released from solution during ascent of deep waters. In this model, we still do not know what raised the chemocline. A small landslide on the inner crater walls may have been the trigger, but other external energy sources could plausibly trigger the eruption. Unfortunately, volcanologists cannot substantiate their hypotheses using geological records alone, since the Monoun and Nyos events did not leave such evidence.

## B. Monitoring

### *1. Visual Observations of Lake Color, Bubbling, and Sulfur Slicks*

The color of a water body results from absorption and scattering of solar radiation by inorganic and organic materials that are dissolved and/or suspended in the waters. Thus, the color of a volcanic lake is affected by chemical precipitation rates, particle sizes and the vigor of convective circulation in the lake. The volcano observatory staff who monitor Ruapehu volcano look for a shift in the lake's color from blue-green, when the water temperature drops to 10–20°C and visible signs of convection are not evident, to pale gray, an indication that bottom sediments are being remobilized by increasing water movements associated with enhanced vent activity. Eruptions through the lakes of Kawah Ijen and Kelut also were reportedly preceded and followed by color changes that apparently involved remobilization of the bottom sediments. Several times, the lake of Poás went from grayish green to bright yellow green following the start of hydrovolcanic eruptions through the lake. Here, the color change was attributed to an increased flux of sulfur dioxide, which causes oxidation of dissolved iron.

### *2. Lake Temperature, Lake Level, and Thermal Energy Budget*

Several eruptions at lake-hosted volcanoes have been preceded by large temperature changes. For example, the Main Crater Lake of Taal recorded a 10°C increase 2 to 3 months prior to the September 1965 eruption. Similarly, the lake temperature at Kelut increased from 30°C in September 1989 to 38°C several days before the 10 February 1990 eruption. About 10 months before the main 1995 eruption of Ruapehu, the lake tempera-

ture reached a 13-year high of 55°C. However, identifying a forthcoming eruption solely on the basis of lake temperature variations is not straightforward. The 30-year record from Ruapehu reveals that a significant decrease of near-surface temperatures over several hours can be associated with rain and snow storms at the summit, whereas the opposite trend may reflect instability of convective heat transfer within the lake rather than changes in magmatic activity.

Because of difficult, dangerous, or limited access to the lake shore, direct recording of temperature on a continuous basis can be disrupted. In the late 1970s, temperature telemetry buoys were deployed at Mt. Ruapehu with transmission by high-frequency radio. Recently, satellite communications have allowed transmission of instrumental data from Ruapehu, Kelut, and Taal lakes. The drawback of this automated method to monitor active volcanic lakes is that instrumentation suffers from the harsh conditions encountered in these environments, causing equipment failure and loss of data.

Results of heat and water budget analysis for which time-series data on lake temperature and lake level are available suggest heat discharge patterns that generally coincide with the onset of a new stage of volcanic activity. At Ruapehu, pre-eruptive periods are characterized by low heat input to the lake (<150 10<sup>6</sup> W compared with a normal average of ~400 10<sup>6</sup> W). At Poás and Yugama crater lakes, departures from a steady heat inflow coincided with increase in the lake activity and sometimes with the number of volcanic earthquakes. In both cases, these perturbations were attributed to the formation of fractures in the envelope surrounding a cooling magma body, allowing release of magmatic volatiles to the overlying hydrothermal system. Upward migration of magma also may have occurred at Poás.

The potential of remote sensing for monitoring volcanic lakes by means of images recorded by satellite was recently explored using visible and infrared data provided by the Landsat Thematic Mapper (TM) platform. A reasonable agreement between remote sensing estimates and ground measurements of temperature and surface area were obtained. Problems arise from atmospheric influences on water reflectance and from the generally small surface area of lakes compared with satellite spatial resolution. In addition, gases rising from hot lakes may complicate the reflectance spectra. Nevertheless, temperature and surface area data can be used to model lake heat outputs in the same fashion as *in situ* data. The Advanced Spaceborne Thermal Emission (ASTER) and Enhanced Thematic Mapper (ETM+), both of which were due for launch in 1998, will offer

improved capabilities for the remote surveillance of volcanic lakes.

### 3. Geochemical Methods

The pH of lakes in degassing craters chiefly depends on the injection rate and composition of the condensing acidic magmatic-hydrothermal fluids. pH is easy to monitor directly or remotely on a real-time or near-real-time basis. Decreasing pH correlated with increasing Cl concentrations at Yugama Lake in 1990–1993. A marked increase in acidity was also reported in the Main Crater Lake of Taal before the 1968–1969 eruptions. By contrast with these hot acidic systems, pH variations at Lake Nyos and Lake Monoun vary with the CO<sub>2</sub> content, because pH is inversely correlated with total CO<sub>2</sub>. Coupled with conductivity-temperature-depth (CTD) profiles, retrieval of pH data allows the estimation of CO<sub>2</sub> concentrations in the water column (Fig. 4). This method is essential to monitor the rate of its accumulation in bottom waters.

Since the 1980s, a Japanese team has been developing a real-time capability for monitoring changes in polythionate concentrations in crater lakes. Polythionates (S<sub>x</sub>O<sub>6</sub><sup>2-</sup>,  $x = 4-6$ ) are transient sulfur compounds produced by reaction of SO<sub>2</sub> with H<sub>2</sub>S in acidic solutions. In acidic crater lakes, their concentrations typically reach a few hundred parts per million. The method relies on the dependence of polythionate stability on the SO<sub>2</sub>/H<sub>2</sub>S ratio in lake waters. Changes in this ratio may indeed indicate fluctuations in the activity of the magma-hydrothermal system at depth. The method was applied to Yugama Lake, Poás, and Ruapehu with success. Sharp declines in polythionate concentrations and corresponding increases in dissolved sulfate correlated in all cases with renewed hydrovolcanic/seismic activity in these lakes (Fig. 5). These observations strongly sup-

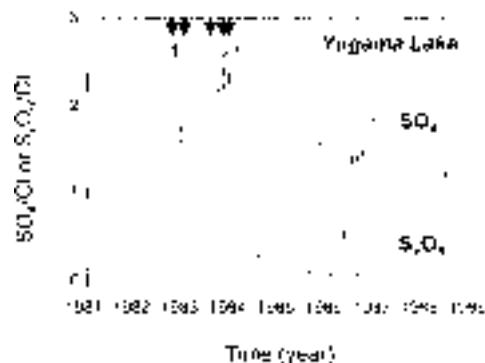

FIGURE 5 Changes in the chloride (Cl)-normalized dissolved polythionate (S<sub>x</sub>O<sub>6</sub>) and sulfate (SO<sub>4</sub>) contents measured between 1981 and 1988 in Yugama Lake on Kusatsu-Shirane volcano, Japan. Black arrows indicate eruptions occurring in the lake. [Modified from *J. Volcanol. Geotherm. Res.* **40**, Takano, B., and Watanuki, K., Monitoring of volcanic eruptions at Yugama Crater Lake by aqueous sulfur oxyanions, 71–87 (1990) with permission from Elsevier Science.]

port the idea that variations in lake chemistry and heat output can be closely related.

The evolution of the Mg/Cl ratio in the waters has been used by New Zealand scientists since the mid-1970s to monitor the crater lake of Ruapehu. As shown in Fig. 6, the five main eruptions that occurred between 1965 and 1995 in the lake (1966, 1968, 1969, 1971, and 1977) were all preceded by six months or more of constant Mg/Cl ratios, followed by an abrupt increase and a long-term decline thereafter. Assuming that Cl is derived solely from the condensation of high temperature volcanic gases into the magmatic-hydrothermal system and that Mg is leached from the rock during water-rock interaction, the increase in the Mg/Cl ratio reflects injection of fresh magma into the vent feeding the lake

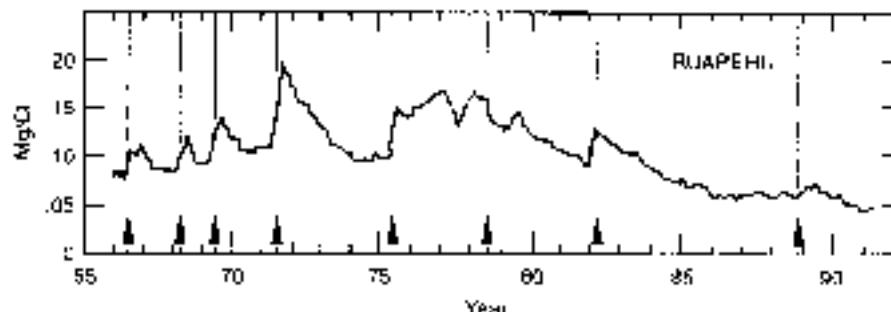

FIGURE 6 Changes in the Mg/Cl ratio measured between 1965 and 1991 in the crater lake of Ruapehu volcano, New Zealand. Arrows indicate time of eruptions into the lake. Data compiled from Christenson and Wood (1983) and references therein.

and its decrease indicates subsequent strong HCl degassing. Apparently, the Mg/Cl ratio can also record smaller perturbations occurring at depth. For example, the variations observed in 1976, 1982, and 1988 seem to be associated with hydrothermal explosions that cleared the subaqueous vent of fluids with compositions differing from those of the lake.

The Mg/Cl method and other chloride-based ion ratios are, unfortunately, not without ambiguities. A survey carried out at Poás from 1984 to 1990 revealed that HCl vapor starts to evaporate at lake temperatures above 50°C, therefore also changing the Mg/Cl ratio in the waters. At Taal, the source of Cl in the crater lake is not only the magma, but also hydrothermal fluids contaminated by seawater. Fluctuations in the Mg concentration in a lake may also relate to dissolution or precipitation of Mg-bearing minerals (e.g., chlorite and biotite) in the underlying magmatic–hydrothermal system. This process is strongly dependent on temperature. We also note that the Mg/Cl method cannot provide real-time information on the state of the lake, since water samples collected on site must be analyzed and interpreted in the lab.

#### **4. Underwater Acoustic Surveys**

Geophysicists have suggested that underwater noise measurements across a broad frequency band can be useful to observe changes in the crater floor region. High-sensitivity hydrophones have been deployed in the lake of Kelut during intereruptive and eruptive phases. During the seismic crisis preceding the 1989–1990 activity, the hydrophones recorded powerful signals of bubbles that originated from subaqueous fumarolic activity. As the crisis progressed, the bubble noise increased and persisted until the eruption destroyed the instrumentation. Ruapehu was the site of a second series of measurements. Between 1993 and 1994, the acoustic and seismic records at Ruapehu revealed the increase of heat transfer to the lake several days before an increase in the lake temperature could be detected. Several weeks of high-energy acoustic signals preceded the 29 June 1995 eruption that destroyed the equipment.

### **C. Mitigation**

#### **1. Drainage Tunnels at Kelut Volcano**

Kelut has erupted 29 times since 1311, with repose intervals between eruptions ranging from 1 to 75 years. The major volcanic hazard for people living near the volcano

is lahars that come from the crater lake. Aware of the permanent threat posed by the presence of  $4 \times 10^7$  m<sup>3</sup> of water stored in the summit crater, the Dutch administration built a dam on the Badak river in 1905 to divert the debris flows from reaching the town of Blitar. Unfortunately, the voluminous lahars from the 1919 eruption swept away the dam.

Upset by this tragic event, which killed 5000 people, the Volcanological Survey of Indonesia decided to drain the crater lake by means of tunnels. This constituted one of the first and most ambitious examples of an engineering project aimed at reducing volcanic hazards. The work started 4 months after the 1919 eruption when the lake had not yet reformed, with the objective to drill a 955-m-long tunnel through the crater wall. This plan could not be completed quickly because of the harsh conditions encountered at the excavation front. By 1923, when the lake had filled with  $2.2 \times 10^7$  m<sup>3</sup> of water, sudden flooding of the tunnel ended the tunnelling efforts. A new strategy was then adopted to lower the lake level progressively by excavating seven superimposed tunnels while draining the lake waters with a siphon pipe. This work was completed in 1926, and the lake volume was successfully lowered to less than  $2 \times 10^6$  m<sup>3</sup>. Later eruptions in 1951, 1966, and 1990 produced only minor lahars whose damage was much more limited. At present, the tunnels of Kelut still control the volume of the 33-m deep crater lake, although their maintenance demands constant attention.

#### **2. Artificial Degassing of Lake Nyos**

Lake Nyos and Lake Monoun have been increasing their CO<sub>2</sub> contents since the last catastrophes in the 1980s, and future CO<sub>2</sub> bursts cannot be discounted. However, these gas disasters are unique because they can be effectively controlled through continuous monitoring and degassing. Scientists and engineers have recently proposed an elegant solution based on the creation of an artificial self-sustained gas eruption to degas the CO<sub>2</sub>-rich waters. The principle consists in tapping the bottom waters by means of pipes. As the waters rise up the pipe, the pressure progressively drops, causing saturation and exsolution of CO<sub>2</sub> gas bubbles. As a result, the density of the gas–water mixture is decreased and the internal buoyancy becomes sufficient to expel the fluid at the surface. Once the process has started, it becomes self-sustaining, requiring no external energy and lasting for several months or years until no gas is left at depth.

A French team has already carried out test experiments on Monoun and Nyos lakes. In March 1995, a 200-m-long pipe was installed vertically in the middle

of Lake Nyos and delivered a 20-m-high fountain of water and CO<sub>2</sub> that lasted several hours until the experiment was stopped deliberately. The team concluded that the gas-lift process is feasible and estimated that 10 years would be necessary to degas the  $5 \times 10^5$  tons of CO<sub>2</sub> stored in Lake Nyos if 12 pipes of 12 cm diameter are used. Similarly, 5 years of pumping through three pipes would completely remove the dissolved gas from Monoun. Scientists have recently submitted a project (Lake Nyos Monoun Degassing Project) aimed at operational degassing of the lakes. In this, they acknowledge that close monitoring of the physical and chemical conditions during the experiment is essential, although numerical simulations suggest that the process is safe.

#### IV. FUTURE DIRECTIONS

Data on the past activity and current status of crater lakes, particularly those on active volcanoes, are too few and, in some cases, unreliable. It is critical to understand how and why the physical and chemical parameters in a crater lake respond to changes in volcanic inputs. The few examples of crater lake energy budget analysis and geochemical monitoring illustrate the complexity and uniqueness of each crater lake system. Ideally, we need to infer and validate a model of heat and mass transport from a magma intrusion to the crater lake bottom, taking gas–rock, gas–water, and water–rock interactions into account. Experience shows that optimum monitoring is achieved by a combination of methods, rather than reliance on one method alone. Toward this end, recent research on stable isotopes to determine lake dynamics by considering heat and mass flow constraints is promising. Similarly, we need to integrate detailed hydrologic considerations into crater lake studies, as these probably play an important role in determining the dynamic state of a lake. Prediction of the evolution of a crater lake system is also important and should give insights into ore forming environments. More biological studies of hot acidic crater lakes may provide insights into life in extreme environments. In the particular case of Nyos and Monoun lakes, the volcanological community faces a formidable challenge to safely degas the lake waters.

## GLOSSARY

**cumulate** An igneous rock formed by the accumulation of crystals that settle out from a magma by the action of gravity. The most common cumulate rocks are ultramafic in composition, formed by the accumulation of olivine crystals.

**dunite** A type of peridotite in which the mafic mineral is almost entirely olivine, with accessory chromite almost always present.

**eclogite** Rock of basaltic composition containing minerals that indicate that it has been subjected to very high pressures deep in the crust.

**geothermal system** A present-day natural system in which hot water, typically heated by magmas, circulates. Sur-

face expressions may be silica sinters, boiling pools, and geysers.

**harzburgite** A type of peridotite composed chiefly of olivine and orthopyroxene.

**hydrothermal system** Any natural system involving the circulation of hot water. The water and the heat can be derived from any source. Presently active hydrothermal systems that we can see near the earth's surface are called geothermal systems.

**kimberlite** A porphyritic alkalic peridotite containing abundant phenocrysts of olivine (commonly altered to serpentine or carbonate minerals) and phlogopite in a fine-grained groundmass of calcite, olivine, and phlogopite with accessory minerals. Kimberlite is the main host rock for diamonds.

**lamproite** A group name for dark-colored intrusive or extrusive rocks rich in potassium and magnesium. Lamproites can contain diamonds.

**herzolite** A type of peridotite composed chiefly of olivine, orthopyroxene, and clinopyroxene, in which olivine is generally most abundant; a two-pyroxene peridotite.

**occelli** A textural feature of some igneous rocks, in which central crystals are surrounded radially or tangentially by small crystals of another mineral, forming rounded eyelike branching forms.

**ore** Naturally occurring material from which economically valuable minerals can be extracted at a reasonable profit. The term is generally but not always used to refer to

rocks containing metals, and is often modified by the name of the metal extracted, e.g., "copper ore."

**peridotite** A general term for a coarse-grained plutonic rock composed chiefly of olivine with or without other mafic minerals such as pyroxenes, amphiboles, or micas and containing little or no feldspar. Peridotite is commonly altered to serpentinite.

**pluton** A general term for an igneous intrusion, typically a large body composed of medium to coarse grain-size minerals.

**porphyry** An igneous rock of any composition showing a texture in which phenocrysts occur in a fine-grained groundmass.

**picrite** A dark-colored rock containing abundant olivine along with pyroxene, biotite, possibly amphibole, and less than 10% plagioclase.

**xenocryst** A crystal that resembles a phenocryst in an igneous rock but is foreign to the body of rock in which it occurs.

reach the surface may represent only about 20–30% of the magma that was generated and brought to crustal levels, with the rest forming intrusive rocks that solidify below the surface. So in considering ores in the volcanic environment, the intrusions below the volcanoes are often more important than the volcanoes themselves.

Intrusive rocks lose their heat in several different ways:

1. By transferring heat to the porewater present in the rocks that host the intrusion. Heating of this water causes it to become less dense and rise, drawing in other water to take its place, which in turn becomes heated. In this way the magma drives a heat pump that takes heat from the magma at depth and carries it to near-surface levels where it becomes dispersed. In the process of fluid convection, the heated fluids can dissolve metals from the country rocks, depositing them near the Earth's surface and possibly forming ore deposits.

2. By expelling the volatiles that they contain. Magmas contain varying amounts of water and sulfur-bearing compounds, and as they solidify the concentration of these builds up in the part that has not yet crystallized. If water becomes saturated, a magmatic hydrothermal fluid forms that, when expelled from the intrusion, can carry away both heat and dissolved metals and may lead to the formation of ores.

3. By conduction through the rocks they have intruded, though this is a slow and relatively inefficient process.

In some cases the relationship between mineral deposits and volcanism is very direct, with both forming at the same time. In other cases more deeply formed ores are more related to the magma chamber that feeds the volcanism. In still other cases the magmas below may only provide heat to drive the hydrothermal processes that produce ores. In these last two cases, the volcanic rocks may simply provide a site for deposition of ores. Although the relationship between ores and volcanism is complex (and we do not fully understand it in many cases), the Earth's volcanic environments are host to a wide variety of different ore deposit types.

---

### I. PROCESSES THAT PRODUCE MINERAL DEPOSITS IN VOLCANIC ENVIRONMENTS

There are three main processes that produce ores associated with volcanic rocks:

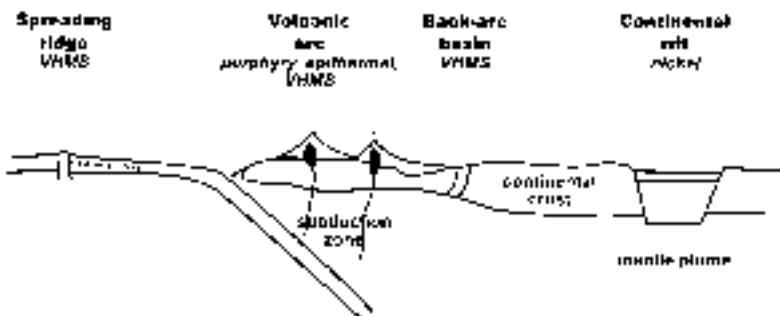

1. Formation from minerals that crystallize from the magma itself
2. Formation from volatile fluids (mostly hot water) that are in the magma and are driven out as it solidifies
3. Formation from fluids that do not come from the magma, but that are driven by heat from magmatic intrusions

Volcanism is a way for the Earth to lose heat, as large amounts of heat are carried to the surface of the Earth and dissipated during volcanic activity. Magmas that

#### A. Tectonic Setting, Volcanic Rocks, and Ore Deposits

There are three main settings for the generation of volcanic rocks that are of the greatest importance for ore deposits (Fig. 1):

1. Mantle plumes or hotspots
2. Mid-ocean ridges
3. Subduction zones

**FIGURE 1** Tectonic settings of volcanic-associated ore deposits. Note the three different settings for volcanic-hosted massive sulfide deposits (VHMS).

All three environments can produce huge volumes of magmatic rocks; however, their volumes and the importance of the ore deposits they host are very different.

### 1. Mantle Plume or Hot Spot Settings

Mantle plumes (or hot spots) can occur beneath oceans or continents and are associated with immense outpourings of tholeiitic and alkalic volcanic rocks. Volcanic rocks generated by this process in oceanic regions (such as Hawaii) are typically barren of major metal deposits. However, where mantle plumes occur below continents, flood basalt provinces can result. Flood basalts occur where mantle plumes well up beneath continents and cause arching of the crust, which results in rifting and massive outpourings of basalts. This process has occurred many times throughout the Earth's history. Although the very well-preserved flood basalt provinces are relatively young, there are remnants of flood basalts of many ages on all continents. Some are host to important nickel–copper and platinum-group metal deposits (see later discussion).

In ancient environments similar processes to those responsible for the flood basalt sequences are believed to have produced another style of nickel sulfide deposit, associated with distinctive magnesium-rich volcanic rocks called komatiites. They host a class of nickel sulfide deposits that are generally referred to as Kambalda-type after the best-known locality in Western Australia. Komatiites are mainly restricted to Archaean sequences (>2.5 billion years old), although some early Proterozoic (2.5–2.0 billion years old) analogues host deposits in Canada.

### 2. Midocean Ridge Settings

At midocean ridges the crust is spreading, allowing magmas to have access to the surface where they form submarine volcanoes and subvolcanic intrusions consisting

of sheeted basaltic dykes and gabbros. The igneous rocks interact with seawater that penetrates and convects through fractured, heated crust to dissolve, transport, and deposit metals. Volcanic rocks generated at mid-ocean ridges are exposed at the Earth's surface where slices of the oceanic crust (ophiolites) become thrust up (obducted) onto continental margins, and so are preserved in older sequences. Many ophiolites contain volcanic-hosted massive sulfide (VHMS) deposits (see later discussion). The settings of these deposits are identical to many of the active “black smoker” systems of hot springs discharging at spreading ridges that have been studied by deep-sea diving over the past 25 years.

### 3. Volcanic Arcs and Subduction-Related Settings

VHMS deposits not only form in association with mid-ocean ridges, but are also associated with volcanic arcs. Volcanic arcs are common throughout the geological record and are best represented today by the volcanic Ring of Fire that surrounds the Pacific Ocean, generated by subduction. Volcanoes form where the plates that cover the Earth's surface come together and one slides under the other. As one plate slides down, parts of it melt to form magmas that penetrate the plate above and erupt in a volcanic arc. As subduction continues it is common for stretching and thinning to occur in the crust behind the arc, forming a backarc basin. In volcanic arcs the VHMS deposits can form within the arc, and in backarc basins. We can see VHMS deposits forming today in both these settings.

The most obvious examples of volcanism on land are related to volcanic arcs (e.g., Mt. St. Helens, Mt. Pinatubo, Mt. Etna). During the early stages of their development volcanic arcs typically contain little or no mineralization of economic value. As they mature, a wide range of hydrothermal systems and thus ore deposit

styles can develop. Porphyry copper deposits, copper-gold skarns, high-sulfidation epithermal gold deposits, and low-sulfidation epithermal deposits all form in this setting (see later discussion).

---

## II. PORPHYRY COPPER, MOLYBDENUM, AND GOLD DEPOSITS

### A. Significance

The porphyry deposits are the world's greatest accumulations of copper and molybdenum and are among the largest gold deposits. They take their name from their characteristic association with shallow depth intrusive rocks with porphyritic textures. Many deposits occur within small intrusions originating from larger plutons at depth that have intruded into volcanic sequences; in some cases these intrusions underlie volcanoes (Fig. 2). The ore can occur in the intrusion, and in the surrounding volcanic rocks. In some cases the intrusion was emplaced in nonvolcanic rocks that formed a basement to the overlying volcanic rocks, and the ores can also occur in these basement rocks.

Important examples include the following:

Escondida	Chile	1800 Mt at 1.6% Cu
Chuquicamata	Chile	9500 Mt at 0.6% Cu, including 800 Mt at 1.85% Cu
Bingham Canyon	USA	2000 Mt at 0.9% Cu, 0.35 g/t Au
Grasberg	Indonesia	3150 Mt at 0.88% Cu, 0.75 g/t Au
Sar Cheshmeh	Iran	1300 Mt at 0.67% Cu, 0.27 g/t Au, 0.03% Mo, including 450 Mt at 1.13% Cu
Ok Tedi	Papua New Guinea	550 Mt at 0.69% Cu, 0.63 g/t Au, including 25 Mt at 2.08 g/t Au
Panguna	Papua New Guinea	950 Mt at 0.48% Cu, 0.56 g/t Au
Climax	USA	907 Mt at 0.240% Mo
Mt = million tonnes		

### B. Distribution and Age

The porphyry copper deposits are widely distributed around the world. The distribution is not regular, and

major deposits are particularly abundant in Chile and the southwest United States. Other important belts of deposits follow ancient volcanic arcs that are no longer active, such as the one that runs along the Tethys Belt from Slovakia, through Hungary, Romania, Yugoslavia, Bulgaria, Greece, Turkey, Iran, and into Pakistan. Other arcs occur in Central Asia, with important deposits in Kazakhstan, China, and Mongolia. In many parts of the world, deposits are known from preserved fragments of ancient volcanic belts.

Most economically important porphyry copper deposits are of Late Tertiary to Cretaceous age (10–130 million years old), although both younger and older deposits are known and new deposits are believed to be forming today beneath some active volcanic areas. This age distribution is probably due to erosion and preservation. The deposits form at depths of 2–4 km below volcanoes. In most cases the very young deposits have not yet eroded enough to be exposed whereas deposits formed in Tertiary to Cretaceous time have eroded sufficiently to be exposed, but not to have been removed entirely. The further back in time we go, the less likely it is for the deposits to be preserved. Despite this, we know examples that have been preserved from very early Earth history, so it appears that these deposits have probably formed throughout geological time.

### C. Classification of Types

Porphyry deposits are classified on the basis of their most economically significant metals, which are copper, molybdenum, and gold, though minor amounts of other metals such as silver and rhenium may occur.

Porphyry molybdenum deposits are distinct from the other combinations and are relatively uncommon. They are characteristically associated with very silica-rich magmas. Porphyry gold deposits are also relatively uncommon and are found associated with calcalkalic composition rocks of Andean volcanic arcs. Porphyry copper–molybdenum deposits occur with calcalkalic magmas associated with continental crust (Andean volcanic arcs). Porphyry copper–gold deposits occur in either of two ways: with calcalkalic magmas emplaced into thin crust (island arcs), or with alkalic magmas emplaced far from subduction zones (e.g., Grasberg, Indonesia).

### D. General Characteristics

Porphyry deposits show characteristic features that make them easy to distinguish from other deposit styles.

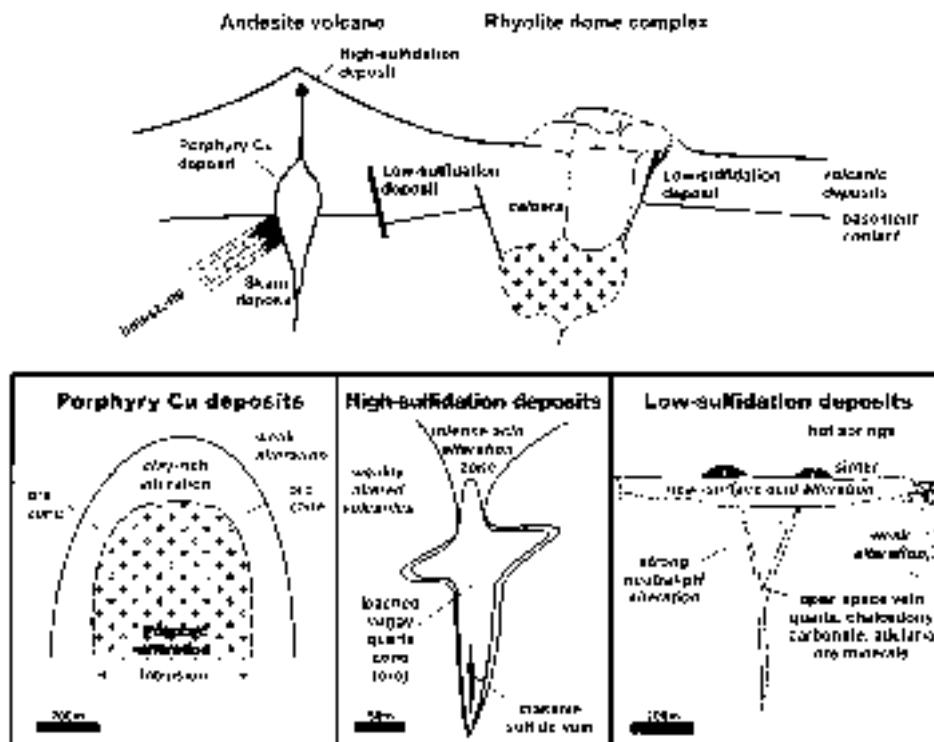

FIGURE 2 Setting of ore deposits in volcanic arcs (top). The small figures below show details of the most important deposit styles. (Left) Detail of a porphyry copper deposit. The intrusion is overprinted by zones of alteration; potassic (central), then clay-rich, and weak alteration of surrounding rocks. The ore zone overprints the alteration, typically focusing in the potassic zone or, more commonly, forming a shell around the contact between the potassic and clay-rich zones. (Middle) Detail of a high-sulfidation deposit. The vuggy quartz ore zone expands upward with irregular shape determined by permeability of the host volcanic rocks. It narrows at the top with a zone of clay-rich acid alteration. (Right) Detail of a low-sulfidation deposit. The ore is typically in structurally controlled veins, surrounded by neutral pH alteration.

The ore in porphyry copper deposits contains copper minerals, usually chalcopyrite, but in some cases with bornite, covellite, or enargite. Typically the ore includes large amounts of pyrite, and in some cases magnetite. Native gold and molybdenite may accompany the copper minerals, and in some cases may be the most economically important minerals. The ore minerals are widely distributed throughout very large volumes of the host rocks, typically at low grade. However, the huge volumes of mineralized rock make these deposits especially suitable for low-cost bulk mining methods.

Ore minerals in the deposits typically occupy very complex sets of small veinlets or are on minor fractures. The distribution of minerals in deposits is zoned, so the level of the deposit that is exposed is important (Fig. 2a). For example, in some deposits the copper is distributed like an inverted cup over and around the margins of the porphyry intrusion. In deeply eroded deposits, the core of the deposit may be barren; in other cases the core may be enriched in gold compared to the margins.

Magnetite is common in the core of deposits, whereas pyrite is especially common on the margins, and in some cases a shell of barren pyrite-rich rock surrounds the copper mineralization. If the intrusion has been emplaced into reactive rocks, such as limestone, skarn mineralization may occur at the contact between the intrusion and the limestone. Skarn commonly consists of copper and gold mineralization, often with abundant magnetite, within a calesilicate rock produced by high-temperature reaction between the intrusion and the limestone.

Most porphyry deposits are low grade, so any process that enhances their grade can be of great economic importance. Weathering processes can enrich deposits near the surface by concentrating the ore metals (possibly as more easily extractable minerals) and by making the rock softer and easier to mine. In some cases (e.g., in Chile) this occurs on a spectacular scale, greatly enriching the value of the deposit.

Some porphyry copper deposits have ore zones that

are over a kilometer in diameter. Ore deposits of this size form from huge hydrothermal systems. The reaction between the rocks and the hydrothermal fluids results in zoned alteration patterns. The margins of the system show signs of reaction with hot water that has changed the mineralogy of the rocks, but has not significantly changed their composition. The intensity of the alteration increases toward the center of the system where the hot fluids have intensely altered the original rocks, substantially changing their composition, mineralogy, and texture. This alteration zoning is an important guide in exploration for new deposits.

### E. Origin of Deposits

Porphyry deposits result from a combination of processes that occur in the Earth's mantle and at shallow crustal levels. The mantle processes determine whether the magma contains significant amounts of the metals required to form ore deposits. The shallow processes determine whether the metals are released from the magma and if they are deposited in a small enough volume of rock to form ore.

The first stage in the genesis of a porphyry deposit occurs in the Earth's mantle with the generation of magma of suitable composition. To form copper and gold deposits, low reduced sulfur content in the source region favors the metals being incorporated into the magma; this can be best achieved if conditions are oxidizing, which means that whatever sulfur is present is dominantly oxidized. This is consistent with the observation that porphyry copper and gold deposits are related to oxidized magmatic systems. The water content of the magma is also important, as it plays a crucial role later in the generation of the deposits.

Once a magma of suitable composition has been generated, it rises into the crust. At this point the amount of water present in the magma becomes important. If there is too much water present, the magma will explode as it approaches the surface, producing pyroclastic volcanic eruptions. If there is insufficient water, the ore-forming process is inhibited as an aqueous fluid cannot exsolve from the magma.

Geologists believe that the intrusions associated with porphyry deposits probably rise to within 2–4 km of the Earth's surface, then stop and begin to cool. An outer surface chills, allowing the still-molten inner parts to evolve. As the intrusion continues to crystallize, the pressure in the molten center builds up. Eventually this pressure cannot be contained; the crystallized rind fractures, causing the remaining magma to quench rapidly

and exsolve a metal-bearing hydrothermal fluid. This fluid streams out along available fractures and deposits sulfides. This process involves complex chemical changes in the released magmatic volatiles due to the pressure release and intense wall-rock reactions. Mixing caused by interaction with dilute groundwater that surrounded the intrusion becomes important over time as the intrusion cools and dissipates its heat.

---

### III. EPITHERMAL GOLD, SILVER, AND BASE METAL DEPOSITS

#### A. Significance

The age distribution of gold deposits is very irregular. Two of the most important gold-forming events were in Archaean time. The third great period of gold deposition is very much younger, mostly during Tertiary to Recent time (less than 66 million years). Most of these deposits occur within volcanic rocks or are related to the magmatism that produced the volcanic rocks.

There are many different styles of gold deposits found in the young period of gold mineralization, including gold porphyries, skarns, and diatreme-hosted deposits. In some of these deposits, gold is not the main metal produced, but is a by-product to the production of other metals (especially copper). Of the deposits in which gold is the main economic metal, the largest and most productive class in this period of geological time is the epithermal deposits. These deposits are themselves quite diverse, but they share characteristics that indicate that they formed at shallow crustal levels (typically from the water table to about 1000 meters below at the time of formation). There are two important classes of epithermal deposits, here called high-sulfidation and low-sulfidation (Fig. 2).

Important examples include the following:

#### *High-Sulfidation*

El Indio	Chile	>12 Mt at 8 g/t Au, 50 g/t Ag, 3% Cu
La Coipa	Chile	52.1 Mt at 1.58 g/t Au, 50 g/t Ag
Summitville	USA	24.3 Mt at 1.46 g/t Au
Lepanto	Philippines	38 Mt at 3.53 g/t Au
Chinkuashih	Taiwan	20 Mt at 4.6 g/t Au, 10 g/t Ag
Pueblo Viejo	Dominican Republic	150 Mt at 7 g/t Au

*Low-Sulfidation*

Martha Hill	New Zealand	83.3 Mt at 3.2 g/t Au, 33 g/t Ag	
McLaughlin	USA	17.5 Mt at 5.2 g/t Au	
Hishikari	Japan	3.2 Mt at 63 g/t Au	
Kushikino	Japan	8 Mt at 6.5 g/t Au, 62 g/t Ag	
Gunung Pongkor	Indonesia	6 Mt at 17 g/t Au, 162 g/t Ag	

**B. Distribution and Age**

Epithermal and related deposits are widespread around the world. They occur principally in the circum-Pacific Rim of Fire, and also in volcanic arc settings in other parts of the world where processes were active that were similar to those now occurring around the Pacific Ocean.

Areas famous for their epithermal deposits include Chile and Peru, Mexico and the southwest United States; Japan, Philippines, Indonesia, and New Zealand. Other significant deposits occur in Serbia and Romania, and ancient examples are known in Sweden, Saudi Arabia, and Australia.

Epithermal deposits typically occur within subaerial volcanic rocks, though they may extend below the volcanic cover into underlying basement rocks. In some very rare cases there may have been a shallow water cover when the deposits formed.

The majority of economically important epithermal deposits are of Tertiary age, and some are undoubtedly forming today beneath areas of geothermal activity. This age distribution is probably due to variations in the intensity of volcanic activity and to the depth of erosion. Erosion has so far exposed few of the very young deposits. Erosion of Tertiary sequences has generally gone on for long enough to expose the deposits, but not enough to remove them entirely. The further back in time we go, the less likely it is that deposits have been preserved. We know rare examples of Precambrian age, so it appears that these deposits have probably formed throughout geological time and have been preserved wherever their host geology has been preserved.

**C. Classification of Types**

We can subdivide epithermal deposits in various ways. First, there is a major difference between two con-

trasting classes, here called low-sulfidation and high-sulfidation (referring to, respectively, the low and high oxidation state of the sulfur in the hydrothermal systems). These two classes are significantly different in many ways, especially the character of deposits, the associated alteration zoning, and the textures of ores (Figs. 2b and 2c). The mineralogy of ores shows some overlap, but there are also distinct differences.

**D. General Characteristics**

The most important characteristics of low-sulfidation deposits are their typically open-space vein-fill character, their diverse range of distinctive textures, their mineralogy (especially adularia and carbonates), and the characteristic alteration zoning (Fig. 2c). For high-sulfidation deposits the most important features are their typically massive, disseminated character, their mineralogy (especially enargite and alunite), and their quite different characteristic alteration zoning (Fig. 2b).

There is no difference in the overall setting for the two styles, as both occur in subaerial volcanic settings of intermediate to felsic composition. Calcalkalic magmatic suites are favorable for either style; alkalic magmatic suites are also favorable for low-sulfidation deposits. High-sulfidation deposits tend to occur close to the centers of host volcanoes, whereas low-sulfidation deposits can occur in any volcanic setting. Both styles are localized by structures, but any suitable permeable structure may be used by hydrothermal fluids.

**E. Origin of Deposits**

Despite decades of study, there are many aspects of the origin of epithermal deposits that we do not understand. The systems are diverse, and it may be that apparently similar deposits form by different mechanisms.

Many *high-sulfidation* deposits have a close association with porphyry copper deposits, so the processes that form the two are probably closely related. Vapors separate from the brines that form porphyry copper deposits and ascend to shallow depths where they condense into groundwater. The magmatic volatiles such as hydrochloric acid and sulfur dioxide that are contained in the vapor produce an extremely acidic fluid, resulting in the intense rock alteration that characterizes high-sulfidation deposits. The ore minerals that deposit in this leached and permeable alteration zone may arrive by one of two mechanisms; we are not sure which actually

happens. The metals may be introduced by high-temperature gases, or alternatively they may be transported by saline magmatic fluids that travel up the same conduits that focused the gases. Deposition of the metals results from mixing with dilute groundwater and boiling of fluids.

The origin of *low-sulfidation* deposits has been debated for many years and is still far from settled. Studies of the origins of the water in the hydrothermal systems clearly show that most of the water was meteoric, but does not preclude a small proportion of magmatic fluid. In a few deposits there is isotopic evidence for a significant magmatic component that appears closely related to the introduction of metals. The main problems are where the metals come from and how they were transported.

Studies of active geothermal systems in different volcanic areas around the world have shown that vast volumes of meteoric water are circulating, driven by heat from deep magmatic intrusions. As this hot water approaches the surface it is focused into structures where the water boils. This is associated with major changes in the fluid chemistry, such as removal of dissolved gases (including hydrogen sulfide that transports the gold), a decrease in temperature, and an increase in pH, and as a result the dissolved metals are deposited. This process produces the low-sulfidation deposits.

Some researchers argue that the metals were introduced into the geothermal systems by injection of concentrated magmatic fluids at depth. Others argue that the circulating meteoric water was capable of leaching the metals from the huge volumes of rock they traversed. It is likely that in different cases both processes occurred.

#### IV. VOLCANIC-HOSTED MASSIVE SULFIDE DEPOSITS

##### A. Significance

These deposits have been variously called volcanogenic massive sulfide deposits, volcanic massive sulfide deposits (VMS), or volcanic-hosted massive sulfide deposits (VHMS). Here we will call them VHMS deposits.

VHMS deposits are an important source for copper and zinc as well as lead, silver, and gold. They are the world's third most important source of copper. They have great historical importance, as the word copper comes from the island of Cyprus where mining of

VHMS deposits dates from the earliest use of metals by prehistoric people. They also have the distinction of being one of the few deposit styles that researchers can directly study while it is forming today.

Important examples include the following:

Kidd Creek	Canada	300 Mt at 9.5% Zn, 1.5% Cu, 0.4% Pb, 130 g/t Ag
Bathurst	Canada	110 Mt at 7.3% Zn, 2.4% Pb, 1% Cu, 65 g/t Ag
Rio Tinto	Spain	500 Mt at 2.5% Zn, 0.8% Pb, 0.7% Cu, 0.8 g/t Au, 30 g/t Ag
Rosebery	Australia	19.4 Mt at 16.2% Zn, 5% Pb, 0.74% Cu, 2.9 g/t Au, 155 g/t Ag

##### B. Distribution and Age

The oldest known deposits of this type are over 3.7 billion years old, and the youngest are forming today. Two styles of VHMS deposits are distinguished, one dominated by copper and zinc, the other by zinc, lead, and copper. Both styles occur throughout the geological record.

Many of the world's Archaean greenstone belt sequences contain copper-zinc VHMS deposits. The Canadian Shield hosts the most important deposits, although many other Archaean provinces also contain deposits. The Proterozoic Churchill province of Canada contains deposits in greenstone belts analogous to the Archaean examples, and similar Proterozoic deposits occur in the USA, Sweden, and Finland. In Paleozoic sequences, there are important copper-zinc VHMS deposits in the Urals of Russia, Newfoundland, and Scandinavia. Mesozoic ophiolites are host to deposits in Cyprus and Oman, and obducted Jurassic ophiolite slabs host deposits in the western United States and South America. Tertiary deposits of this type occur in ophiolites in the Philippines and New Caledonia.

The zinc-lead-copper style is poorly represented in Archaean rocks apart from some small deposits in Western Australia. The largest deposit of this style occurs in the Paleozoic of Canada. Other Paleozoic belts include the deposits of eastern Australia and the Iberian pyrite belt in Spain and Portugal. The most famous deposits in this group are of Miocene age and occur in the Hukuroko district of Japan. These deposits have led to the name Kuroko-type deposits, a synonym for this style of deposits.

### C. Classification of Types

VHMS deposits are typically subdivided in two ways. The first (discussed earlier) considers the proportions of the dominant metals. On this basis we can define two major groups, namely the copper-zinc and zinc-lead-copper deposits. The zinc-lead-copper deposits have felsic rocks (including micaceous sediments) in their underlying sequences, whereas the copper-zinc group has dominantly mafic volcanic rocks beneath them.

The second classification considers the tectonic setting in which the deposits are interpreted to have formed. On this basis we recognize two types of VHMS deposits. The more important formed in subduction settings (volcanic arcs) and are commonly referred to as Kuroko-type. They can be either copper-zinc or zinc-lead-copper deposits. The second type formed at spreading centers and is commonly called Cyprus-type: They are typically copper-zinc deposits.

Morphologically, two broad settings of VHMS deposits can be recognized: (1) proximal, which are thick lens-shaped deposits formed in or around a seafloor hydrothermal vent, and (2) distal, which are sheetlike deposits, possibly formed in depressions peripheral to the hydrothermal vent (Fig. 3).

### D. General Characteristics

Most VHMS deposits show very similar features. The seafloor hydrothermal vent system is represented by an underlying stockwork, overlain by the massive sulfide lens that developed on the seafloor as sulfides precipitated from the venting hydrothermal fluid. Individual deposits vary widely in size and shape, and most mines consist of several closely spaced lenses.

In the copper-zinc deposits, the massive sulfide lenses are dominated by pyrite with pyrrhotite, chalcopyrite, and sphalerite normally forming the other major sulfide minerals. Magnetite is a common accessory mineral, and quartz, chlorite, barite, gypsum and carbonates are the main gangue minerals. Grain size of the minerals and the textures of ores vary widely, depending on the depositional processes and the effects of subsequent recrystallization. Metal ratios in the orebodies commonly are strongly zoned with copper enriched at the base of the deposit, and zinc (and lead) at the top. An extensive thin cherty sedimentary unit containing variable amounts of pyrite or hematite may mark the regional ore-equivalent stratigraphy. This unit, commonly referred to as an exhalite, is believed to form as a chemical sediment mixed with tuffaceous material.

The zinc-lead-copper orebodies represented by the Kuroko deposits also show a mineralogical zonation. The basal part of the orebody comprises a siliceous stockwork containing pyrite and chalcopyrite, interpreted to be the hydrothermal feeder zone. Above this is massive pyrite and chalcopyrite, overlain by layered sphalerite, galena, and chalcopyrite with pyrite and barite. Flanking the massive sulfide body there may be a zone rich in gypsum and anhydrite, which may pass to a zone dominantly composed of barite. Capping the orebody there is typically an exhalative ferruginous chert layer.

Hydrothermal alteration in the rocks that underlie (and sometimes overlie) the copper-zinc deposits is extensive. It takes the form of either discrete pipelike features or broader semiconformable zones. The zinc-lead-copper deposits also show zoned alteration beneath the ore lenses, typically forming a diffuse pipelike zone.

The tectonic setting of ancient deposits is difficult to determine; however, in Phanerozoic sequences, VHMS deposits can be shown to have formed in association

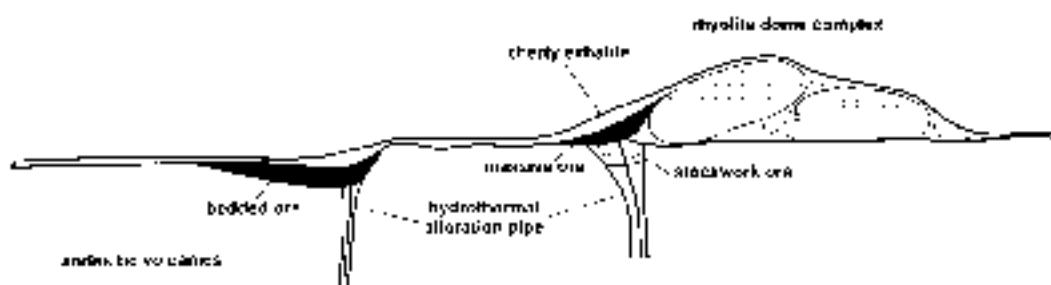

FIGURE 3 Setting of formation of submarine volcanic-hosted massive sulfide deposits. Proximal ores sit directly above the hydrothermal alteration pipe, which represents the pathway along which the ore fluids were introduced to the seafloor. Distal ores occur laterally away from the vent site.

both with spreading ridges and with volcanic arcs. In volcanic arcs the deposits can form within the arc and in backarc basins. The volcanic rocks that are the immediate hosts for VHMS deposits are typically of two types. Bimodal tholeiitic basalt–rhyolite sequences are important copper–zinc hosts in Archaean greenstone sequences, and tholeiitic basalts are copper–zinc hosts in Phanerozoic spreading ridge settings. Differentiated calc-alkaline volcanic sequences are important hosts for zinc–lead–copper deposits.

Many ophiolitic sequences in the geological record have associated Cyprus-type VHMS deposits. These deposits are generally hosted in basaltic pillow lava sequences that are typically several kilometers thick. Active black smoker systems developing at spreading ridges (Mid-Atlantic Ridge, Juan de Fuca Ridge, East Pacific Rise) are forming similar VHMS deposits in a similar geological setting. Actively forming seafloor massive sulfide deposits are also being studied in modern backarc basins with active volcanism (e.g., Okinawa trough); these are modern analogues of the Kuroko deposits.

A very common feature of ore settings is the occurrence of clusters of deposits around felsic eruptive centers. Rhyolitic domes are very commonly associated with VHMS deposits of any age, and of both copper–zinc and zinc–lead–copper type, though the significance of the association is not well understood.

In districts containing VHMS deposits it is very common to find that most (not necessarily all) deposits occur at a single stratigraphic position. This position is commonly related to a pause or change in the character of volcanism or to the end of volcanic activity. In many ore fields it is marked by the occurrence of a regionally extensive exhalite, and most deposits occur immediately under this thin unit. It seems that whatever triggers the formation of VHMS ores commonly does so over an entire district and is likely to produce many individual centers of mineralisation. This provides a useful guide for exploration.

## E. Origin of Deposits

As early as the middle 19th century, French researchers recognized that VHMS deposits formed from seafloor hydrothermal exhalations, and Japanese workers in the early 1920s proposed exhalative origins for the Kuroko deposits. In the 1970s researchers discovered submarine hydrothermal vents depositing base metal sulfides, dramatically confirming what geologists had believed for over a century. Since then, many more sites of submarine

base metal deposition have been found and are being studied to learn about the processes that form these deposits.

Studies of the modern active sites, and of ancient ore deposits, have shown that VHMS deposits form from hydrothermal fluids venting onto the seafloor, precipitating sulfides around the vent. These vent sites are colonized by unique communities of organisms based on the reduced sulfur in the hydrothermal fluid. Some of the ancient VHMS deposits have preserved assemblages of vent fossils, demonstrating the similarity of the environment in both ancient and modern VHMS deposits. Isotopic studies show that the dominant source of the hydrothermal fluids is seawater. Nevertheless, there is still controversy surrounding the source of the ore fluid and the transported metals, and three contrasting models have been proposed.

In one model, downward percolating seawater penetrates the crust, becomes heated by subvolcanic intrusions, leaches metals, and returns to form VHMS deposits on the seafloor. In this model, downward-migrating seawater interacts with massive volumes of underlying rock to produce a metal-bearing fluid. One problem with this model is that the volume of leached rock necessary seems impossibly large to produce some of the huge deposits that exist. However, the observation that the metal content of deposits more closely reflects underlying rock types, rather than the chemistry of closely associated magmatic rocks, supports this model.

A second model proposes that the ore fluids originate from a porous horizon where fluids (in chemical equilibrium with host rocks) were trapped during burial. The brine heated during burial was able to scavenge metals and then be catastrophically released by tectonic activity, with the brine expelled onto the seabed. The third model proposes that the fluids have a magmatic origin. It is proposed for the Kuroko district of Japan because of the close association of the sulfide deposits with rhyolite domes. The presence of very saline (therefore unlike seawater) ore-fluids in some systems supports this model, but the lack of a clear relationship between magma composition and ores does not.

Whatever the ultimate source of the metals and the fluids that introduced them, the character of the depositional environment is clear. Deep water is essential to prevent hydrothermal fluids boiling and precipitating sulfides before they exhale on the seabed. This requires a minimum seawater depth of the order of 500 to 700 m. Deposition in deep water also enhances the chances of preservation, as the deep marine environment favors rapid burial and preservation of these deposits.

## V. DEPOSITS ASSOCIATED WITH CONTINENTAL FLOOD BASALTS

### A. Significance

The world's nickel resources occur as two main types: deposits developed by lateritic weathering of ultramafic rocks (nickel laterite deposits), and nickel sulfide deposits. Although nickel laterites contain huge amounts of nickel, for economic reasons the most important production to date has come from the sulfide deposits, though this may change with the introduction of new extraction technology. There are three main types of nickel sulfide deposits: those associated with layered ultramafic intrusions (principally Sudbury in Canada); those associated with Archaean-age ultramafic volcanic rocks (considered later); and those associated with continental flood basalts.

The nickel sulfide deposits associated with continental flood basalts include some of the largest nickel deposits known. The best known examples are Noril'sk in Russia, Jinchuan in China, and Voisey's Bay in Canada. The great importance of these deposits results from their high grade and relatively low-cost extraction of nickel. In addition they commonly contain significant amounts of other valuable metals, particularly copper and platinum group metals. The immense economic significance of these deposits is indicated by these figures for the three main examples:

Noril'sk, Russia	900 million tonnes	Average grade 2.70% nickel
Jinchuan, China	515 million tonnes	Average grade 1.06% nickel
Voisey's Bay, Canada	>80 million tonnes	Average grade 1.93% nickel

### B. Distribution and Age

Flood basalts are generated by mantle plumes (hot spots) that well up beneath continents and cause arching of the crust, as described earlier. Despite their wide distribution on the Earth, not all flood basalt provinces have nickel sulfide deposits associated with them. Special conditions (discussed later) appear necessary to produce the nickel sulfides, and then to trap and retain them in ore deposits.

### C. General Characteristics

These deposits consist of huge masses composed dominantly (>80% by volume) of sulfide minerals, plus large amounts of disseminated sulfides. The relative proportions of the two styles of mineralization vary widely, with massive mineralization dominant at Noril'sk, but minor at Jinchuan. The principal minerals are pyrrhotite, pentlandite, and chalcopyrite, though there are minor amounts of many other minerals.

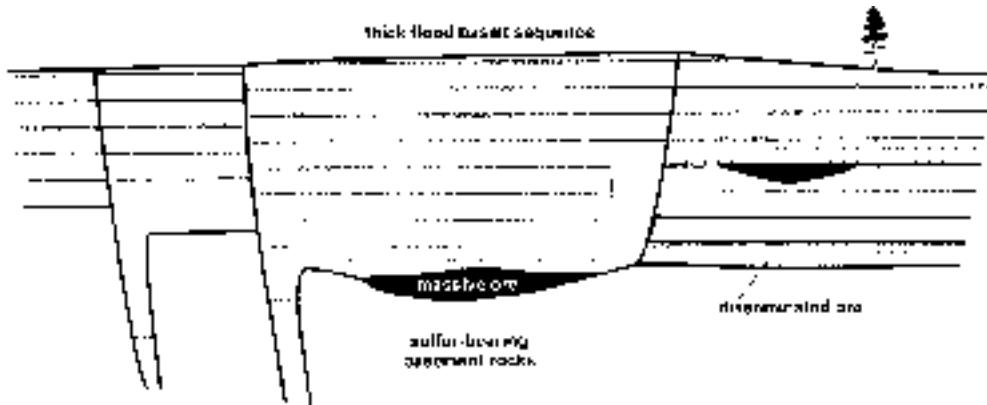

The igneous provinces that host these deposits are typically very large, commonly over 1000 km in diameter. They are mostly made up of tholeiitic rocks, though alkaline volcanic rocks may also be present. An important feature of the volcanic sequence is the presence of picrites and other olivine-rich rocks, indicating high-temperature partial melting.

### D. Origin of Deposits

There is no doubt about the source of the metals in these deposits, as the host rocks contain significant amounts of the metals that form the ores. The key question is how the metals can be carried in the magma, then deposited as sulfides, and the sulfides accumulated. Part of that question is the source of the sulfur.

The largest, best-preserved, and best-studied deposits of this style occur at Noril'sk, in Russia, and most of our understanding of these deposits has developed there. It appears that at Noril'sk a major mantle hot spot developed during late Permian to early Triassic times, and it generated an upwelling plume of mantle material. The overlying crust cracked open along deeply penetrating faults, allowing high-temperature magma to form in response to the pressure drop and ascend to the surface along the faults. The huge flood basalt province known as the Siberian Traps that formed as a result has a volume of over 1.5 million cubic kilometers.

Studies of the chemistry of the Noril'sk volcanic and intrusive rocks show that the earliest-erupted volcanic rocks have lost metals that partition into sulfide minerals (nickel, copper, and platinum group metals). By contrast, the late-erupted lavas show much less depletion. Some of the volcanic rocks show strong evidence for having reacted with sedimentary rocks, as they are severely contaminated with crustal material. The ores are associated with late-stage magmas that were injected as sills and sheets into the base of the volcanic pile and into the basement sedimentary rocks (Fig. 4). Some of the massive nickel and copper ores appear to have injected as melts late in the history of the pile.

**FIGURE 4** Setting of formation of nickel sulfide deposits associated with continental flood basalts. Ores are localized where the dense sulfide droplets can accumulate at the base of a conduit through which magma was flowing to erupt at higher levels.

Our present understanding of the genesis of the sulfide ores at Noril'sk is that interaction of the early magmas with sedimentary rocks caused the melt to become saturated with sulfur. Sulfide droplets formed as a result and, despite their high density, were swept along with the erupting magma. Where the eruptive conduit flattened and had embayments, the sulfides were able to settle out and accumulate, but were regularly swept by successive pulses of magma. This allowed more sulfides to accumulate, but also exposed the early-formed sulfides to more of the metal-rich melt. They progressively scavenged metals from the successive eruptions, so becoming more and more enriched in ore metals.

A key element in our current understanding of these deposits is the need for well-established magma flow paths, so that very large volumes of magma flow along the same conduits. In this way sulfides in these conduits can be exposed to huge volumes of magma in successive pulses. It is also important that the geometry of the conduit allow the dense sulfide droplets that settle to be trapped, rather than drain back down into the lower crust or mantle.

The huge scale of sulfide entrapment in these deposits is illustrated at Taldnakh (Noril'sk). There the massive ore zone covers an area 1 km by 3 km, with a thickness of greater than 20 m. Its grade averages 3.72% nickel and 3.78% copper with high platinum and palladium values. At Voisey's Bay the Ovoid is a pod of massive sulfide 600 m long by 350 m wide, with a thickness up to a maximum of 110 m.

At both Voisey's Bay and Jinchuan the nickel orebodies are preserved within Precambrian-age intrusive rocks. The general scenario involved in forming the ores is strikingly similar to that at Noril'sk, so a similar origin seems very probable. The mass and grade of the sulfides

present demands that a far greater volume of magma than is now preserved in the associated intrusions had to be involved, so it seems inescapable that the extra magma required must have erupted to form flood basalts that have since been eroded away.

---

## VI. NICKEL SULFIDE DEPOSITS ASSOCIATED WITH KOMATIITIC LAVAS

### A. Significance

Komatiites form a suite of igneous rocks, the most characteristic representatives of which are ultramafic (i.e., low silica, high magnesia) volcanic rocks. They host the Kambalda-type nickel deposits that are responsible for over 10% of historic nickel production from sulfide deposits, and substantial reserves remain. Although individual deposits are typically small, their grade is high, which can make them economically significant. The Kambalda camp consists of many individual deposits and contains an aggregate 25 million tonnes of ore averaging 3.5% nickel.

### B. Distribution and Age

Komatiites are mainly restricted to greenstone belts, which consist of volcanic and sedimentary rocks of Precambrian age. Although komatiites are very rare after the Precambrian, there are some much younger ones found in Colombia, and very similar high magnesia lavas

(boninites) of late Cretaceous age occur in Colombia and Costa Rica. The komatiite-hosted nickel sulfide deposits are mostly mid to late Archaean in age, with the best known examples from the greenstone belts of Western Australia, notably Kambalda, but good examples occur in Zimbabwe and Canada, and deposits are also recorded in Brazil and Russia. Some younger rocks (early Proterozoic age) host similar deposits in Canada. Older (early Archean) sequences in southern Africa and the Pilbara region of Western Australia contain only a few minor deposits, and younger (post-early Proterozoic) sequences do not contain deposits of this style. This limited range in age seems to be related to a stage in the evolution of the Earth.

### C. General Characteristics

Deposits of this type show distinctive characteristics, both in their ores and in their host rocks. The nickel sulfide orebodies consist of variable amounts of massive and matrix or disseminated ores hosted by ultramafic komatiites. They have been subdivided into stratiform and stratabound types.

Stratiform deposits typically occur as tabular or ribbon-shaped bodies, situated at the base of the host units (Fig. 5). They have dimensions from a few hundred meters to 5 km in length, but mostly the stratigraphic thickness of the sulfide zone is less than 10 m, with distinct lower and upper contacts. Massive and matrix sulfides are present at the base of the host unit, and there is usually an abrupt boundary between the massive and matrix sulfide. Disseminated sulfides overlie the matrix sulfides. In some cases the orebodies show marked elongation parallel to the regional volcanic or tectonic grain; these orebodies are believed to have formed at the base of relatively thin flows.

Stratabound mineralization is not confined to the base of ultramafic units, but can be distributed through the lower to central portion of the host unit. The shape and size of these deposits are more difficult to quantify because of their diffuse, gradational character; the margins are defined by economic grades. Broadly, they have oblate to elongate lens shapes, depending on the shape and size of the host unit. Dimensions are generally much larger than equivalent stratiform deposits, particularly stratigraphic thickness, which may be up to several hundred meters. Stratabound deposits consist of disseminated or blebby mineralization, with rare local accumulations of matrix sulfide. These orebodies are believed to have formed in very thick lava flows or large feeder dykes.

Primary magmatic sulfide minerals characterize most komatiite-hosted nickel deposits, with dominant pyrrhotite and pentlandite. Chalcopyrite, pyrite, and chromeite are the other principal minerals present. Copper, cobalt, and the platinum-group elements are minor components of the mineralization.

The nickel sulfide ore deposits are always found in komatiitic host rocks that are part of mafic-ultramafic volcanic sequences. These commonly occur in the lower to central parts of the greenstone stratigraphy, with the komatiites overlying apparently unrelated thick tholeiitic basalt sequences. The normal hosts for komatiite-associated nickel deposits are ultramafic olivine cumulates, metamorphosed to serpentinite or talc-carbonate rock. Ultramafic lavas differentiate strongly during eruption, largely because of fractionation and accumulation of olivine at the base of flows. The magnesia content ranges from 50% in the olivine adcumulates at the base to 15% or less in the upper parts of flows; ores only occur with the most magnesia-rich parts.

The thickness and composition of the host flows vary widely. Thick cumulate sections are closely associated with ores and may represent near-vent sequences, or

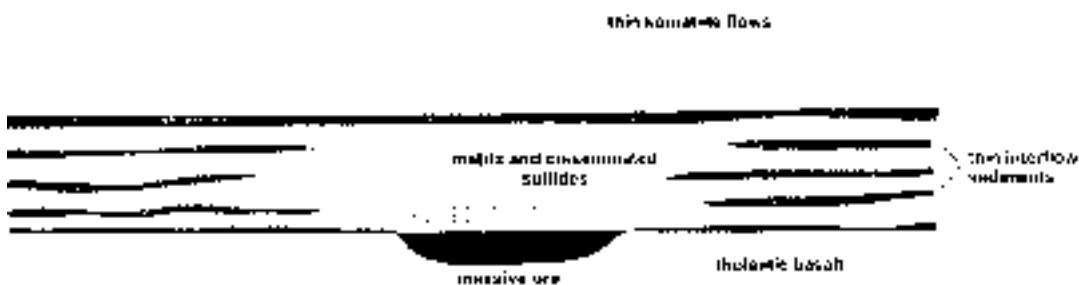

FIGURE 5 Setting of nickel sulfide deposits associated with komatiite lavas. Above ore the character of the host volcanic sequence is markedly different from other areas, which is an important guide in exploration for these deposits.

else deep lava channels. These thick sections have their upper contacts marked by flow top breccias and chill zones passing down to a zone with distinctive spinifex-textured skeletal olivine crystals. This then passes down to crystal-rich cumulate sections of dunite or peridotite (commonly more than 100 m thick), at the base of which the ores occur.

Sections of flows overlying or laterally equivalent to sections containing ores are distinctly different from the ore-bearing sections, having numerous thinner flows and an absence of thick olivine-rich cumulates. These sections of thin komatiites or komatiitic basalts are typically completely barren of nickel sulfides. This suggests that the conditions of formation for mineralized and unmineralized flow units were markedly different. The restriction of sulfide concentrations to the base of distinctive, anomalously thick olivine accumulations is an important guide in exploration, and the clear textural zoning across individual flow units allows detailed mapping, which assists in recognition of favorable sites for mineralization. On a regional scale clustering of deposits is common.

#### D. Origin of Deposits

Models for the formation of the sulfide deposits have varied widely, but researchers now favor magmatic processes for formation of these deposits. Both nickel and sulfur in the deposits appear to have a primary mantle source. The silicate and platinum group element geochemistry of komatiite lavas indicates that the parent magmas had a high sulfur capacity and were undersaturated in sulfur at depth in the mantle. It seems that the sulfur saturation occurred upon ascent, but only near the surface, allowing accumulation of sulfides in the lava flows.

Sulfur saturation could have resulted from cooling of the magma, from mixing of magmas, or from contamination of the magma with chemically distinct wallrocks. The addition of silica or sulfur, or reducing agents (such as carbon), can significantly lower the solubility of sulfur in a mafic magma, which leads to the separation of an immiscible sulfide melt.

In the past decade some major advances in the study of komatiites have been achieved through consideration of the physical properties of the melts and the consequent fluid dynamic and volcanological implications. Komatiite magmas must have ascended through the crust rather rapidly. The low viscosity and high temperature of a komatiite melt would result in turbulent flow, both during ascent and after eruption. Turbulence

would have allowed rapid transfer of heat from the magma to adjacent rocks, which could melt and be incorporated in the magma. Melting of and incorporation of underlying rocks is the favored mechanism for inducing sulfur saturation and sulfide accumulation in komatiite lavas. Careful mapping by geologists at Kambalda showed that the sulfide-hosting komatiites embayed the underlying rocks. Also in the Kambalda area, rare felsic ocelli found at the upper margins of ore-hosting flows are believed to be remnants of molten sediments in the process of being assimilated into the melt, and subtle geochemical evidence of assimilation of sediments is also recognized. This fits with the observation that siliceous, sulfidic, and carbonaceous sediments are common between flows regionally, but are absent in the immediate area of the orebodies.

---

## VII. DIAMOND DEPOSITS

### A. Significance

Annual sales of uncut diamonds are about \$5 billion per year (many times higher when converted to jewelry), making them one of the world's most valued commodities. They have a unique relationship to volcanism: Without volcanism there would be no diamond deposits, yet there is no direct genetic relationship between diamonds and the volcanic rocks that host them.

### B. Distribution and Age

Diamonds occur widely around the world; however, most occurrences are very minor and result from the great durability of diamonds. They probably eroded from their original source and deposited in sedimentary rocks, then eroded from those and recycled again, perhaps many times, in the process becoming widely dispersed. These widespread occurrences are mineralogical curiosities and generally do not produce deposits of economic significance.

The major diamond-producing regions of the world are in southern Africa (South Africa, Botswana, Angola), Russia (Siberia), and Western Australia. Other important diamond-producing areas are Brazil, China, and West Africa, and a major new field has recently commenced production in Canada. Because every diamond is unique, it is not possible to describe deposits simply in terms of tonnage and grade. Some deposits produce few carats, but their average value is very high, whereas

other deposits produce many carats but their average value is low. This makes it very difficult to assess the economics of mining a diamond deposit.

Economic diamond deposits occur with volcanic centers of unusual, very alkaline volcanic and subvolcanic intrusive rocks, called kimberlites and lamproites. Important economic deposits can also form by erosion of these primary deposits and accumulation of the diamonds in river and coastal marine placer deposits.

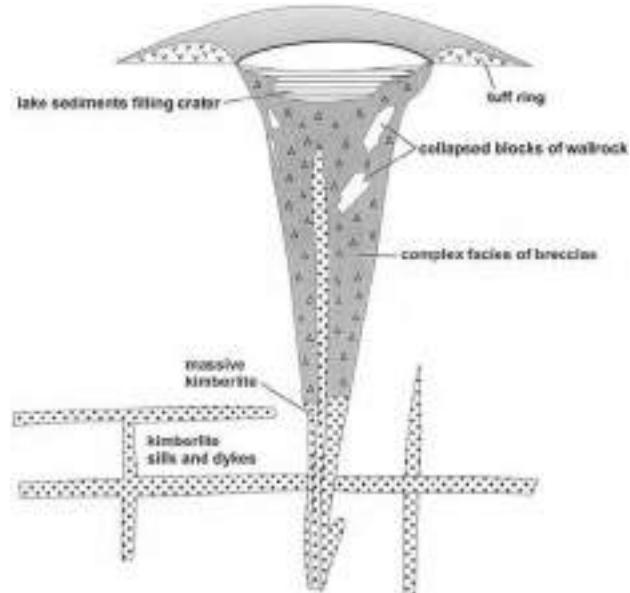

Kimberlites and lamproites are widespread though volumetrically very minor volcanic rocks, and in most cases they do not contain diamonds. Diamond-bearing kimberlites and lamproites only occur around the margins of, or within, stable cratonic blocks that have not undergone major deformation or metamorphism. Productive kimberlites (there is presently only one lamproite-hosted diamond deposit being mined) vary widely in age from Precambrian to Mesozoic. It is probable that the process that brings diamonds to the surface has gone on throughout geological time (and is continuing). Whether an economic deposit occurs depends on a number of factors, including the depth of erosion that has occurred since eruption of the volcanic host.

### C. General Characteristics

Both kimberlites and lamproites are formed from very volatile-rich magmas that are generated at great depth in the earth (about 200 km for lamproites, 200–300 km for kimberlites). Kimberlites are more gas-charged (with carbon dioxide) than lamproites, so they have a more distinctive mode of occurrence. In both cases they occur as dykes, sills, and minor plugs formed at depths of several kilometers; however, these are generally small and so cannot provide the tonnage required for an economic deposit.

Kimberlite magma expands rapidly as it approaches the surface of the Earth because of its high gas content, producing a deep conical explosion crater or diatreme (Fig. 6). Depending on the magma supply and depth of exposure, these so-called pipes typically range from 50 to 500 m in diameter. Characteristic facies occur at different levels. The diatreme facies consists of fragmented wall rocks and material brought up from deep below. The maar facies contains bedded material that fell back into the crater after eruption. The crater facies includes finely bedded ash and crater-lake sediments, locally containing fossils. The pyroclastic facies forms as a tuff ring around the vent. All facies can contain diamonds, though the grade usually varies widely.

The shape of kimberlite pipes is typically steeply coni-

**FIGURE 6** Cross-section through a kimberlite diatreme or pipe. Rapid expansion of the kimberlite magma near the surface produces the pipe. Within it there are different breccia facies composed of varying proportions of intrusive kimberlite, kimberlitic tuff, and wallrock fragments. Near the surface a crater lake may have formed and filled with fine lake sediments, redeposited tuff, and eroded wallrocks.

cal, rather like a carrot. Lamproites, by contrast, form conical to irregular bodies that commonly do not continue to great depth.

### D. Origin of Deposits

There is no genetic relationship between diamonds and their host volcanic rocks. Diamonds are xenocrysts ripped off the walls of the vent as the magma rose. The reason for the characteristic association between diamonds and kimberlite and lamproite magmas is very simple: These two magma types are generated very deep, so they have to rise through the diamond-bearing levels of the Earth and so may bring diamonds up with them. Other magmas are generated at depths that are above where diamonds occur, and so they are not capable of bringing them up.

Studies of small mineral grains sometimes found inside diamond crystals led to recognition of three types of diamonds, two derived from the Earth's mantle, and one from the crust. The deepest diamonds occur with garnet lherzolite within the asthenospheric mantle. From shallower depths there are diamonds that occur with garnet lherzolite or garnet harzburgite within the

lithospheric mantle. Diamonds of crustal origin may occur between the level of these two types of mantle diamonds. They occur in eclogite, which formed by high-pressure metamorphism of a subducted slab of oceanic crust. Under conditions of moderate temperature but extremely high pressure, any carbon remaining in the subducted slab must convert to diamond, and the broken-off slabs may accumulate below cratonic blocks along the lithosphere–asthenosphere boundary.

The upper limit of diamond stability depends on pressure and temperature. The higher the temperature, the higher the pressure required for diamond to remain stable, hence the deeper the boundary between regions of diamond stability and graphite stability. Only in the cool, deep ancient roots of continents that have not been deformed or metamorphosed are there sufficient diamonds at shallow enough depths to be brought up by magmatism. Most magmas are generated at relatively shallow depths in regions of graphite stability, and so are not capable of bringing diamonds to the surface. Only kimberlites and lamproites are generated below the level of diamond stability, which is why the largely accidental relationship between diamonds and kimberlites and lamproites is so important.

---

### VIII. THE STATE OF KNOWLEDGE AND FUTURE RESEARCH

Ore deposits have received a great amount of research attention because of their economic importance. However, in most cases we are forced to interpret their origin from the faint traces of evidence left long after the processes have ceased. The major exceptions to that are for VHMS deposits, which can be seen forming today on the seafloor, and epithermal deposits, which formed beneath geothermal systems similar to ones now active.

A major consequence of this is that many of our beliefs are based on limited evidence, and so new evidence can force major changes: There is still a great deal for us to learn. Of recent years there are two major controversies that keep recurring in research into ore deposits: (1) From where are the metals derived, and (2) what determines whether a major deposit forms, or just a minor occurrence?

The source of metals is relatively clear for the magmatic nickel deposits, which are only found with nickel-rich magmatic rocks, but in all cases of hydrothermal

ore deposits, the source for the metals is far from clear. In porphyry deposits the weight of evidence favors a source in the associated magmas, but some systems suggest involvement of other sources. In the case of VHMS and epithermal deposits the source of metals is uncertain. There are two schools of researchers, one that favors magmatic sources, and another that believes that a magmatic source is not essential, based on knowledge of the related fluids and the processes believed to have formed the deposits. The debate arises from the fact that we have no reliable means of tracing metal sources except for lead, so we need to rely on inference from the geochemistry of other elements that can be modeled (such as isotopes of hydrogen and oxygen).

Even as our insights into the processes that form deposits improve, we are still left with the problem of what determines whether a great deposit forms, or just an ordinary one. For all deposits there are processes that occur far from the deposit in the source region, along the transport path, and in the region of deposition. What is the relative importance of these? Are there recognizable systematic controls that determine that a giant deposit forms, or is it the accidental consequence of essentially random processes? We simply do not have answers for these fundamental questions, which could have immense economic importance if we could predict where the major metal resources of the Earth will occur. Because of the immense scope for discovery of new insights into ore deposits, and the potential for them to be of great economic importance, the future for ore deposit research should be assured.

# VOLCANIC HAZARDS

Volcanic eruptions are major natural hazards on Earth. The hazard from a volcanic eruption depends on the type of volcano, time since the last eruption of that volcano, geographical location, local climate, and time of year. The longer a volcano is dormant between eruptions, the larger the eruption tends to be. Thus, while Kilauea (Hawaii) and Etna (Sicily) are active volcanoes that erupt almost continuously, the direct risk to humans from their eruptions is negligible. The risk to property and the environment is not diminished, however. In this section, the various types of hazards posed by volcanoes are discussed mostly from the point of view of their effects on people and the environment. The processes that give rise to these hazards are discussed in Part III (Effusive Volcanism) and Part IV (Explosive Volcanism).

The location and timing of a volcanic event affect the risk, as wind direction and strength in the upper atmosphere vary with latitude and season, so that ash from an explosive eruption might be transported around the globe at one time but remain confined to a small region at another time. The area affected by volcanic activity may range up to several tens of square kilometers, depending on the eruption type. For example, lavas may flow between 1 m to 30 km per hour for distances of several tens of kilometers. Explosive eruptions may eject large quantities (0.1 to 100's of km<sup>3</sup>) of volcanic ash into the atmosphere, much of which falls out locally. The collapse of an explosive eruption column may form a glowing cloud of volcanic debris (nuees ardentes) or pyroclastic flows. Most eruptions are accompanied by sulfur dioxide gas release. This may escape into the upper atmosphere to form a volcanic aerosol that can have global consequences, or it may combine with water vapor at lower elevations and form aerosols that cause local acid rain. Eruptions occurring on volcanic islands or close to the sea may produce tsunamis (tidal waves)

with devastating effects reaching tens or even hundreds of kilometers.

Passenger airliners that encounter volcanic ash clouds are subject to complete engine failure, which can have catastrophic effects. The first chapter of this section, *Volcanic Ash Hazards to Aviation*, documents several cases of eruption-induced aviation incidents and explains why this hazard is becoming increasingly important.

The release of gases to the atmosphere is one of the hazards associated with volcanic eruptions. The several million tons of gases released during large eruptions can be of global significance. Etna volcano (Sicily) emits about 13 Mt of CO<sub>2</sub> per year, equivalent to a 1000-MW coal-fired power station in terms of greenhouse gas production. Etna also produces some 1.4 Mt of SO<sub>2</sub> per year. The 1991 eruption of Pinatubo (Philippines) ejected 15 Mt of SO<sub>2</sub>, causing surface temperatures to fall globally by about 0.1° C. The aerosol formed from this gas contributes to global cooling by absorbing incoming solar radiation. The next chapter, *Volcanic Aerosol and Global Atmospheric Effects*, documents unusual climatic features caused by volcanic eruptions as far back as the 17th century B.C.

The following chapter, *Hazards from Pyroclastic Flows and Surges*, illustrates the power of pyroclastic flows and surges to devastate whole communities. The speed and great extent of pyroclastic flows make them by far the greatest and most lethal volcanic hazard. Lava flows represent a much more sedate volcanic eruption process, but the effects, as the chapter *Lava Flow Hazards* demonstrates, are still significant.

Volcanic eruptions can trigger secondary events if significant quantities of groundwater, snow, or ice are involved. Risk may then extend beyond the immediate region of the eruption. A relatively minor eruption of Nevado del Ruiz (Colombia, 1985) resulted in the loss of 23,000 lives as the glacier on the top of the volcano melted. Water flowed down the river valleys, removing the loose material from the banks, and the muddy torrent rushed downslope at 30 km per hour to cover the village of Armero to a depth of 3 m. A similar muddy torrent (lahar) resulted in the death of about 900 people after the eruption of Mount Pinatubo in 1992. The Hazard from Lahars and Jökulhlaups illustrates how these devastating events can continue to occur even without further volcanic activity, sometimes for decades after the eruption has ceased.

The next chapter, *Hazards of Volcanic Gases*, illustrates the effects that various volcanic gases have on people, but perhaps more importantly when these gases fall as acid aerosols on crops, vegetation, and communities downwind. Persistent gas release may cause asphyxiation

by inhalation locally and asthma more regionally. Acid rain may also produce skin disorders. All these phenomena are devastating to wildlife and farmland for the duration of the eruption and sometimes far longer.

Most of the world's volcanoes are below the sea, and many are located in coastal areas. Explosion or collapse of a volcano can therefore often cause a large body of water to move suddenly, creating a tsunami. The chapter *Volcanic Tsunamis* presents several mechanisms that are thought to produce tsunamis and shows that in the last 250 years some 25% of volcano related fatalities have been attributed to tsunamis.

Volcanic earthquakes have different characteristics from the deep and tectonic seismic events that occur along great faults. They are considerably less devastating and may continue at a detectable level for weeks or months prior to eruption. As the chapter *Volcanic Seismicity* demonstrates, they are the most important window to the processes going on inside a volcano before eruption, and their study has considerable scientific value and application to risk mitigation.

As human populations continue to grow and expand, many people live close to active or potentially active volcanoes. The chapter *Impacts of Eruptions on Human Health* presents a graphic account of the nature of injuries and the cause of death from various types of eruptions. On a more global scale, the next chapter discusses the origin and fate of carbon and sulfur from volcanic sources and the implications for climate. Following this, the chapter *Ecology of Volcanoes* considers the various effects of volcanic activity on plant and animal communities. It is striking how resilient life is in the face of volcanic activity. Eruptions do not completely eradicate life and many species survive; even newly formed volcanic islands soon become home to a wide range of opportunists.

A look back through the geological record reveals considerable evidence for huge eruptions. If we scale up the observed effects of recent eruptions, the global consequences of large eruptions are awesome. The concluding chapter of this section, *Volcanism and Biotic Extinctions*, provides compelling evidence for a correlation between mass extinctions and the largest basalt lava flows on Earth. Whether these flood basalts, mass extinctions, and asteroid impacts are related in some way is a matter of ongoing debate.

Thus, volcanic hazards have always impinged on life and the environment, and an understanding of their past and present effects is vital for effective monitoring, prediction, and mitigation.

**J**EET AIRCRAFT ENCOUNTERS with airborne volcanic ash between 1980 and 1998 caused more than U.S. \$250 million in damages to engines, avionics, and airframes not only in areas proximal to erupting volcanoes but at distances of up to 3000 km away. Loss of life was narrowly and fortuitously averted following sudden multiple engine loss to individual aircraft during major eruptions in Indonesia, Alaska, and the Philippines. The hazard is compounded by the development of large (wide-body) jet aircraft whose engines operate at such high temperatures as to make them even more susceptible to damage by volcanic ash. Increasing commercial air traffic worldwide, and the post-cold war opening of heavily traveled air routes close to active volcanoes, add to the problem (Figure 1). Volcanologists, the airline industry, and government officials have only recently recognized the seriousness of this newly emerging hazard.

---

## I. HAZARD

Volcanic ash clouds are not detectable by aircraft radar and often not easily visible; complete avoidance of volca-

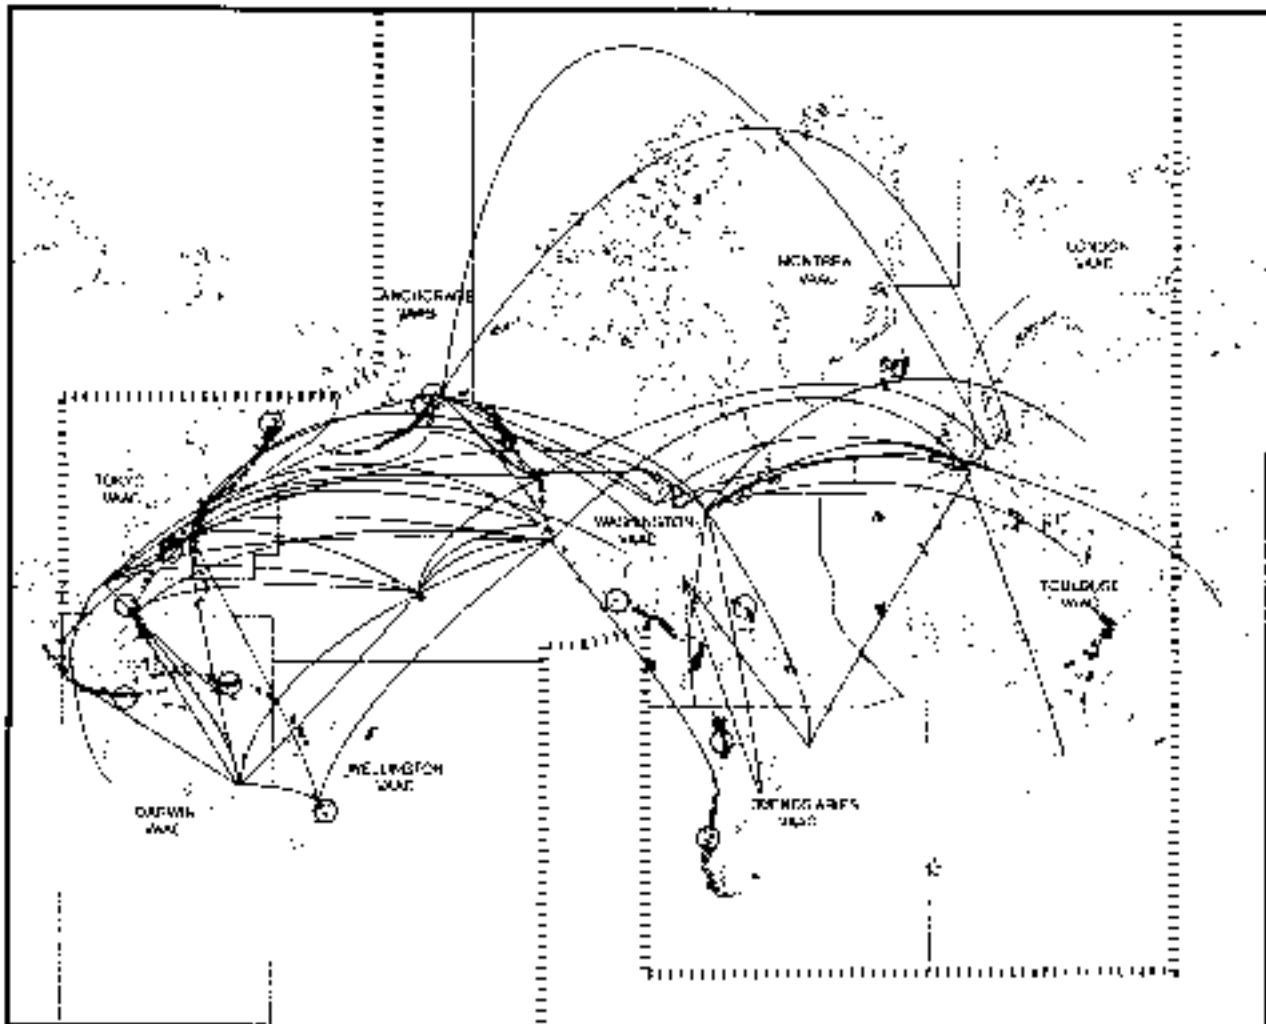

FIGURE 1 A world map of active volcanoes, principal air routes (modified from Casadevall and Thompson, 1995), and the areas of responsibility of individual Volcanic Ash Advisory Centers (VAACs). VAACs are located in Montreal (Canada); Anchorage, Alaska (USA); Washington, DC (USA); Buenos Aires (Argentina); London (England); Toulouse (France); Darwin (Australia); Wellington (New Zealand); and Tokyo (Japan). Open circles indicate volcanoes that produced ash clouds that damaged aircraft or disrupted air traffic between 1990 and 1999. Note that areas outside hatched boundaries in northern Russia, the central Atlantic Ocean, and the Indian Ocean are not presently covered by a VAAC.

nic ash clouds is considered the only procedure that guarantees flight safety from airborne volcanic ash. Increasing international cooperation between volcanologists, meteorologists, airline dispatchers and pilots, and government aviation groups, a hitherto unlikely combination of disciplines, produced a series of actions to lessen this hazard.

Volcanic ash is composed of fine-grained rock and mineral fragments and glass shards, commonly with acid droplets coating the ash-grain surfaces. The properties of the ash depend mostly on the relative proportions of

their main constituents. Ash results from fragmentation of foamy magma (following decompression) and of country rock (during rapid expansion of steam) and from explosive mixing of magma with water. Shard shapes and sizes depend upon the shape and size of gas bubbles in the magma immediately before eruption and fragmentation of the magma. Particle sizes range from several meters across for large proximal blocks to micron and submicron sizes for fine ash and aerosol droplets within distal eruption plumes. Particle size in ash clouds away from the volcano is usually less than 0.5 mm.

## THE 1991 PINATUBO ERUPTIONS AND THEIR EFFECTS ON AIRCRAFT OPERATIONS

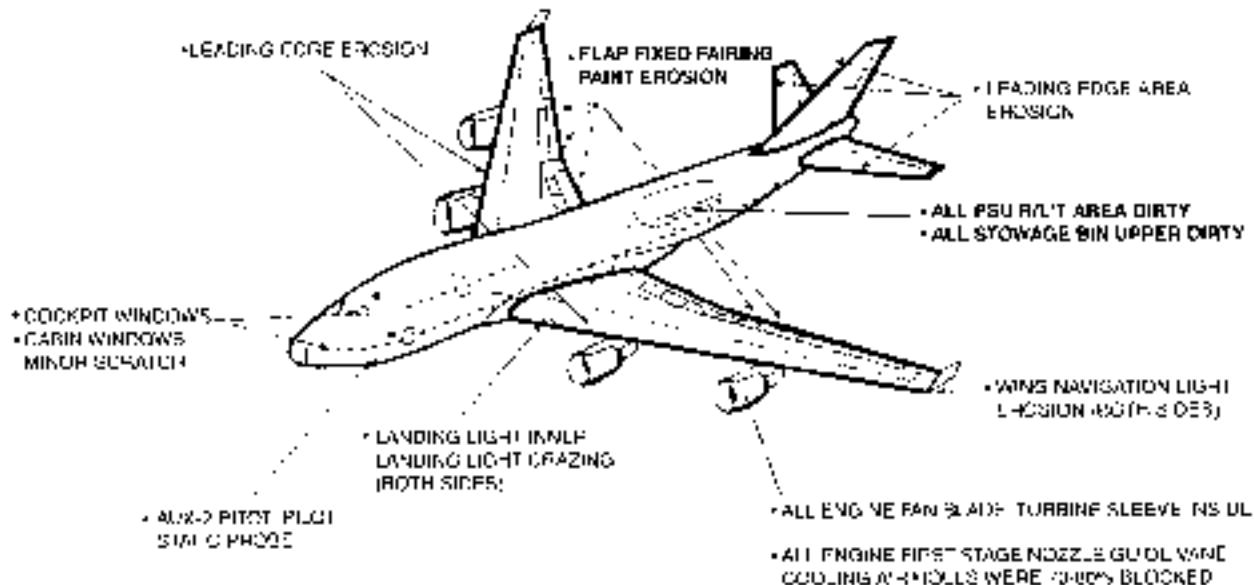

FIGURE 2 Damage to exterior surface of a 747-400 jumbo jet following an encounter with the June 15, 1991, ash cloud from Mount Pinatubo volcano in the Philippines [from Casadevall et al., 1996]. Damage of this type is typical of encounters between jet aircraft and airborne volcanic ash.

Although volcanic ash is produced to at least some degree in most eruptions, it is generally silicic magmatic eruptions as opposed to effusive basaltic, hydromagmatic, or phreatic eruptions that constitute the chief hazard to aviation.

### A. Damage and Impact

When a jetliner flying in excess of 840 km/hour enters a cloud of finely fragmented rock particles and acid gases, the principal damage will be abrasion of the exterior forward-facing surfaces and accumulation of ash into surface openings, including engines (Figure 2). The hardness and angularity of the ash fragments often cause complete frosting of windshield surfaces and further damage to the onboard avionics and fuselage surfaces. Ingestion of ash into the engines causes abrasion damage, especially to compressor fan blades.

Numerous examples of engine failure, complete loss of visibility, and loss of critical navigational and operational instruments have occurred in volcanic ash and aircraft encounters around the world (Table I). The primary problem centers around the composition (and hence the melting point), hardness, and abrasive charac-

ter of ash's constituents. Volcanic glass in the ash has melting temperatures that lie within the operating temperatures (in excess of 700°C) of modern large jet engines. Hence ingestion of volcanic ash in a jet engine can result in melting and accumulation of resolidified

TABLE I Volcanic Eruptions in the 1990s That Caused Damage or Significantly Affected Aircraft Operations around the World

Popocatepetl	Mexico	1996–1998

ash on turbine nozzle guide vanes in the engine (Figure 3), causing compressor stall and, in the worst cases, complete loss of engine thrust. Studies of ash deposits that caused engines to stop operating reveal that volcanic ash melts and accumulates more commonly when engines are operated at maximum power during takeoff

or climb than at cruise altitudes. Recognition of this condition resulted in these manufacturer operational recommendations for pilot response when an ash cloud is inadvertently entered: a pilot should not attempt to climb out of a cloud but should reduce power and quickly exit the cloud by turning 180°. This and other similar

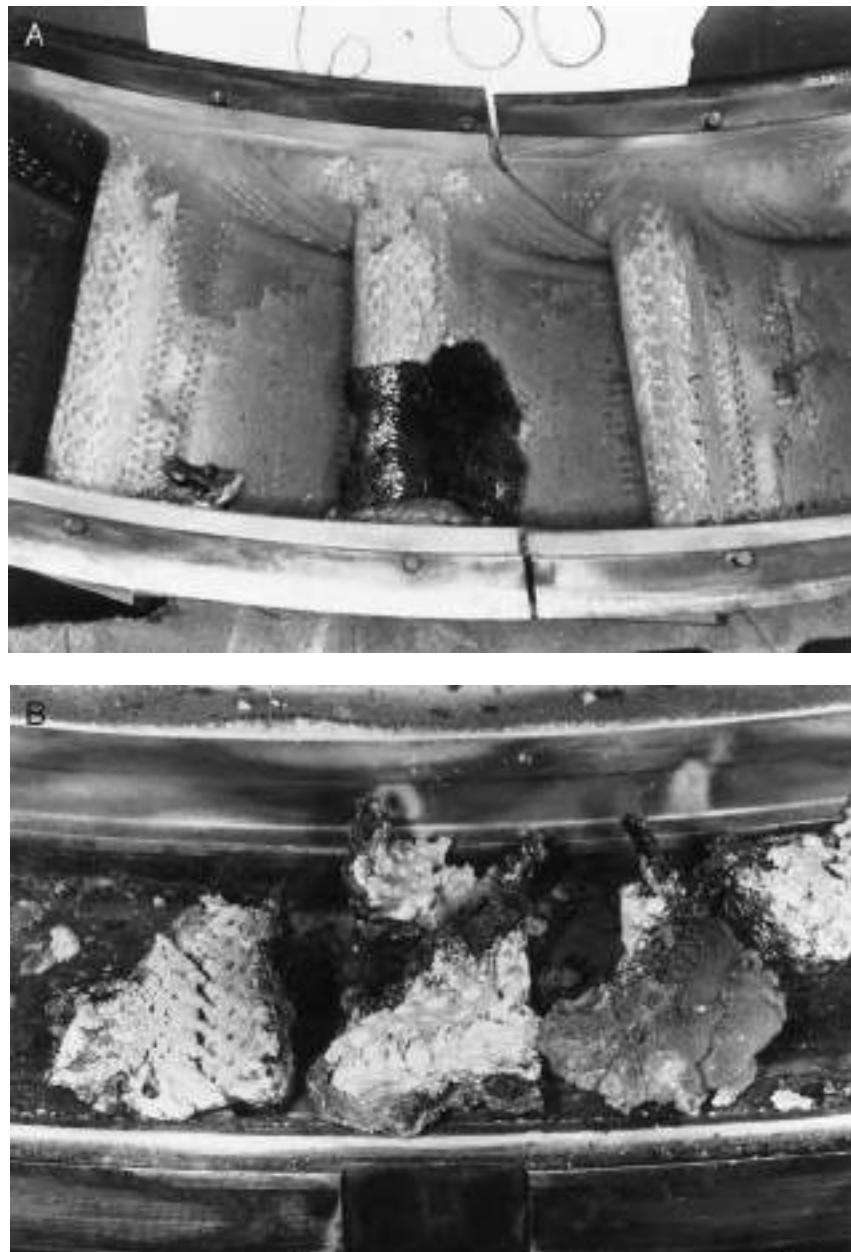

FIGURE 3 Examples of remelted volcanic ash in jet engines following the encounter of a 747-400 with airborne volcanic ash from the Redoubt eruption of December 15, 1989 (Przedpelski and Casadevall, 1994). (B) Leading-edge deposits dislodged during disassembly of high-pressure-turbine nozzle guide vanes.

recommendations have been included in official Operations Manual Bulletins. A number of airline companies worldwide began including ash-avoidance training for their pilots in the 1990s.

Eruptions which release very large amounts of sulfur dioxide, such as El Chichon (1982) and Mount Pinatubo (1991) in the Philippines, have caused longer-term damage through crazing of acrylic windows. A year after the Mount Pinatubo eruption in June of 1992, a jumbo jet suffered engine power loss that was traced to an accumulation of sulfate deposits in the engines. Isotopic studies suggested that the sulfate was derived from SO<sub>2</sub> and sulfuric acid aerosols that originated from the Mount Pinatubo eruption.

Volcanic ash can have an important economic impact on aviation without causing direct damage to aircraft or facilities. The mere possibility of jet aircraft flying into a volcanic ash cloud and its potential risk to life and property or the possibility of "trapping" an aircraft at an ash-bound airport for up to several days is enough to cause widespread cancellations, rerouting of aircraft, and decreasing payload by adding fuel.

Besides affecting in-flight operations, volcanic ash presents other threats to aviation as it eventually settles to the ground and affects airport runways, taxiways and aprons, buildings, ground services, electrical utilities, communication facilities, and aircraft parked on the ground. The characteristics of volcanic ash that are dangerous to aircraft in flight (high glass content, hardness, and abrasiveness) cause problems on the ground. Recently deposited fine ash is easily entrained in the air by wind or vehicle movement (e.g., taxiing aircraft), and can rapidly contaminate parked aircraft and the ancillary operations necessary to support them at the airport.

Generally airports have been unprepared for handling of even minor amounts of volcanic ash and each incident has been a learning experience for the individual airport. However, while volcanic ashfall at an airport may be considered a relatively rare event, the increase in commercial aviation in the Pacific region means that the closing of an airport for any length of time causes major air traffic disruptions and has serious economic ramifications. Between 1980 and 1998, over 35 airports in 11 countries (USA, Japan, New Zealand, Mexico, Guatemala, Colombia, Argentina, Indonesia, Papua New Guinea, Philippines, and the Falkland Islands) have been closed or had operations severely impacted because of ashfalls that were as light as 3 mm.

Airport managers have gradually developed mitigation procedures that include rapid communication; handling of deposited ash (moving it as few times as possible) using plows, water, and emulsions; shutting down of

nonessential equipment, and restriction of on-the-ground aircraft movement. In spite of these procedures developed by trial and error, aircraft caught on the ground during an ashfall have been trapped for days in some cases until the ash has stabilized and the aircraft decontaminated. A Boeing 767, for example, was stranded at Manila airport for 6 days during the Mount Pinatubo eruption due to ash contamination. This situation points out the importance of advance warning of an impending ash cloud so as to move aircraft out of the impacted area.

## B. Chronology and Case Histories

Volcanic ash is harmful to the mechanical parts of any engine, be it reciprocating or jet, and numerous accounts of damage to aircraft from volcanic ash have been reported since the first airplane flight in 1903. Prior to about 1975, events were minor and typically consisted of abrasion of windshields and leading wing edges. The ingestion of sharp abrasive particles into reciprocating engines was certainly harmful but neither the frequency of incidents nor the damage done was sufficiently high to merit much concern in the aviation community. Economic losses were small and encounters of piston-engine aircraft with volcanic ash were regarded more as interesting oddities than hazards of significant import. Probably the most serious incident occurred during World War II when 88 U.S. B-25 Mitchell bombers parked on airfields near Mount Vesuvius had to be scrapped after their fabric control surfaces were burned off and all clear plexiglas was crazed following ashfall from the volcano in March 1944.

The advent of widespread use of jet aircraft, particularly large so-called "wide-body" types such as Boeing 747s, DC-10s, and MD-11s, with their high-operating-temperature engines, exposed the extent of the hazard presented to modern aviation by airborne volcanic ash. By the late 1970s, several jet aircraft had flown into volcanic ash clouds in Japan and Alaska but the damage sustained was still minor and primarily to surface edges. The 1980 eruption of Mount St. Helens in Washington marked a threshold in the recognition of the seriousness of the hazard posed by airborne volcanic ash. During this eruption, a four-engine (turboprop) C-130 lost two engines while climbing through an ash cloud at 3400 m above sea level and suffered damage to the remaining two engines; total damage amounted to about U.S. \$500,000. In addition, numerous other aircraft suffered minor surface damage.

Between 1980 and 1999, more than 100 jet airliners were known to have sustained at least some damage after having flown through volcanic ash clouds. Although at least eight different types of aircraft were involved in these incidents, the most severe damage occurred to wide-body (747, DC-10, MD-11, etc.), or jumbo, jets. Wide-body aircraft began to enter commercial service in large numbers in the early 1980s and the number and severity of volcanic ash encounters slowly began to grow. In at least eight instances, one or more engines were lost; in three incidents, all four engines were lost. Examining five of the more consequential incidents between 1982 and 1994 in chronological order illustrates both the increasing severity of the problem and the efforts to mitigate it.

In June 1982, a British Airway Boeing 747 with 240 passengers on board unexpectedly penetrated an ash cloud 150 km west-southwest of Galunggung volcano in Indonesia at 11,300 m ASL (above sea level) and lost power in all four engines. The aircraft lost 7500 m of altitude in 16 minutes before restarting the engines and making a safe emergency landing in Jakarta. Soon after, in mid-July 1982, a Singapore Airlines Boeing 747 with 230 passengers at 9000 m ASL lost three engines in an ash cloud from the same volcano. The aircraft was able to get one engine restarted after losing 2400 m of altitude and make an emergency landing. Both incidents occurred at night; in each incident, serious damage was done to the engines and major loss of life was only narrowly averted. Both aircraft suffered extensive damage to engines and exterior surfaces; in each instance, a glassy ceramic layer was found deposited on the surfaces of the turbine section along with ablation damage to other engine parts.

An even worse ash encounter (and probably the most serious to date) occurred after a 7-year hiatus. On December 15, 1989, at 11:46 A.M. local time, a KLM Boeing 747 in Alaska flying at 8500 m ASL with 231 passengers on board flew into a volcanic ash cloud from an eruptive event at Redoubt volcano located 150 km away (Figure 4). The aircraft lost all four engines and dropped 4450 m in 4 minutes to an altitude of 4050 m ASL in a mountainous region whose peaks ranged from 2130 to 3350 m ASL. The aircraft's engines were thus restarted only within 1–2 minutes of impact, and the aircraft was able to land safely in Anchorage. Damage to the aircraft's engines, avionics, and airframe was estimated at over U.S. \$80 million and it was several months before it flew again.

The explosive eruptions of Mount Pinatubo in June 1991 ejected voluminous clouds of volcanic ash and acid

gases into the stratosphere to altitudes >30 km and provided the setting for the next significant encounter of volcanic ash and aircraft. An ash cloud from the June 15 eruption spread laterally into some of the world's busiest air traffic corridors. At least 20 commercial jet aircraft were involved in the incidents related to volcanic ash from the eruptions of Mount Pinatubo volcano. Three of these occurred within 200 km of the volcano when the cloud was less than 3 hours old, while 12 others took place over Southwest Asia 720 to 1740 km west of the volcano when the ash cloud was 12 to 24 hours old. No loss of life occurred but damage estimates to aircraft may have exceeded U.S. \$100 million.

By 1991, recognition of the gravity of the hazard resulted in the First International Symposium on Volcanic Ash and Aviation Safety, held in Seattle, Washington, USA. It was sponsored by the Airline Pilots Association, the Air Transport Association of America, the FAA (Federal Aviation Administration), the National Oceanic and Atmospheric Administration, and the U.S. Geological Survey. Following closely after the late-1989 incident related to the Redoubt eruption in Alaska and the 1991 Mount Pinatubo eruption, the meeting was packed with attendees from around the world, many of whom had just recently become aware of this "new" hazard following damaging encounters or disruptions. The awareness of the extent of this hazard following this seminal meeting was reflected in the response to the two major incidents which are described next.

Crater Peak vent on the south side of Mount Spurr volcano 125 km west of Anchorage, Alaska, erupted on June 27, August 18, and on the evening of September 16–17, 1992. Each eruption produced an ash column that rose to 13–15 km above sea level; the ash clouds were carried downwind across eastern Alaska, western Canada, and the northcentral United States. Ashfall from the August 18 eruption deposited 1–3 mm of ash at the Anchorage airport (one of the busiest airports in the United States), causing closure and diminished operations for several days. Ash removal and associated costs were estimated at over U.S. \$680,000, and revenue loss because of flight cancellations was estimated at \$276,000. No aircraft were damaged by ash clouds from this eruption, principally because a streamlined process of eruption warnings and monitoring, tracking of volcanic ash clouds, education of pilots and dispatchers, and communication had been developed in the region following the Redoubt eruption only 2 years earlier.

A dramatic example of the rapid transport of volcanic ash across air routes occurred when Klyuchevskoy volcano, one of the most active volcanoes in Kamchatka,

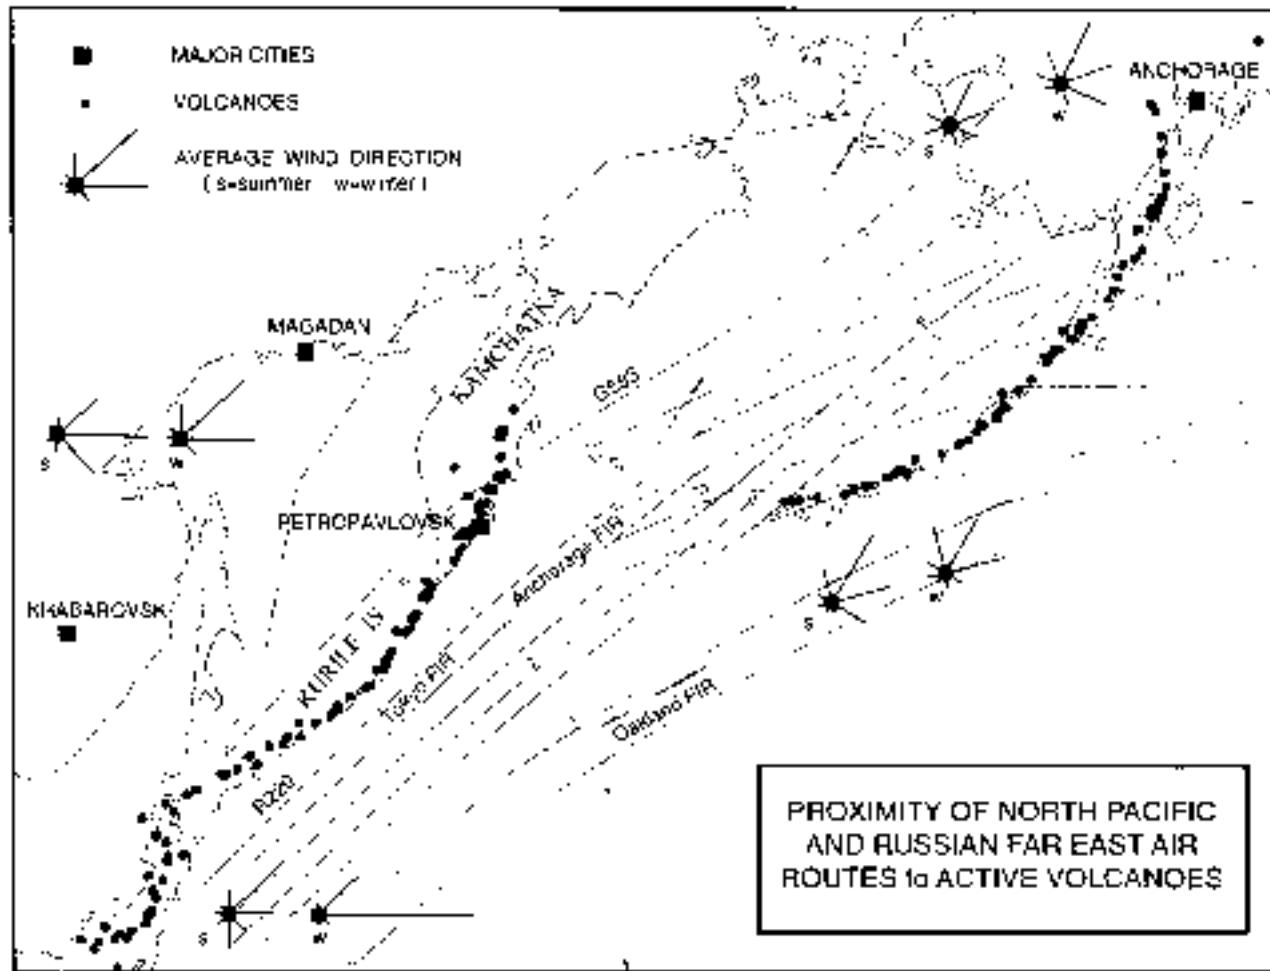

FIGURE 4 North Pacific (NOPAC) air routes and the 100 active volcanoes in Alaska, Kamchatka, and the Kurile Islands; wind-rose diagrams show that most of these air routes are downwind or cross the belt of active volcanoes. In 1998, more than 20,000 passengers and millions of pounds of cargo were being transported daily over these routes, including more than 90% of the all-cargo flights between Asia and North America.

Russia, erupted in 1994. On October 1, the volcano erupted explosively, sending volcanic ash to an estimated height of 12–15 km (Figure 5). A strong jet stream rapidly carried the ash to the southeast across the NOPAC (North Pacific) composite air routes, where it was visible on satellite images (Figure 6). Pilots reported extensive visible volcanic ash clouds as much as 80 km wide and up to 1000 km from the volcano at altitudes ranging from 9 to 11.5 km ASL. The major explosive phase of the eruption lasted about 36 hours and was intense for about 10 hours. Because of excellent communication between Russian and American volcanologists, meteorologists, and air traffic controllers, aircraft were

quickly rerouted for the next 48 hours and no damaging incidents occurred.

## II. EXTENT

On numerous occasions volcanic eruptions have wreaked havoc with mankind, causing catastrophic loss of life and damage to property. Indeed, R. J. Blong has identified 564,612 deaths associated with volcanic eruptions between 1600 and 1986. The horrific loss of

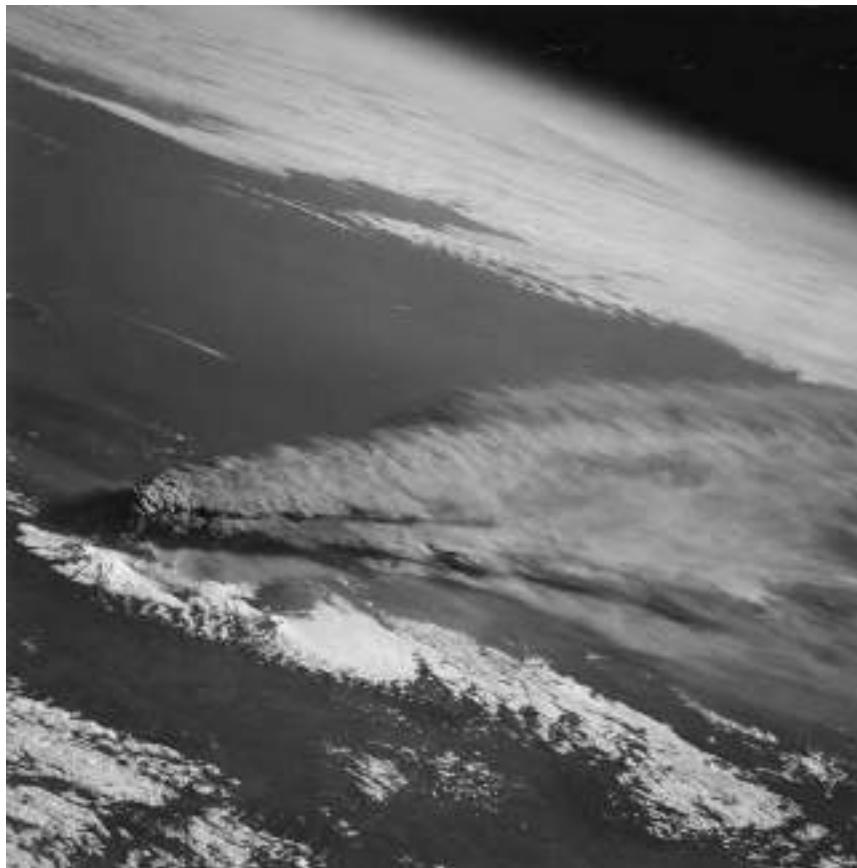

FIGURE 5 Shuttle photo of 4723-m-high Klyuchevskoy volcano, Kamchatka, Russia, erupting on October 1, 1994. View is looking northeast; the top of the ash cloud is estimated at about 15 km ASL. Bezymianny volcano, another frequently active volcano, is visible under the ash cloud to the right of Klyuchevskoy. A thin white-vapor plume can be seen trailing from the summit and the volcano is separated from Klyuchevskoy by the Holocene Kamen volcano.

thousands of lives following eruptions at Mount Pelée, Krakatau, Tambora, Unzen (in 1792), and Nevado del Ruiz in the past 2 centuries is etched in volcanologists' minds. Before 1900, most deaths were by starvation, but pyroclastic flows and lahars account for most fatalities in the 20th century, and volcanogenic tsunamis remain a worrisome hazard. The prominence of pyroclastic-flow- and lahar-related deaths has focused attention on proximal hazards of volcanic eruptions. When hundreds of thousands of people live within a few tens of kilometers of active explosive volcanoes, volcanologists and public safety officials understandably devote much of their efforts to the local hazard.

The hazard to modern aviation from airborne volcanic ash, however, is a newly recognized and emerging hazard that is both proximal and distal in character, and that presents problems in response and mitigation. Significant incidents of aircraft damage or disruption of

air traffic by volcanic ash clouds emanating from 12 volcanoes have been reported every year in the decade between 1990 and 1999 (Table I). Since the number of volcanic eruptions is assumed to have been constant throughout this period, the frequency of incidents attests to the global increase of air traffic, particularly wide-body jet aircraft.

Most of the volcanoes that have produced hazardous ash clouds in the past decade are located along the Pacific Basin Rim (Table I) but the hazard should not be regarded as confined to that region. The 1996–1998 eruptions at Soufrière Hills did not cause significant damage to aircraft but did disrupt air traffic in the Caribbean and adjacent Atlantic Ocean. The eruptions of Hudson and Lascar volcanoes in 1991 and 1993, respectively, produced ash clouds that were carried east over the Atlantic Ocean where they interfered with air traffic and damaged aircraft as far away as the Falklands. A 1998

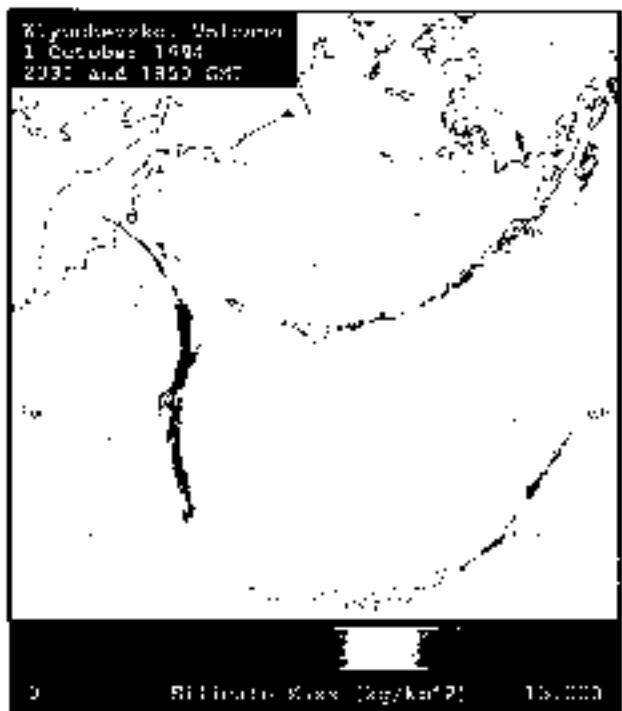

FIGURE 6 Satellite-derived volcanic ash mass retrieval of the ash cloud from the October 1, 1994, eruption of Klyuchevskoy volcano which traveled across NOPAC composite air routes, severely disrupting commercial air traffic for 48 hours.

eruption of Grimsvotn volcano in Iceland carried a notable potential for disrupting traffic across the North Atlantic, as will be discussed later.

Consideration must be given both to the nature of flight operations, that is, whether aircraft are in extended flight operation (cruising at >9 km for long distances) or in terminal flight operation (landing or taking off), and to the type and duration of eruptive activity that might be occurring. The proximity of many of the world's active volcanoes to major cities with their airports and to commercial air routes is well illustrated in Figure 1. Those airports and terminal flight operations close to volcanoes erupting ash and coarser ejecta obviously run a higher risk of aircraft damage than do those farther away because of higher rates of sedimentation from airborne ash clouds. Rinjani volcano in Indonesia erupted several times between June 1994 and March 1995 and caused much disruption of air traffic throughout this heavily populated region. Although ash clouds were generally below 6 km ASL, they interfered with terminal traffic approaches and takeoffs at the numerous nearby airports in the region, causing extensive re-routing.

A similar situation at Sakurajima volcano, located only 22 km from Kagoshima City, Japan, has been at least partially mitigated by real-time seismic monitoring at the airport itself. Sakurajima has been in sporadic eruption since 1957 with over 4000 short-lived volcanic eruptions causing numerous damaging ash and aircraft encounters. Extensive mitigation procedures introduced in 1991 included the installation at the airport of a seismometer and infrasonic microphone to detect air shocks caused by explosive events, which allowed aircraft to be quickly notified and plan their approach or takeoff accordingly, thus allowing continued use of a busy airport.

The nature of the eruptive activity must be kept in mind. Eruptions that are chiefly effusive (e.g., the long-lived Kilauea eruption in Hawaii that began in 1983) obviously pose little likelihood (but not zero) of producing much ash although acidic gases can be a hazard to low-flying aircraft or aircraft on approach or takeoff from nearby airports.

The size of eruptions (and the amount of emitted ash) that constitutes a hazard varies, as does the areal extent of the cloud. Aircraft have been damaged or operations disrupted from eruptions ranging from short-lived vulcanian episodes of a few tens of millions of cubic meters (Mount Spurr, Alaska, 1992) to long-lived caldera-forming eruptions (Mount Pinatubo, 1991) of several cubic kilometers of ejecta. Also, an "eruption" may consist of single to multiple explosive events spread over minutes to months. The 1989–1990 eruption of Redoubt volcano in Alaska, for example, had over 20 explosive episodes, each of which affected aviation over a 4- to 5-month period, yet had an overall VEI (volcanic explosivity index) of 2–3. The 1992 eruption of neighboring Mount Spurr volcano, with a similar VEI, had only 3 explosive events over a 3-month period. For this reason, it is impossible to merely look at a listing of VEIs for volcanoes or groups of volcanoes to estimate probabilities of ash eruptions hazardous to aviation. Once a slug of ash of any size is ejected to altitudes of >9 km and carried into air routes, it is a hazard. The duration and/or size of the eruption or of the ash slug itself will, of course, effect the extent of the hazard. Additional related items include how long an aircraft might actually be exposed to volcanic ash—for example, whether the ash cloud crosses the aircraft's flight route orthogonally or obliquely will be a significant factor.

As was stated, the hazard posed by volcanic ash to aircraft is not only proximal but distal as well—that is, it is not confined to the country or region containing the eruptive volcano but can persist for 2000 km or more based on reported damage figures. An example of

the far-flung effects of airborne volcanic ash on air traffic is shown in Figure 7. The long-distance transport of an ash cloud emitted from the Crater Peak vent of Mount Spurr, Alaska, on September 17, 1992, beginning ~0940 Z, is illustrated from AVHRR satellite imagery over a 3-day period. The cloud followed a U-shaped track across western Canada and the northern tier states (USA) into eastern Canada. Approximately 48 hours

after the eruption, the ash cloud was spotted near Cleveland, Ohio, extending over a length of 1320 km at an altitude of 5.5 to 10 km. The presence of this ash cloud, some 5000 km downwind of the erupting volcano, caused major disruption of commercial air traffic in the eastern United States for about 12 hours. This disruption highlights the fact that the concentration of ash in an eruption cloud that constitutes a potential hazard to

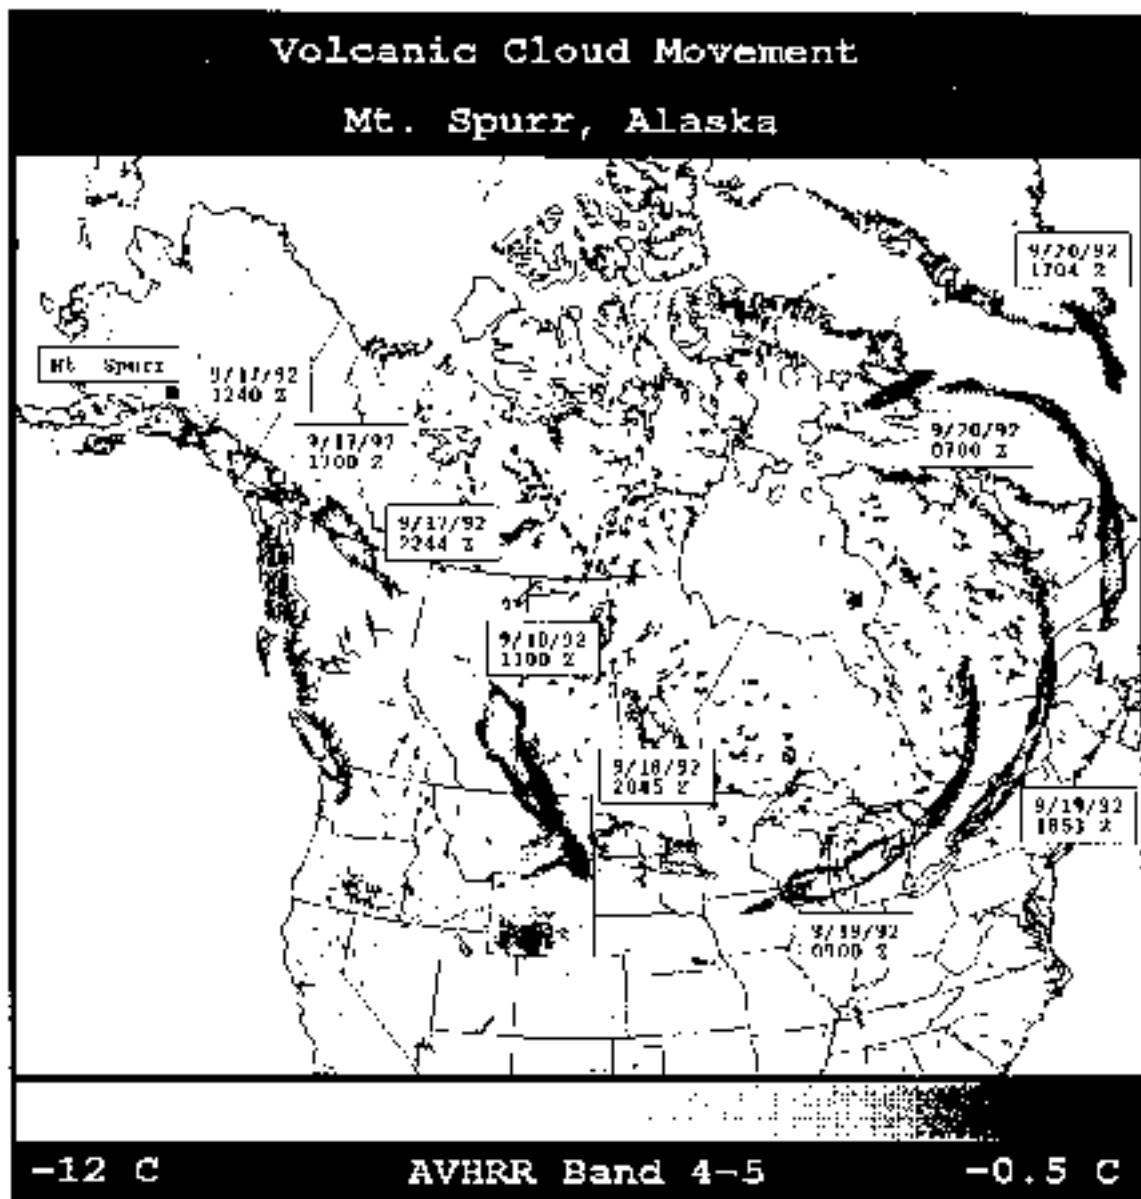

FIGURE 7 Composite satellite image illustrating the movement of the ash cloud from the September 16–17, 1992, eruption of Mount Spurr volcano, Alaska, across Canada and the northern tier states of the United States. On September 19th (more than 2 days after the eruption and 5000 km downwind), the ash cloud disrupted air traffic near Cleveland, Ohio, as pilots refused to fly through the visible ash cloud.

aircraft is unknown, as is the distance beyond which an ash cloud is no longer a hazard.

Some areas of the Earth's airspace are at greater risk from volcanic ash clouds than others simply because of the juxtaposition of volcanoes and air routes (Figures 1 and 4). Critical regions include the North Pacific, Southeast Asia (including Japan), Central and northern South America, Mexico, the Caribbean, and Iceland (the North Atlantic). The nature of the hazard differs significantly between the regions, however, being of importance chiefly to extended flight operations in the remote NOPAC and North Atlantic regions and to both terminal and extended flight operations in heavily populated Southeast Asia and the Americas.

The North Pacific region is instructive in considering the extent of the hazard (Figure 4). Air routes in this region are heavily traveled: over 200 flights per day in 1999 carried 20,000 passengers and more than 12 millions pounds of cargo between Asia and the USA and Europe. These air routes cross or lie downwind of 100 historically active volcanoes in Alaska, Kamchatka, and the Kurile Islands (Figure 4) that average 5–6 eruptions a year. It has been estimated that on 4–5 days a year, on average, volcanic ash will actually be in the NOPAC routes at altitudes of 9 km or more (above which most modern jet airliners fly), causing a major threat to thousands of passengers and tons of cargo. This estimate is empirical and based on a combination of the past 20-year record and a 200-year historical record. On an additional 10–12 days per year, volcanic ash clouds are estimated to be close enough to flight routes to be a matter of concern to aviation.

This analysis for the NOPAC composite routes can perhaps be extended further to a worldwide perspective. The North Pacific region has 100 active volcanoes, or about 20% of the world's 534 historically active volcanoes. If the (very) broad assumption is made that the same empirical likelihood of hazardous ash encounters with aircraft that exists for the North Pacific holds for other volcanic belts, then perhaps on a worldwide basis, volcanic ash could be expected to be in air routes at altitudes greater than 9 km 20–25 days per year on the average, and would be a matter of concern an additional 50–60 days per year. Having volcanic ash in the air routes at high altitudes does not mean that encounters with aircraft will necessarily occur given the speed of the aircraft, the length of time the cloud is in the air route, and its area. However, some support for the general validity of these figures comes from the reported 100 damaging encounters to aircraft from volcanic ash over a 15-year period, which yields an average of 5 encounters per year. These figures almost certainly rep-

resent underreporting of the actual number of damaging incidents but they give credence to the rough estimate of about 20 days per year that volcanic ash is in air routes worldwide.

Similar volcanic ash hazards to extended flight operations in the NOPAC region affect flight operations in the other aforementioned critical regions. These latter regions, however, are much more populated than the remote NOPAC region and are the locations of concentrated terminal flight operations in and out of busy local and regional airports. These landing and takeoff operations add the problems of dense ash clouds, heavy ashfall, and short warning times to the hazards described above for extended flight operations.

---

### III. MITIGATION

No onboard cockpit instruments currently exist that can detect volcanic ash clouds. Ash clouds can usually be detected visually during daylight hours from the cockpit of an aircraft at altitudes of more than 9 km, but identification is much more difficult if meteorological conditions are poor, and it is essentially impossible at night. Yet if an eruption and associated ash cloud is unreported, the first knowledge of a hazard can come from an aircraft flying into the cloud, as happened in the Galunggung incidents in 1982. The time between the start of an eruption and the first notification is thus a period of great risk to the aircraft and so early detection of the eruption and ash cloud is essential to flight safety. Pilot groups have gone so far as to propose that notification messages announcing a potentially hazardous eruption should be in the cockpit of an in-flight airliner within 5 minutes after detection. So how are volcanologists, meteorologists, flight controllers, and modelers addressing this problem?

#### A. Monitoring

Reports of volcanic activity typically originate from volcano observatories, pilot reports, satellite observations, and ground observers. The need to integrate and evaluate reports received from these varied sources is typically the responsibility of the volcano observatories and similar establishments who rely on instrumental monitoring networks and knowledge of past eruptive activity at the volcano in question. Increasingly, the widespread availability of volcanic information on the Internet has be-

come a valuable source of readily accessible near-real-time information for aviation user groups.

Volcano observatories use a number of techniques in monitoring volcanoes of interest to aviation. Real-time seismic monitoring of potentially active volcanoes, for example, has proven highly successful in providing warnings of impending or actual eruptions by detecting changes in the rates and character of volcanic earthquakes. These warnings have been largely based on empirical observations of volcanic seismicity. Strong increases in the rates of the activity, appearance of distinctive long-period events and continuous tremor, and shallowing of earthquake hypocenters are signs that have been attributed to rising magma or increases in magmatic pressure. Seismic networks around erupting volcanoes can usually detect explosions associated with major ash eruptions in real time (assuming appropriate telemetry exists). During the eruptions of Redoubt (1989–1990) and Mount Spurr (1992) volcanoes in southcentral Alaska, notification of more than 20 explosive eruptive episodes was made to aviation user groups (among others) within 3–8 minutes of the actual event.

Although seismic monitoring of active volcanoes has been shown to be effective, less than 20% of the world's active volcanoes have adequate seismic networks around them. Recognition of the frequency at which airborne volcanic ash occurs in the North Pacific region, however, has led to increased funding from the U.S. government over the past 10 years for monitoring and mitigation of the hazard. For example, in 1999 real-time seismic monitoring was available for 20 of 41 active volcanoes in Alaska, allowing identification of eruptive events and, in some instances, prediction. Other volcanic areas of the world are slowly experiencing similar increases but large gaps exist in coverage, particularly in remote and economically depressed parts of the world.

Satellites are an important source of information on volcanic activity and have the advantage of providing global coverage (depending on the sensors on board) at reasonable cost. Satellite imagery has been useful in detecting significant changes at remote volcanoes where other monitoring techniques are not feasible, and it complements seismic monitoring techniques by providing information on the height of an eruption cloud and on the presence of volcanic ash when an eruption is detected. Remote sensing data from the AVHRR, GOES, GMS, and TOMS (see Glossary) satellite-borne sensors are now used routinely across the North Pacific and elsewhere to monitor volcanic activity by initially detecting (in some cases) thermal anomalies and then identifying and tracking potentially hazardous volcanic ash clouds. Imagery is utilized to detect a variety of

volcanic phenomena at a number of different wavelengths, including ultraviolet (volcanic ash and sulfur dioxide), visible (volcanic aerosols), short wavelength infrared (thermal anomalies), and thermal infrared (volcanic ash). Satellite monitoring of the entire North Pacific is now done routinely twice a day by the Alaska Volcano Observatory (AVO), and more frequently during times of volcanic unrest. Imagery from these sensors gives snapshots at intervals ranging from 15 minutes to once or twice a day, depending on the sensor and location of the volcano. Particular use has been made of thermal image data from two channels of the AVHRR, GOES, and GMS sensors to detect and to distinguish volcanic ash plumes from meteorological clouds using the split window brightness temperature difference between spectral bands 4 (10.3–11.3  $\mu\text{m}$ ) and 5 (11.5–12.5  $\mu\text{m}$ ). The routine use of high-spatial-resolution imagery by volcano observatories has been limited due to the high cost of obtaining commercial imagery, but this should change in 1999 with the successful launches of noncommercial satellites such as Landsat-7 (operated by the U.S. Geological Survey) and Terra (the first NASA EOS satellite).

A 5-cm C-band ground-based radar system in the Cook Inlet region of Alaska proved helpful in estimating cloud height during the 1992 Crater Peak (Mount Spurr) eruptions in Alaska. This system has now been replaced by a network of seven NEXRAD (Next Generation Weather Radar) doppler radars operated by the NWS (National Weather Service) primarily for other aviation purposes, but their increased power and sensitivity will allow monitoring of ash clouds at ranges of <200 km.

Forecasts of ash cloud movements are provided by the use of one or more volcanic ash tracking models. A number of transport and dispersion models exist; in the North Pacific, the VAFTAD (Volcanic Ash Forecast Transport and Dispersion) and PUFF models are used most commonly.

Visual observations by pilots themselves are obviously a valuable aid in the detecting and monitoring of eruptions and their ash clouds. Pilot cooperation is essential to the successful avoidance of airborne ash, and a special Volcanic Activity Reporting (VAR) Form has been devised to be carried in the cockpit for this use. This form allows for the description and location of the ash cloud and the erupting volcano, and numerous other characteristics along with directions as to where to send the information.

Other standard monitoring techniques such as ground deformation, gas analyses, geologic field studies, and aerial observations have correspondingly been in-

creased. The ultimate goal of these efforts in terms of aviation is to provide notification of eruptions to user groups within minutes of their occurrence, detect thermal anomalies, track volcanic ash clouds across air routes in this remote region, and furnish information on size, character, and likely duration of an eruption.

## B. Communication

Knowledge of an erupting volcano is of little use in mitigating hazards unless it is immediately conveyed to the proper authorities and users. At Mount Pinatubo, information regarding the restless state of the volcano was available to the aviation industry and government officials for up to 2 months before the June eruptions, yet over 16 aircraft were damaged during the eruptions. A posteruption analysis suggested that information and warnings about the hazard either did not reach the proper aviation authorities or that pilots, dispatchers, and air traffic controllers were not sufficiently educated about the hazard to take preventative action.

The key to communicating information about volcanic eruptions in a timely and readily understandable form is to involve all interest groups, including volcanologists, meteorologists, atmospheric modelers, pilots, and air traffic controllers, in the development of information, and to streamline the distribution of this information between essential parties. To avoid volcanic ash clouds, pilots and dispatchers need to be informed that a volcano has erupted, the time of eruption, whether ash has been produced, and the altitude of the plume. When this information is integrated with wind speed and direction, the trajectory of the cloud is forecast, an area of concern is identified, and a warning is issued alerting pilots to the hazards.

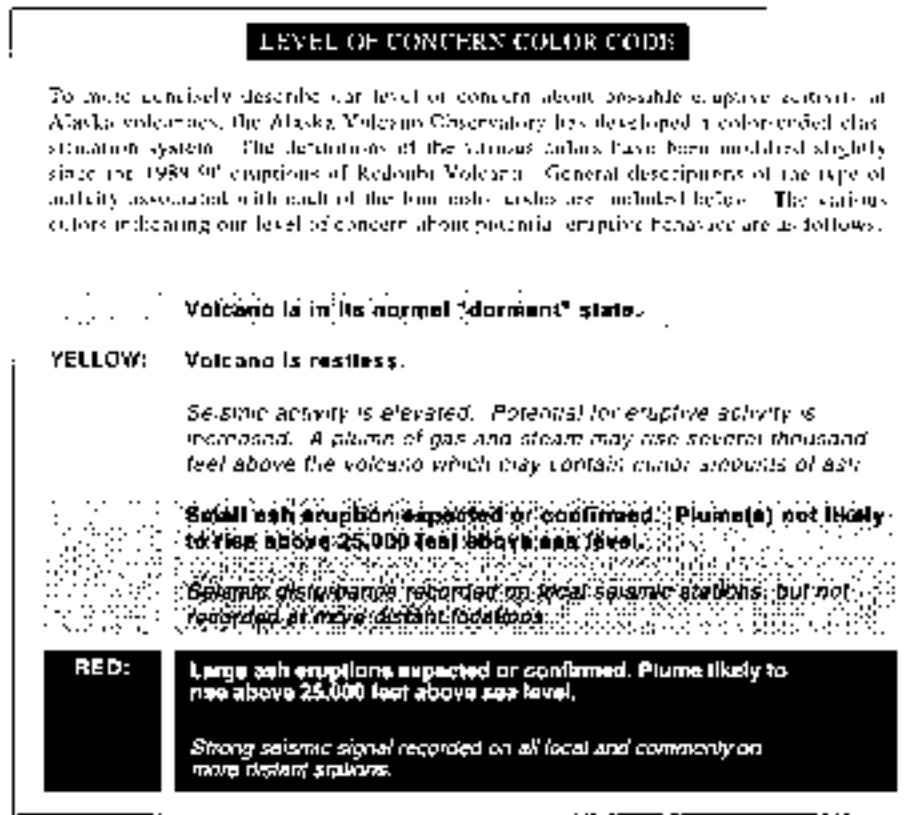

The first step in this coordinated response is the reporting of an eruptive event that could impact aviation. A simple but useful aid in communicating that a potential hazard exists to aviation was developed by the Alaska Volcano Observatory during the eruption of Redoubt volcano in 1990. This was a level-of-concern "color code" (Figure 8) to communicate rapidly and clearly to the nonscientific community the likelihood of an eruption at a restless volcano. The color code procedure for summarizing the status of a volcano has proven extremely effective in alerting the aviation community to potential ash hazards across the North Pacific, and the ICAO has recommended its use on a worldwide basis.

In the North Pacific (Figure 4), the Alaska Volcano Observatory monitors volcanoes in Alaska and works

closely with the Kamchatka Volcanic Eruption Response Team (KVERT) to monitor and report on volcanic activity throughout the region. An interagency operating plan for volcanic ash episodes has been developed to provide a coordinated structure to mitigate volcanic ash hazards. This plan outlines the response procedures for the AVO, the NWS, the FAA, the U.S. Air Force, the Alaskan Division of Emergency Services, and the adjacent U.S. airspace Flight Information Regions (FIRs). It includes responsibility for communicating information on volcanic ash transported by upper-level winds from erupting volcanoes outside the U.S. FIRs into Alaskan airspace. Although the initial report of an eruption may originate from the AVO, from pilots or other observers, or from satellite imagery, information is immediately shared.

The response to frequent eruptions in the region, plus drills, formal written agreements, and conferences, has yielded a rapid flow of information to user groups (ultimately the airlines) through the Anchorage Volcanic Ash Advisory Center (VAAC) and AVO. At the AVO, for example, upon determination that an eruption potentially hazardous to aviation is occurring, or about to occur, a short telephone call-down list is utilized to inform the NWS and the FAA of the situation. The phone message follows a rigid format as follows: THIS IS AN ERUPTION NOTIFICATION FROM THE ALASKA VOLCANO OBSERVATORY. SEISMIC (or other) DATA INDICATE THAT A (small, moderate, large) ERUPTION OF \_\_\_\_\_ VOLCANO, LAT \_\_\_\_\_, LONG \_\_\_\_\_, BEGAN AT \_\_\_\_\_ UTC ON (date). THE LEVEL OF CONCERN COLOR CODE IS (orange, red). An immediate follow-up update message is sent out by e-mail and fax to an extended list of government, airline industry, and media users with more detailed information on the eruption and a prognosis of future activity. Phone messages concerning significant changes in the eruption are repeated as necessary during the course of the activity. Updates are sent out on a situation-warranted basis as often as several times a day.

The other participating agencies, the NWS and the FAA, immediately communicate information on potentially hazardous eruptions and ash clouds to airliners and dispatchers. The NWS sends out a Volcanic Ash Significant Meteorological Advisory (SIGMET) as its primary notification and the FAA issues a Notice to Airmen (NOTAM). Although much remains to be done, these multidisciplinary efforts to date have been successful in the mitigation of hazards to aircraft operations from numerous volcanic eruptions in the North Pacific and serve as a model to be used elsewhere in the world.

Alaska Volcano Observatory's level of concern color code. This code and eruption updates are distributed to government agencies, the media, airlines, and the public.

FIGURE 8 A level-of-concern color code developed by the Alaska Volcano Observatory to rapidly and clearly communicate the likelihood of an eruption at potentially dangerous volcanoes. This format for summarizing the status of a volcano has proven extremely effective in alerting the aviation community to potential ash hazards in the North Pacific region.

### C. Volcanic Ash Advisory Centers

Ash clouds often drift far from their source volcanoes, crossing over national boundaries and between FIRs, so regional air traffic facilities and carriers must be informed about potential volcanic threats not just in their local flight region but in adjacent regions as well. The hazards posed by volcanic clouds thus have a scope that requires both local and global approaches to ensure a solution.

Recognition of this feature of the hazard led the World Meteorological Organization (WMO) to establish the International Airways Volcano Watch (IAVV). The purpose of the IAVW is to address the threat to aviation safety and the economic loss from aircraft encounters with volcanic ash clouds. As a key part of the IAVW, nine regional Volcanic Ash Advisory Centers

have been established around the world (Figure 1) under International Civil Aviation Organization (ICAO) auspices to advise Meteorological Watch Offices (MWOs) on the issuance of volcanic ash warnings to aircraft. The VAACs have been specifically tasked with the detection, tracking, and forecasting of the movement of volcanic ash clouds within their respective areas of responsibility. In addition, they cooperate in "passing off" a drifting ash cloud from VAAC to VAAC as it moves around the globe. Fulfillment of this task requires international cooperation among the meteorological, volcanological, and aviation communities to provide the VAACs with current information. To further foster the VAAC efforts, the WMO and the ICAO cosponsor international workshops to provide a forum for interaction between providers and users of volcanic ash advisories and warnings.

---

#### IV. DISCUSSION

A new volcanic hazard with a significant attendant risk has developed that quite simply did not exist in any notable way before 1980. In the last 2 decades of the 20th century, more than 100 jet aircraft have flown into drifting clouds of volcanic ash in air routes and near airports around the world. This has resulted in hundreds of millions of dollars in damages, placed thousands of passengers at risk, and disrupted air commerce. This marks a time when the number of jet transports in the world's civilian air fleet has expanded to approximately 13,000 aircraft as of 1999.

This hazard extends to life and property, and is a dynamic phenomenon that can occur in regions far from erupting volcanoes. An explosive eruption from a remote volcano with only a sparse local population would formerly have been chiefly of scientific interest. Now, however, such a volcano can suddenly threaten large segments of unsuspecting airborne travelers and commerce. The response to this hazard has resulted in international cooperation among the meteorological, volcanological, and aviation communities.

Anticipated increases in aviation traffic globally and changes in equipment type and operational procedures will increase the probability of aircraft and volcanic ash encounters. In the North Pacific and Russian Far East region alone, air traffic is projected to increase by a factor of 3 from about 200 flights per day to 600 flights by the year 2017, with a corresponding increase in passenger load from 20,000 to 60,000 people per day. These figures are impressive given the thousands of passengers involved and the monetary value of the aircraft and cargo. Modern trends in commercial aviation point to similar vigorous growth across the globe. If the number of volcanic eruptions remains constant over sufficiently long periods of time but the number of encounters increases (i.e., the number of flights increases without mitigation procedures), then the risk of a catastrophic accident will increase dramatically.

Other airline operational factors raise the potential for route disruption because of volcanic eruptions. Increasingly, airlines are using large twin-engine jet aircraft for transoceanic flights because of favorable operating costs. However, many countries have placed restrictions on operation of twin-engine aircraft that require the aircraft to be within 3 hours of flight time from an alternate airport at all times. One of the heaviest flight paths in the world is across the North Atlantic, and airports in Iceland are used to meet the availability

restriction. If airports are not available because of volcanic ash, regardless of whether it is airborne or deposited at the airport, air traffic can be shut down. An additional complicating factor is that the ever larger engines, because of higher operating temperatures, are more susceptible to damage from ash.

Clearly, the volcanology community needs to work closely with the airline community and with government aviation groups to address these problems. A successful start in mitigation of airborne volcanic ash hazards by a multidisciplinary group provides encouragement that the hazard can be mitigated. However, given the expected growth in global air traffic, much remains to be done if the successes to date are to continue. Tracking of ash clouds by satellite imagery has improved, but future generations of GOES satellites will lose the ability of split window detection of ash. The ability to detect volcanic ash needs to be considered along with other meteorological requirements when designing future satellite sensors. The availability of adequate orbital platforms and the transfer of satellite data between VAACs and to other user groups continues to present problems. Standard dispersion models must be agreed upon using more realistic eruption parameters, particularly in the critical first few hours of an eruption.

Advances in satellite remote sensing technology will further aid in the detection and tracking of volcanic ash clouds (observable parameters) but will not provide immediate information on the probable character, size, type, and likely duration of the eruption (interpretive parameters). Prognostic information needs to come from thorough pre-eruption studies of the volcanic history and petrology of the erupting volcano. Increased monitoring by real-time continuously recording seismic, ground deformation, and gas sampling networks will increase the demonstrated ability to predict at least some explosive events.

The necessity for the immediate communication of eruption information to the cockpit of a jet aircraft traveling at over 800 km/hour has always been paramount: location of the volcano, start time of eruption, duration, plume height, and wind direction have been and will remain critically important elements. However, as information on these observable parameters has become available, aviation stakeholders have demanded more information from volcanologists and atmospheric modelers. How long might an eruption be expected to last? Will it wax and wane in intensity? What will its volume be? These are factors that effect the payload versus fuel equation and the safety of the aircraft. They are questions that are among those asked at any eruption

by any concerned group, but now they must also be addressed from an aviation perspective.

The establishment and utilization of contact volcanology groups that are knowledgeable about hazards to aviation for a particular eruption is very important. At many erupting volcanoes, volcanologists are understandably deeply involved in mitigating hazards proximal to the erupting volcano. Concern for aircraft up to hundreds of kilometers downwind from the volcano and over other countries, while often acknowledged, gets lost in the immediate local response. The existence of a knowledgeable contact group that can be contacted by dispatchers, pilots, and air traffic officials can help rectify this situation.

It is unlikely that jet engines, air frames, and avionics will ever be built that can safely withstand flying through a volcanic ash cloud without a serious risk to life and property. It is also unlikely that in the foreseeable future jet aircraft in extended flight will be operating at altitudes totally above the reach of volcanic ash clouds. These factors suggest that the problems posed by airborne volcanic ash to aircraft will concern volcanologists for a long time to come.

## GLOSSARY

- aerosol** A suspension of fine liquid or solid particles in air. Natural aerosols include fog, smoke, and stratospheric sulfate.
- albedo** The fraction of incident radiation reflected by a surface. The Earth's planetary albedo is the fraction of the Sun's incoming radiation that reflects off the Earth and back into space.
- coagulation** The process of two particles fusing to become one larger particle.
- condensation** The process by which gas (vapor) changes into liquid. Stratospheric aerosol particles grow by condensation of water, sulfuric acid, and nitric acid.
- denitrification** The removal of active nitrogen species from the stratosphere by sedimentation of polar stratospheric clouds containing large amounts of nitric acid.

**direct effects of aerosol** Attenuation of atmospheric radiation by absorption and scattering on atmospheric particles.

**evaporation** The process by which liquid changes into gas (vapor). Evaporation prevents the presence of aerosol in the relatively warm upper stratosphere.

**greenhouse gases** Gases such as carbon dioxide, water vapor, and methane that allow incoming sunlight to pass through but absorb infrared rays radiated back from the Earth's surface, heating the atmosphere.

**heterogeneous chemistry** Reactions occurring between reactants of different phases. In the atmosphere, these are reactions of gases with species in solid or liquid aerosol, forms.

**indirect effects of aerosol** Processes such as cloud modification by which aerosols affect the Earth's radiation budget without interacting with radiation.

**microphysics** The processes affecting the size, number, and distribution of aerosol particles. Microphysical processes include nucleation, condensation, evaporation, coagulation, and sedimentation.

**mixing ratio** The abundance of a chemical species as a fraction of the total volume (number), or mass of ambient air. Mixing ratios of gas-phase constituents are often expressed as parts per million by volume (ppmv), parts per billion by volume (ppbv), or parts per trillion by volume (pptv). Mixing ratios of condensed-phase constituents, such as liquid sulfate, are often expressed as mass fractions, such as parts per billion by mass (ppbm).

**nucleation** The process by which gas- or liquid-phase species form new liquid or solid particles. Nucleation may

occur by heterogeneous means, if an involatile substrate (e.g., soot particles or meteoric dust) is present on which molecules aggregate. Homogeneous nucleation occurs in the atmosphere when molecules cluster together spontaneously in the absence of preexisting nuclei. Binary nucleation is the formation of nuclei from two different chemical species. The source of liquid stratospheric sulfate aerosol is believed to be binary homogeneous nucleation of water vapor and sulfuric acid vapor.

**optical depth** A measure of the cumulative attenuation of electromagnetic radiation in transit through a medium, such as the Earth's atmosphere. At an optical depth of one, the irradiance of radiation is diminished to 1/2.7 of that entering the atmosphere.

**sedimentation** The process by which aerosol falls through the atmosphere due to gravity.

**sulfate** The  $\text{SO}_4^{2-}$  radical molecule found in solution with liquid water; the dissolved form of sulfuric acid ( $\text{H}_2\text{SO}_4$ ).

**H**UMANS HAVE LONG experienced the global atmospheric effects of volcanic eruptions. Benjamin Franklin may have been the first to report the link between volcanism and unusual atmospheric phenomena in 1784, when a strange "dry fog" and unseasonably cold weather struck Europe. Franklin speculated that the fog was the cause of the cold summer, and that it originated as smoke from either meteorites or volcanic eruptions he knew to have occurred in Iceland over the course of the previous year. The eruption of Krakatoa in 1883, however, produced the first widespread reports of strange atmospheric effects linked to volcanoes. The arrival of global communications ensured that the intense sunsets seen for several years subsequent were attributed to the news of the massive eruption. In retrospect, historical records back through antiquity reveal numerous examples of atmospheric anomalies that correlate with major volcanic eruptions, often in an entirely different part of the world.

## I. INTRODUCTION

One of the greatest volcanic disasters to have occurred in human history was the eruption of Santorini, also known as Thera, which occurred circa 1620 B.C. The eruption transformed a 3000-feet-high mountain rising from the Aegean Sea into an island ring surrounding an enormous crater filled with 2000 feet of seawater.

Such was the power and notoriety of the Santorini eruption that some have linked it with the parting of the Red Sea described in the Bible and the demise of the 1400-year-old Minoan civilization on nearby Crete, itself sometimes linked to the fabled lost continent of Atlantis. While serious doubt surrounds such speculation, historical records reveal that the atmospheric effects of the eruption were felt around the globe.

Much of astronomer Kevin Pang's research focuses on examining historical records of the atmospheric disturbances due to volcanic eruptions. While there are no written European records describing the 17th Century B.C., Pang has searched provincial records from China to discover accounts of severe climatic hardships experienced there at around the same time as the Santorini eruption. These include "yellow fog," a "distressed" and "dimmed" sun, floods, followed by a 7-year drought, crop failure, famine, and the appearance of "three suns ... together." The latter is often seen in a cold atmosphere, due to refraction of the Sun's image by ice crystals. Pang dates the period of these events as 1600 B.C. plus or minus 30 years, correlating well with ice core and tree ring samples showing the volcanic influences of Santorini.

In 44 B.C., Romans marked the appearance of a bright red comet, a planet Venus "stained with dark rust," and a Moon "stained with blood" as signs of divine displeasure with the murder of Julius Caesar on the ides of March that year. Caesar's biographer Plutarch described the Sun that year as "pale and without radiance ... and the fruits, imperfect and half ripe, withered away and shriveled up on account of the coldness of the atmosphere." The Romans knew of the eruption of Mount Etna in Sicily, which threw a vast cloud of ash, dust, and sulfur into the atmosphere, but did not attribute these atmospheric and climate changes to the event. Tiny particles freshly nucleated from the nearby eruption would have scattered blue light, making celestial bodies appear red as the volcanic cloud passed over Rome. In China, the year 43 B.C. marks the first of six consecutive failed harvests in a period of summer frosts and widespread famine. Tree rings from the bristlecone pines of the western United States show frost damage in the year 42 B.C. Ice cores from the glaciers of Greenland show evidence of volcanic fallout in the atmosphere at some time between 80 and 20 B.C.

In 1453, after over a century of chipping away at the Byzantine Empire, the Ottoman Turks finally won possession of its coveted capital, Constantinople. In the triply walled city's final days, ancient myths about its demise after a sign from the Moon seemed to come true. On May 22, 7 weeks into the Turks' siege, the full

Moon was eclipsed for 4 hours, and was pitch dark, similar to a 1992 eclipse which followed the eruption of Mount Pinatubo. A few days later a hailstorm of unprecedented strength pelted the city, followed by an unheard-of and unseasonably dense fog. When the fog lifted, lights could be seen flickering like fires on the horizon, where there should be no lights, as well as around the dome of Constantinople's great cathedral. Chinese records from that period indicate that tens of thousands of people and animals froze to death in 1453, the Yellow Sea froze more than 20 km out from the shore, and a southern region of China with a climate like that of Florida experienced 40 days of continuous snow. German and Swedish records show extensive crop damage for up to 9 years following 1453. Tree rings from around the world show frost damage for several years starting in 1453.

Pang, who uncovered many of these records, believes the culprit to have been the eruption of Kuwae, a volcanic island in the South Pacific. For over 500 years, the eruption was known only in the oral tradition of the local tribes in what is now the Republic of Vanuatu. Archaeological research into these legends and radiocarbon dating of vegetation burned in the blast indicate that the eruption occurred between 1420 and 1475. Antarctic ice cores show strong volcanic influence for several years following 1453, while cores from Greenland show a weaker signal in that year. Geologists put the size of the eruption as the second largest known to have occurred in recorded human history.

The most explosive eruption of the last 10,000 years was that of Mount Tambora on the Indonesian Island of Sumbawa in 1815. Of the island's 12,000 inhabitants, 26 survived. In all, the eruption and accompanying earthquake killed some 90,000 people. The area within 200 miles of the volcano experienced 3 days of total darkness.

Half a world away, 1816 became known as "the year without a summer," or "eighteen hundred and froze to death." Average temperatures fell 1 to 2.5°C below normal throughout New England and western Europe, and the global average is estimated to have fallen by 0.4 to 0.7°C. New England experienced snows or frosts in every month of that year. The cold summer of 1816 drove farmers from New England to warmer climes to the south and west. It is estimated that Vermont's population was diminished by 8% of what it would have otherwise been. Agricultural staples failed, and in New York and France, wheat reached its highest price in the 19th century. The winter of 1816 proved a hardship to endure. Europe, just beginning its recovery from the devastation of the Napoleonic Wars, suffered famines

and riots. In late 1816, a typhus epidemic, which has been linked to famine, began to spread from Ireland to the rest of the British Isles; 1816 also saw bad harvests in India, leading to famine and the spread of cholera.

Few experiencing the climatic abnormalities of 1816 had heard of the eruption of Tambora. The speed of communications at the time meant the news would have taken at least 6 months to reach New England. There appear to have been no attributions of the frosty summer to the volcano.

The first intensive scientific studies of the atmospheric effects of volcanoes followed the 1883 eruption of Krakatoa. In this article we review current scientific knowledge of the atmospheric effects of volcanoes based on studies of numerous eruptions in the period since Krakatoa. While the climatic effects of volcanic eruptions recorded in human history have been sometimes extremely severe, these eruptions pale in comparison to those we know that the Earth produced over its history. The eruption of Toba, 75,000 years ago, for example, ejected 20 to 50 times the volume of material ejected by Tambora in 1815.

---

## II. THE ATMOSPHERE

In order to understand the ways in which volcanic input influences the atmosphere, we first review the structure and dynamics of the atmosphere. The atmosphere is divided into a number of regions based on its thermal structure. The troposphere is the region closest to the surface. From the surface, temperature decreases with altitude to a minimum at the top of the troposphere, known as the tropopause. The temperature and altitude of the tropopause vary from about 190 K and 18 km at the equator to 220 K and 8 km in polar regions. In the region above the tropopause, known as the stratosphere, the ozone layer heats the atmosphere by absorption of high-energy ultraviolet rays from the sun. Temperature increases with altitude to a maximum at the top of the stratosphere, known as the stratopause, near 50 km. In the layer above the stratosphere, known as the mesosphere, temperature decreases again to a minimum at the mesopause. Together the troposphere, stratosphere, and mesosphere make up the homosphere, a region in which the composition and molecular weight of air varies little throughout. While the mixing ratios of trace constituents may vary greatly, the homosphere is dominated by N<sub>2</sub> and O<sub>2</sub>, which make up about 80 and 20%,

respectively, of the total number density of gas molecules.

The troposphere, the region of the atmosphere we inhabit, is a turbulent and dirty region. Absorption of solar radiation at the surface heats air, which may then rise through colder, denser air above. We experience such instability as weather. Particles of limitless composition and type, many arising from surface sources such as soil and organic gases, pollute this region heavily. Tropospheric particles, however, are destined to be removed from the atmosphere in a period of several weeks by frequent precipitation. Rainout provides the dominant sink for volcanic sulfur injected into the troposphere. Most volcanic eruptions have little chance to impact the global atmosphere, because their plumes do not penetrate the tropopause. Some types of volcanoes, such as those in the Hawaiian Islands, do not have significant explosive eruptions. It is only those volcanoes with very explosive eruptions that are of concern to climate and stratospheric chemistry.

Because warm air is less dense than cold air, the increasing temperature profile of the stratosphere ensures it is a much more stable region of the atmosphere than the troposphere. Air from the troposphere enters the stratosphere in the tropics, where convective storm systems create strong updrafts capable of breaking through the cold tropical tropopause. In the process, much of the water vapor freezes out of the rising air, leaving the stratosphere much drier than the troposphere. Particles in the stratosphere are therefore not rained out, and may remain in the stratosphere until removed with ambient air parcels. At midlatitudes, tongues of stratospheric air are folded into the troposphere. This removes about three-quarters of the air that enters the stratosphere. Air removed at midlatitudes experiences an average stratospheric residence time of approximately 2 years. The remaining quarter of stratospheric air is removed by descending air at the poles, when a ring of rapidly moving wind is established in winter. Observations of chemical tracers indicate that stratospheric air is about 3 to 5 years old by the time it reaches high latitudes.

### III. STRATOSPHERIC AEROSOL

Triangulation measurements of twilight effects following the eruption of Krakatoa led to the formal proposal of the existence of a layer of particles in the stratosphere. Proof of the existence of this layer was left until 1961

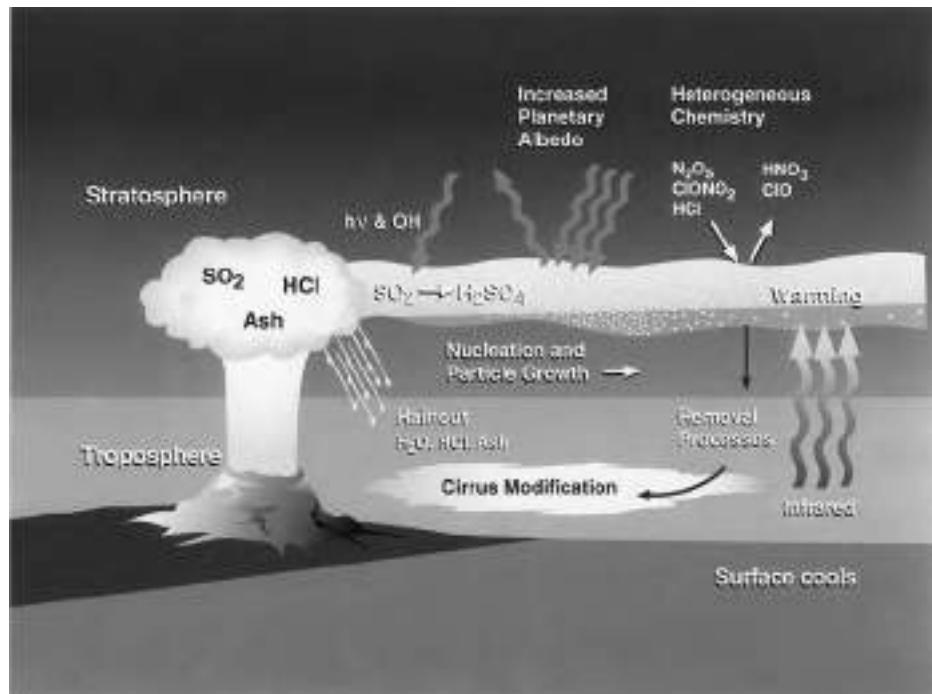

and the pioneering work of Christian Junge and co-workers. Junge's team sampled aerosol directly from high-altitude balloons and measured concentrations of particles in two size ranges. These measurements showed concentrations of larger particles (0.1 to 1  $\mu\text{m}$ ), which contain the bulk of sulfate mass, peaking at 20 km, or 8 km above the tropopause. Vaporization measurements later determined the particles to be liquid solutions of sulfuric acid ( $\text{H}_2\text{SO}_4$ ) in water, or sulfate ( $\text{SO}_4^{2-}$ ).

Junge's measurements followed a period of unusually low volcanic activity. The observation of a peak in aerosol mass in the stratosphere under such conditions suggested a nonvolcanic source is responsible for maintaining stratospheric sulfate aerosol. In 1976, Paul Crutzen suggested carbonyl sulfide (OCS) as the major source of this "background" layer. OCS originates from biological, volcanic, and some anthropogenic sources, such as coal combustion. In the troposphere, it is relatively inert, having a chemical lifetime of about 30 years. Thus it accumulates uniformly throughout the troposphere to a mixing ratio of about 500 parts per trillion by volume (pptv), making OCS the most abundant sulfur-bearing compound in the atmosphere. In the stratosphere, ultraviolet light and reaction with atomic oxygen destroy OCS, producing  $\text{SO}_2$ , which then oxidizes to sulfuric acid. While OCS clearly provides an important source of stratospheric sulfate, it dissociates too high to account for much of the aerosol observed in volcanically quiescent periods.  $\text{SO}_2$  of tropospheric origin, arising from industrial pollution and reduced sulfur compounds produced biologically, appears to have a major influence on aerosol in the lower stratosphere.

### IV. VOLCANIC AEROSOL

In the period since Junge's first measurements, the vast bulk of total sulfate mass in the stratosphere has originated from volcanic eruptions. With the exception of the volcanically quiescent periods in the early 1960s, the late 1970s, the late 1980s, and the period since 1996, most of our measurements of stratospheric aerosol include signals of volcanic influence. The greatest of these have resulted from volcanic plumes that rise well into the stratosphere in the tropics. Plumes which do not break through the troposphere, or which occur at high latitudes, have fewer global consequences.

Figure 1 shows many of the atmospheric perturbations induced by volcanic eruptions that we will be dis-

**FIGURE 1** Volcanic eruptions that penetrate the tropopause can significantly perturb the Earth–atmosphere system via a number of processes shown here. Volcanic clouds may include ash, water vapor, sulfur dioxide ( $\text{SO}_2$ ), and hydrochloric acid (HCl). Water vapor and soluble gaseous components, such as HCl, condense as temperatures drop in the upper troposphere and fall out of the cloud before it enters the stratosphere. Ash that survives the journey may remain in the stratosphere for several months before sedimenting out due to its relatively large size.  $\text{SO}_2$  oxidizes within about a month to produce sulfuric acid, which together with ambient water vapor is responsible for nucleation and growth of stratospheric sulfate aerosol. Depending on the latitude and altitude of the initial injection, stratospheric aerosol may remain at elevated levels for several years following an eruption. Volcanic aerosol may cool the Earth's surface by reflecting additional solar radiation back to space, and may warm the stratosphere by absorbing infrared radiation escaping from the surface and troposphere. Chemical reactions between gaseous and aerosol components activate anthropogenic chlorine, amplifying stratospheric ozone depletion at midlatitudes and polar regions. Sedimentation and atmospheric circulation eventually remove aerosol to the troposphere, where it may be taken up in clouds or rain. When taken up by clouds, the aerosol may again increase planetary albedo by decreasing the average size of droplets in cirrus clouds, modifying their optical properties. [Reprinted by permission from *Nature* (McCormick et al., 1995), copyright 1995 Macmillan Magazines Ltd.]

cussing in some detail in this article. Volcanic eruptions introduce large quantities of ash and magmatic gases into the atmosphere. The major gases released are water vapor (>80% by volume) and carbon dioxide (~10%), with smaller, more variable contributions of  $\text{SO}_2$ ,  $\text{H}_2\text{S}$ ,  $\text{CO}$ ,  $\text{H}_2$ ,  $\text{N}_2$ , HCl, and HBr.

Of these gases, sulfur dioxide ( $\text{SO}_2$ ) creates the only major stratospheric perturbation. Many explosive volcanic eruptions, such as that of Mount St. Helens in 1980, have little  $\text{SO}_2$  in their plumes, and consequently produce minor climatic or chemical effects. Equally explosive events such as that of El Chichón in 1983 contained much more  $\text{SO}_2$  and do impact climate.

$\text{H}_2\text{S}$  may add some sulfur to the stratosphere, but it quickly oxidizes to  $\text{SO}_2$ , and is generally much less

abundant than  $\text{SO}_2$  in volcanic plumes that penetrate the tropopause. The stratospheric masses of many species, such as  $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{N}_2$ , and  $\text{H}_2$ , are much larger than that which could be released by volcanic eruptions. The background stratospheric mass of water vapor (~ $10^{15}$  g) is comparable to that released by only the most massive eruptions, such as Tambora in 1815. Water vapor and the highly soluble species HCl and HBr are rained out of the volcanic plume as it rises, expands, and cools. Volcanic ash provides effective nuclei on which water and soluble species condense, forming large water droplets or ice particles which fall out of the atmosphere. The cold trap at the tropopause effectively prevents HCl or HBr from entering the stratosphere.

Sulfur dioxide is less soluble than HCl, and reaches the stratosphere in considerable quantities, which vary considerably between volcanic events. In the stratosphere, SO<sub>2</sub> oxidizes by reaction with the hydroxyl radical (OH) to produce products which quickly yield sulfuric acid. Satellite observations of the SO<sub>2</sub> cloud produced by the eruption of Mount Pinatubo in 1991 indicate that this oxidation occurs on a timescale of about 1 month. Pinatubo, the largest eruption of this century, put about 20 million tons of SO<sub>2</sub> into the stratosphere.

temperatures increase with altitude in the stratosphere, the equilibrium vapor pressure increases dramatically. At about 30–40 km (varying with latitude, season, and volcanic state) all aerosol boils away as the equilibrium vapor pressure exceeds the available sulfuric acid. Volcanic injections increase available sulfuric acid and the altitude of the top of the aerosol layer.

Stratospheric air contains 3 to 5 parts per *million* by volume (ppmv) of water vapor, compared to 0.5 to 10 parts per *billion* (ppbv) of sulfuric acid. The exchange of water between vapor and aerosol occurs about 10<sup>8</sup> times faster than that of sulfuric acid, and water equilibrates within a few seconds. As sulfuric acid condenses or evaporates, water vapor quickly adjusts to maintain a constant fractional composition, determined by temperature. A particle descending in the stratosphere usually will cool and “swell” with water. In the extremely cold winter polar lower stratosphere, aerosol begins to take up significant amounts of nitric acid as well, becoming a ternary solution.

When aerosol particles run into one another, they coagulate, producing one larger particle from two smaller ones. Coagulation occurs predominantly due to the Brownian motion of the particles, at timescales proportional to the number density of particles (number per cm<sup>3</sup>). It is effective at reducing the number of small particles in the lower stratosphere, but does not significantly increase the size or number of larger particles. As air parcels containing freshly nucleated particles rise from the tropical tropopause, particle mixing ratios (number of particles per milligram of air) are observed to decrease due to coagulation, up to about 22 km. (In the absence of a source or loss process, atmospheric motions do not change the mixing ratio of a gas or aerosol contained in an air parcel. Hence chemists refer to atmospheric abundances in mixing ratio, rather than concentration, to exclude changes induced by changing air density as air parcels move.) At higher altitudes, particle concentrations (which decrease with air density) are too small for coagulation to be important, and particle mixing ratios remain constant.

As particles grow larger than about a micrometer, they begin to fall rapidly. Sedimentation plays an important role in redistributing mass at the top of the aerosol layer. As particles fall to lower altitudes, however, rising pressures slow their fall. In the nonvolcanic aerosol layer, sedimentation does not play a significant role in removing particles from the stratosphere because the particles are so small. Volcanic input, however, can cause particles to grow larger than 0.5  $\mu\text{m}$  and sediment from the lower stratosphere before they are removed with ambient air parcels.

## V. AEROSOL MICROPHYSICS

Processes affecting the size and atmospheric distribution of aerosol particles fall under the field of microphysics. These processes include nucleation, condensation, evaporation, coagulation, and sedimentation. Aerosol microphysics determines the influence of volcanic perturbations on the stratosphere.

Very small aerosol particles are produced in the tropical upper troposphere by a process known as binary homogeneous nucleation. This process is distinguished from heterogeneous nucleation in that particles do not form on existing solid nuclei, but directly from the gas phase. Under atmospheric conditions, binary clusters composed of both sulfuric acid and water molecules are required to create stable nuclei. For a given concentration of water and sulfuric acid, nucleation will proceed faster at colder temperatures. The formation of significant concentrations of new particles in the atmosphere requires the extreme cold of the tropical tropopause. The gently rising motions in the tropics loft these small particles from the tropopause region into the stratosphere, where they grow to become stratospheric aerosol. New particles are also nucleated in the polar stratosphere in winter and spring, also under extreme cold conditions. Following large volcanic eruptions, nucleation of new particles also occurs in the stratosphere. However, much of the new sulfate injected into the stratosphere condenses on particles that were previously present or formed during the earliest weeks following the eruption.

Condensation of sulfuric acid molecules on existing particles provides an important growth mechanism for stratospheric aerosol. Even under volcanic conditions, concentrations of sulfuric acid in the stratosphere are small enough that it takes several months for condensation to equilibrate the vapor and aerosol phases. As

## VI. CHARACTER OF VOLCANIC INPUT

Microphysical calculations and observations show that volcanic SO<sub>2</sub> generally results in larger particles, rather than greater concentrations, because coagulation limits the particle concentrations. As Table I shows, stratospheric aerosol mass may increase by one or two orders of magnitude following a significant eruption. Aerosol properties such as surface area and optical depth (which determines the probability that an arbitrary photon will encounter a particle in its path through the atmosphere) show similar increases. Figure 2 shows global satellite observations of aerosol optical depth before and after the June 1991 eruption of Mount Pinatubo. Aerosol in the initial equatorial band was 100 times optically thicker than the pre-eruption background throughout the second half of 1991. Two and a half years after the eruption, aerosol had spread to higher latitudes, at about 10 times the background optical depth.

The global distribution of aerosol from volcanoes depends primarily on the latitude at which the eruption occurs. The atmospheric influence of eruptions outside the tropics is almost entirely contained within the middle and polar latitudes of the hemisphere of origin. Volcanic sulfur and ash are rained out of the troposphere within days or weeks of the eruption, much faster than interhemispheric exchange of air occurs in the troposphere. In the stratosphere, the circulation carries aerosol poleward and downward from the tropics. A branch of stratospheric circulation also carries air up into the mesosphere at the summer pole. Mesospheric circula-

tion then brings air back across the equator to the winter hemisphere, where it descends back into the stratosphere. The mesosphere, however, contains about 1% of the mass of air in the stratosphere, limiting the influence of this method of interhemispheric exchange.

Aerosol from tropical eruptions has the potential to spread globally in the stratosphere, as was the case with Mount Pinatubo (15°N). However, aerosols from many tropical eruptions, such as El Chichón (17°N) in 1982, have remained largely in their hemisphere of origin. In the next section, we examine how volcanic aerosol can affect the dynamics that determines its own distribution.

Observations of volcanic aerosol have taught us much about the meridional transport of air in the stratosphere. The eruptions of El Chichón in 1982, Nevado del Ruiz in 1985, and Pinatubo in 1991 each produced enhanced reservoirs of aerosol in the tropical stratosphere that persisted for several years. The transport of air out of the tropics to higher latitudes depends on the direction of zonal winds over the equator, which vary with altitude and time. Winds over the equator change direction between easterly and westerly with a periodicity that varies about a 28-month average. This variation, known as the quasi-biennial oscillation (QBO), dominates the circulation of the lower stratosphere. In periods when easterly winds lie over the equator, wind shear inhibits transport out of the tropics to the winter hemisphere, where westerly winds circulate through the extratropics. Poleward mixing occurs more rapidly during westerly phases of the QBO, when wind shear is weaker.

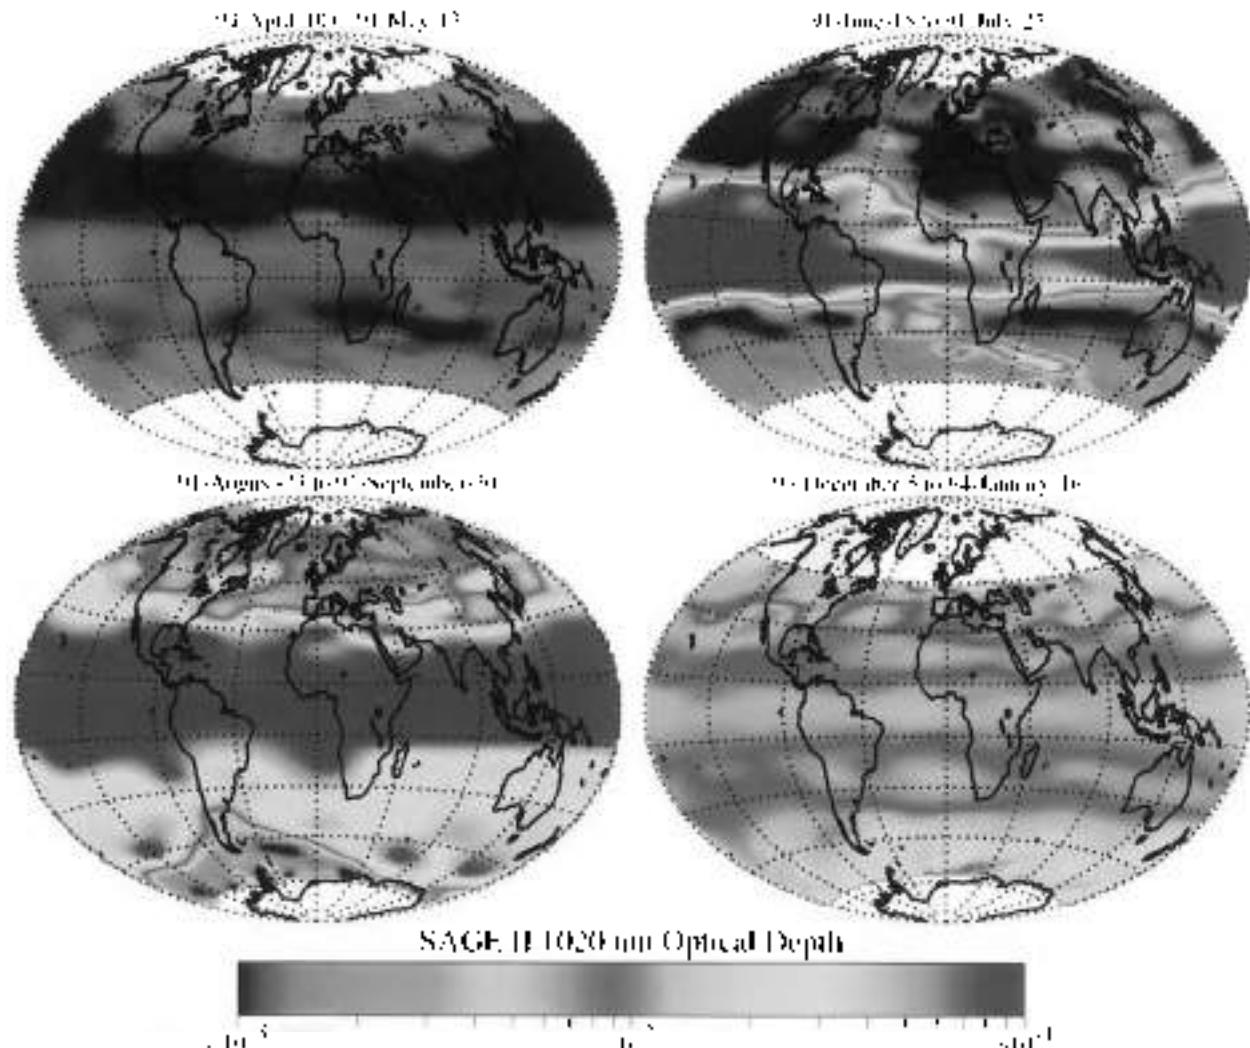

For example, easterly winds prevailed at altitudes above 23 km in the tropics for 6 months following the Mount Pinatubo eruption. The initial dispersion of aerosol in the stratosphere toward the higher latitudes therefore occurred at altitudes below 23 km. This aerosol produced the first spectacular sunsets seen in northern midlatitudes due to the eruption. Above 23 km, a tropical reservoir formed, with sharp boundaries near 20°N and 20°S. Progression of the QBO allowed much of this tropical reservoir to disperse in 1992, after which stratospheric aerosol mass decreased for several years with a lifetime of about 1 year.

TABLE I

Eruption	Date	Estimated stratospheric aerosol loading (Tg of SO <sub>4</sub> )
Tambora (Indonesia)	April 1815	>100
Krakatoa (Indonesia)	August 1883	~50
Katmai (Alaska)	June 1912	20
Agung (Indonesia)	March 1963	16–30
Fuego (Guatemala)	October 1974	3–6
Stratospheric background?	1979	<1
El Chichón (Mexico)	April 1982	12
Pinatubo (Philippines)	June 1991	30
Cerro Hudson (Chile)	August 1991	3

## VII. VOLCANIC EFFECTS ON STRATOSPHERIC DYNAMICS

The input of volcanic aerosol may affect atmospheric dynamics, and thereby determine its own distribution throughout the stratosphere. By absorbing infrared en-

**FIGURE 2** The stratospheric aerosol and gas experiment (SAGE) II was one of several satellite-borne instruments to monitor the distribution of stratospheric aerosol following the June 1991 eruption of Mount Pinatubo. Initially confined to the tropics, Pinatubo aerosol increased the 1- $\mu\text{m}$  optical depth by two orders of magnitude. Over 6 months, the aerosol spread to higher latitudes, as evident in the one order of magnitude increase in optical depth globally. The stratospheric aerosol layer continued to be dominated by steadily decreasing volcanic aerosol for 3 years. [Reprinted by permission from *Nature* (McCormick et al., 1995), copyright 1995 Macmillan Magazines Ltd.]

ergy rising from the Earth's surface as well as sunlight at near-infrared wavelengths, aerosol can heat the atmosphere and alter both vertical and meridional winds. The extent of this affect appears to depend on the mass of volcanic input.

For example, while aerosol from the 1982 eruption of El Chichón ( $17^\circ\text{N}$ ) and other subtropical eruptions remained largely in its hemisphere of origin, that from the 1991 eruption of Mount Pinatubo ( $15^\circ\text{N}$ ) spread within several weeks to a latitude band covering nearly all of the tropics. Numerical simulations of atmospheric transport point to local heating, rather than planetary-

scale transport patterns, as the cause of the unusual southward movement of Pinatubo aerosol.

In the lower tropical stratosphere, temperatures increased by about  $3.5^\circ\text{C}$  within 4 months of the Pinatubo eruption, putting them more than three standard deviations above the mean. The warm air rose more vigorously than usual, lifting aerosol to altitudes above 35 km within 5 months of the eruption. The increased vertical motion had strong consequences for the Earth's ozone layer.

Ozone and atomic oxygen make up the "odd oxygen" family of atmospheric species. The two species inter-

change rapidly with one another by numerous chemical reactions. Reactions that produce or destroy total odd oxygen, however, are much slower. The lifetime of odd oxygen varies sharply with altitude in the stratosphere. While odd oxygen is produced and destroyed within several hours at 60 km, it survives for weeks at 35 km, and for several years at 20 km. Because transport in the stratosphere generally takes weeks to months to move air over planetary distance scales, we say that odd oxygen (hence, ozone) concentrations are dynamically controlled in the lower stratosphere, and chemically controlled in the upper stratosphere.

Changing the atmospheric dynamics in a region where ozone is dynamically controlled will result in a changed distribution of ozone. When volcanic aerosol heats and loftes tropical air, ozone has less chance to accumulate in the tropical lower stratosphere before being pushed up and out to higher latitudes. In the first several months following the eruption of Pinatubo, total column ozone over the equator was observed to decrease by 6–8%. This effect is substantially greater than ozone depletion in the tropics caused by anthropogenic compounds. Tropical ozone loss is of some concern because the Sun can be directly over head at these latitudes and is less attenuated by the atmosphere than at higher latitudes. However, this natural dynamical perturbation lasted less than a year in the case of Pinatubo, making it less worrisome than long-term ozone depletion observed at midlatitudes.

---

### VIII. RADIATIVE AND CLIMATE EFFECTS

History has shown us that volcanic eruptions are associated with colder-than-normal temperatures at the Earth's surface. However, it turns out that volcanic aerosol affects the Earth's radiation budget in a variety of ways, some of which involve heating.

In the Earth's radiation budget, incoming radiation from the Sun must be balanced by outgoing radiation. The Sun's rays cover a broad spectrum of wavelengths, which penetrate the atmosphere to varying depths. Much of the high-energy radiation is absorbed by atmospheric species high in the atmosphere. Ozone efficiently absorbs ultraviolet rays in the stratosphere, allowing life intolerant of its effects to exist below. Much of the remaining radiation is absorbed at the surface. Radiation absorbed by matter heats it, causing the matter itself to radiate to maintain balance. The Sun heats the Earth to temperatures that cause it to radiate in the

infrared, wavelengths shorter than visible light. On its way out to space, some of this infrared radiation is itself absorbed by greenhouse gases and particles in the atmosphere, increasing atmospheric temperatures substantially.

Some of the sun's incoming radiation is not absorbed, but reflects off the Earth's surface, or scatters off of particles in the atmosphere, and returns to space (Figure 1). Increases in the planetary albedo decrease the amount of radiation absorbed, decreasing the Earth's temperature. The scattering efficiency of a single particle varies as a complex function of particle radius and wavelength. Generally, for a given mass of aerosol, a large number of small particles provide greater optical depth than a small number of large particles. The albedo of an aerosol layer also depends on its optical depth. The radiative response to volcanic input therefore depends on the increased optical depth due to increased aerosol mass and the change of optical depth with scattering efficiency due to increased aerosol radius.

The satellite-borne Earth Radiation Budget Experiment (ERBE) made the first unambiguous, direct measurements of large-scale volcanic forcing following the June 1991 eruption of Mount Pinatubo. These measurements determined the albedo between 30°N and 30°S in August 1991 to be more than five standard deviations above the 5-year mean for that region in August, with similar increases in July and September 1991. The increased optical depth (Figure 2) which accompanied more than an order of magnitude increase in aerosol mass was the predominant factor, termed the "direct effect" of volcanic aerosol. Pinatubo's eruption had the greatest relative effect on albedo over regions of the Earth usually free of clouds.

ERBE also measured increased albedo in regions frequented by high-albedo deep convective clouds. This albedo increase may have been due to an indirect effect of volcanic aerosol. Aerosol may indirectly change the optical properties of clouds. In this case, an eruption dramatically increases the number of particles in the atmosphere available to act as nuclei for cloud particles. The same amount of water distributed over a larger number of particles means the average particle will be smaller. Smaller cloud particles scatter visible radiation more efficiently, increasing albedo.

#### A. Stratospheric Warming

As we noted in our discussion of volcanic effects on atmospheric dynamics, aerosol absorbs the Earth's infrared radiation, thereby heating the tropical stratosphere.

(Because the Earth is colder at high latitudes, it provides less infrared radiation to heat the stratospheric aerosol layer there.) Significant temperature anomalies in the lower tropical stratosphere were observed within two seasons of the eruptions of Agung (Bali, 8°S) in March 1963, El Chichón, and Pinatubo. Adjusting for the temperature cycle associated with the QBO, researchers have shown that each of these eruptions raised lower stratospheric temperatures by nearly 2°C in the tropics, with lesser or no effects at higher latitudes. These anomalies are three to four standard deviations above the mean of the 13 QBO cycles between 1958 and 1996 that do not include these eruptions. The warming events lasted up to 2 years following these eruptions, and extended at least as high as 30 km in the case of El Chichón. Although Pinatubo is believed to have injected considerably more SO<sub>2</sub> into the stratosphere than the other two eruptions studied, Agung was found to have raised stratospheric temperatures by approximately the same degree. Possibly this near equality is due to the wider distribution of the Pinatubo debris, which diluted its input. The Agung and El Chichón clouds were primarily concentrated in one hemisphere.

By the end of 1993, stratospheric temperatures had moved from higher than average to new lows. This cooling is likely the result of an observed decrease in stratospheric ozone following the eruption of Pinatubo. Ozone heats the stratosphere, and is responsible for the increasing temperature profile there. In the section on stratospheric chemistry, we discuss how volcanic aerosol amplifies the depletion of ozone by anthropogenic chlorine.

## B. Tropospheric Cooling

Whether the net effect of aerosol absorption and reflection is to cool or to heat the Earth depends on particle size. For the warming effect to overcome the cooling effect, particles must be larger than about 2 μm in radius. The Pinatubo eruption is estimated to have caused the mass-averaged aerosol radius to increase from 0.3 μm to about 1 μm, resulting in a net cooling of the Earth. Particles of radius greater than 2 μm fall at rates of more than 30 km per year in the lower stratosphere, ensuring their removal within months. Thus, sedimentation limits the size of stratospheric aerosol, making it unlikely that volcanic aerosol could be large enough to warm the Earth for significant periods.

Recent major volcanic eruptions have clearly produced significant cooling anomalies in the troposphere for 1 to 3 years. The magnitude of volcanic effects can

be masked by natural variations in temperature and the global warming trend seen in the last several decades. Just as stratospheric temperatures are driven by the quasi-biennial oscillation in high-altitude tropical winds, so the average annual temperatures we experience in the troposphere are strongly correlated to the El Niño-Southern Oscillation (ENSO) in sea surface temperatures in the eastern equatorial Pacific. Removal of the ENSO-driven variability clarifies the influence of major volcanic eruptions.

Examination of global average temperature data from 1958 to 1992 shows the two greatest departures from the mean temperature for this period occurred in 1964 and 1992, the years immediately following the eruptions of Agung and Pinatubo. Both of these eruptions cooled the troposphere by about 0.4°C, compared to the average temperature for the phase of ENSO in these years. That the ENSO-adjusted temperature anomalies are similar is surprising, given that Agung is believed to have injected significantly less SO<sub>2</sub> into the stratosphere than Pinatubo. However, Agung's cloud was primarily limited to the southern hemisphere. Also, Pinatubo erupted in an atmosphere containing more greenhouse gases, and followed 6 years of above-average temperatures. As perhaps the largest eruption of the 20th century, Pinatubo more than offset the climate forcing of all greenhouse gases added to the atmosphere since pre-industrial times, at least for a short time. While a background of rising temperatures made 1992 was the 8th warmest year since 1951, Pinatubo made it the 2nd coolest since 1987.

There exists significant evidence for global tropospheric cooling following many other major volcanic eruptions, with the greatest data and study associated with those of recent decades. The 1982 eruption of El Chichón also produced a cooling which lasted 2 or 3 years, and which becomes evident only when the warming influence of the very strong 1982–1983 El Niño is taken into consideration. The great eruptions of the 19th century, Krakatoa and Tambora, present greater uncertainties in global surface temperatures and in the influence of ENSO. Estimates from northern hemisphere temperature data suggest that Krakatoa may have cooled the atmosphere by about 0.3°C and Tambora by 0.4 to 0.7°C.

Larger eruptions do not necessarily produce greater or more protracted temperature anomalies. Microphysical calculations show that greater input of volcanic SO<sub>2</sub> results in larger particles, rather than greater numbers. In addition to falling out of the stratosphere faster, larger particles have a smaller optical depth per unit mass than smaller particles. These properties moderate the radia-

tive and climate influences of volcanoes, and may limit them as the size of a volcanic eruption increases.

---

## IX. EFFECTS ON STRATOSPHERIC CHEMISTRY

As we have discussed, volcanic clouds can contain large volumes of HCl and some HBr, which rain out before they enter the stratosphere. Observations following the eruption of Pinatubo confirmed that HCl did not increase significantly from pre-eruption levels. Stratospheric chlorine is derived from anthropogenic chlorofluorocarbons (CFCs) and methyl chloroform (which has natural sources), rather than volcanic eruptions. Stratospheric bromine comes from anthropogenic halocarbons and methyl bromide, not volcanoes. Volcanic aerosol, however, does alter stratospheric chemistry in such a way that it activates chlorine and bromine for ozone depletion. It does so by means of reactions on surfaces, whose importance to atmospheric chemistry was not appreciated until the report of a rather alarming development in 1985.

### A. The Antarctic Ozone Hole

Since the mid-1970s, scientists have understood that CFCs, used for a variety of purposes since the 1930s, could break down in the stratosphere, releasing chlorine which was predicted to deplete ozone in the upper stratosphere by a few percent by the middle of the 21st century. In 1985, the British Antarctic Survey astounded the world by reporting the development of a seasonal ozone hole over Antarctica in the lower stratosphere each spring. The observed depletion was much lower in altitude and far greater in magnitude than the predicted depletion. In fact, in the region where ozone normally reaches peak concentrations, springtime observations now showed ozone to be almost completely depleted. In the lower stratosphere, chlorine and bromine are partitioned in favor of inactive chemical forms that should not participate in catalytic destruction of ozone. The explanation for the development of the Antarctic ozone hole each spring focused attention on chemical reactions which occur on atmospheric particles.

While much of stratospheric chemistry focuses on reactions that occur in the gas phase, heterogeneous chemistry also occurs between atmospheric gases and

liquid or solid aerosols. The rates of most heterogeneous reactions increase strongly as these aerosols become more dilute, at low temperatures. Thus heterogeneous reactions often go faster at colder temperatures. The Antarctic stratosphere is cold enough to encourage heterogeneous reactions, which directly repartition chlorine and bromine from inactive reservoirs (HCl, ClONO<sub>2</sub>, HBr, and BrONO<sub>2</sub>) to active forms (Cl<sub>2</sub> and BrCl). Cl<sub>2</sub> and BrCl break down into highly reactive Cl and Br, which participate in numerous catalytic cycles that destroy ozone. Direct observations of ClO, a product and participant in such cycles, have confirmed that anthropogenic chlorine and bromine are responsible for the ozone hole.

As winter approaches and temperatures decrease in the polar stratosphere, sulfate aerosol becomes very dilute, taking up not only water but also significant quantities of nitric acid (HNO<sub>3</sub>). This process results in severe losses of gas-phase reactive nitrogen species, such as NO<sub>2</sub> and N<sub>2</sub>O<sub>5</sub>, which produce nitric acid. The resulting H<sub>2</sub>O/HNO<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub> liquid ternary solution aerosols constitute a type of polar stratospheric clouds (PSCs). Some of these may freeze or otherwise solidify to form PSCs composed of solid particles. As PSC aerosol grows large, it can fall out of the stratosphere, bringing the condensed nitric acid with it. This results in irreversible denitrification of the polar stratospheric vortex. Denitrification greatly reduces the formation of the inactive reservoirs of ClONO<sub>2</sub> and BrONO<sub>2</sub> from active chlorine and bromine species.

Heterogeneous reactions proceed at rates proportional to the surface area of aerosol present in the polar stratosphere. At the low temperatures of polar winter, these reactions occur quite rapidly on liquid or solid aerosol. Ozone loss does not begin until the spring, however, with the return of the sunlight necessary for ozone photochemistry.

Model studies have shown that variations in observed stratospheric aerosol due to volcanic eruptions over the 1975–1994 history have modulated the severity of the Antarctic ozone hole. Following the eruptions of El Chichón and Pinatubo, springtime Antarctic ozone declined relative to pre-eruption levels by about 15 to 20%, respectively, before recovering somewhat as aerosol declined for several years. Model chemistry shows that interannual variations in the magnitude of the ozone hole result from volcanic perturbations to stratospheric aerosol, while longer-term declines are related to increasing stratospheric chlorine over the period examined. Thus, while stratospheric chlorine and bromine are expected to decline over the 21st century due to international treaties regulating CFCs and halocarbons,

their ozone-depleting effects may be greatly magnified over this period by volcanic eruptions. As we shall see, this concern is not limited to the relatively unpopulated polar regions.

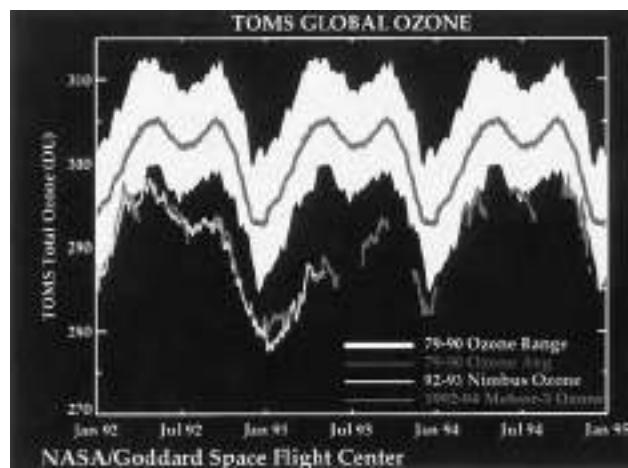

### B. Midlatitude Ozone Depletion

Many of the reactions responsible for directly converting chlorine and bromine reservoir species into active forms do not occur at significant rates in the warmer middle latitudes. Heterogeneous hydrolysis of bromine nitrate is an exception, and remains fast. In addition, heterogeneous hydrolysis of nitrogen pentoxide ( $N_2O_5$ ), which forms nitric acid, occurs on sulfate aerosol independent of temperature. This reaction has important implications for the partitioning of chlorine and bromine in the lower stratosphere.  $N_2O_5$  forms in the atmosphere only at night, and interchanges with short-lived  $NO_2$  on a timescale of several days. At midlatitudes, nitric acid has an atmospheric lifetime of several weeks. Heterogeneous hydration of  $N_2O_5$  therefore moves nitrogen from a moderately active species to a long-lived reservoir, reducing nitrogen available to form  $NO_2$ . Decreased  $NO_2$  concentrations decrease formation of the  $ClONO_2$  and  $BrONO_2$  reservoirs from active chlorine and bromine. Thus heterogeneous chemistry pushes the partitioning of chlorine and bromine toward active, ozone-depleting forms.

As with the Antarctic ozone hole, northern middle latitudes experienced interannual ozone variations between 1979 and 1994, which model calculations have linked to volcanic influences on stratospheric aerosol. Following the eruptions of El Chichón and Pinatubo, respectively, observed ozone at  $45\text{--}55^\circ N$  fell by 2 and 4% before recovering somewhat. The model showed that, in addition to causing these losses lasting 2–3 years, volcanic aerosol, evident as increases in surface area relative to 1979, suppressed ozone throughout the entire period studied. The primary mechanism by which aerosol modulates midlatitude ozone loss in the model is suppression of  $NO_2$  and related species. However, observed variations in ozone were 50% greater than those modeled, leaving room for the involvement of additional chemistry, not currently understood, in aerosol modulation.

### C. Global Ozone Loss from Mount Pinatubo

The effects of the Mount Pinatubo eruption on global ozone are powerfully illustrated in Figure 3. This figure

**FIGURE 3** Global mean ozone in Dobson units (DU) from the total ozone mapping spectrometer (TOMS) carried aboard the NIMBUS 7 and METEOR 3 satellites. Measurements from the 1992–1994 post-Pinatubo period (in thinnest and medium lines) are compared to the range of measurements from 1979 to 1990 (in white, repeated for three annual cycles). The thick line shows the average total ozone for this period. Global ozone remained at record lows throughout the 1992–1994 period due to increased heterogeneous activation of anthropogenic chlorine on aerosol. In the tropics, ozone loss resulted mainly from dynamical uplifting that resulted from aerosol heating. Tropical ozone loss, measured by TOMS, did not last beyond mid-1992. [Reprinted by permission from *Nature* (McCormick et al., 1995), copyright 1995 Macmillan Magazines Ltd.]

contrasts the global mean ozone measured in the period from 1992 through 1994 to the full range of observations from 1979 to 1990. Six months after the eruption, column ozone had fallen to the low range of the normal annual cycle. By mid-1992, the global mean was well below previous minima, and on a downward trend that continued well into 1993. As previously mentioned, ozone loss observed over the equator in the months following the eruption resulted primarily from dynamical uplifting, not heterogeneous chemistry. This tropical ozone loss did not last beyond mid-1992, while global losses persisted a year and a half longer. Midlatitude ozone loss was most severe in the northern hemisphere. Over the United States, record low ozone values were set between January and April of 1993. Globally, ozone levels began to recover in the second half of 1993, although, as Figure 3 shows, they persisted at record lows throughout 1994. Observations of highly perturbed concentrations of  $NO_2$  and nitric acid, correlated with enhanced aerosol, confirm the importance of heterogeneous chemistry in this prolonged ozone loss.

---

## X. LESSONS FOR THE FUTURE

The timing of the eruption of Mount Pinatubo provided a demonstration of the combined atmospheric effects of volcanic aerosol and anthropogenic perturbations. For ozone, the presence of volcanic aerosol accelerates the destructive effects of anthropogenic halogens. At the same time, the radiative effects of volcanic aerosol can act to offset global warming from anthropogenic greenhouse gases.

The volcanic risk to global ozone will remain high as long as stratospheric halogens remain significantly elevated from preindustrial levels. Current international treaties banning chlorinated and brominated source gases should reduce stratospheric halogen concentrations to natural levels toward the end of the 21st century. In the absence of anthropogenic halogens, volcanic eruptions are not expected to chemically reduce ozone, although their dynamical effects may result in short-term, localized losses such as that seen in the tropics following the Pinatubo eruption.

While the atmospheric cooling that follows volcanic eruptions may seem a relief from projected increases in global temperature, the social disruptions they have been known to have caused throughout human history serve as a grim warning of the dangers of even small changes in global mean temperature. If famine and disease resulted from just a few years of abnormally cold temperatures, the consequences of longer-term climate changes could be dire.

By tracking the changes caused by volcanic perturbations to the natural laboratory of the Earth's atmosphere, scientists have been able to study the dynamical and chemical processes around us that affect our lives. What they have learned may help predict future consequences of global change due to both natural and anthropogenic disturbances. The study of the atmospheric effects of volcanoes better prepares us for not only future volcanic eruptions, but also aerosol generated by everything from stratospheric aircraft to impacting comets and nuclear war. Our better understanding can tell us which patterns of human behavior are destructive to the well-being of life on Earth, and allow us the choice of changing such patterns before it is too late.

## GLOSSARY

**base surge** This is usually formed when an eruption starts in a lake or coastal environment and is due to the explosive interaction of hot magma with water. Water-surface-hugging ash clouds move outward from the base of an eruption column. In the 1965 eruption at Taal volcano, Philippines, base surges traveled more than 4 km over the water surface of the lake in which the eruption center was located and impacted on lakeside villages, killing 189 people.

**DRE** Dense rock equivalent, this refers to the volume or mass that erupted material would have if it were dense (unvesiculated) rather than vesiculated.

**hazard map** A map used to illustrate geographic regions in terms of expected hazard.

**lateral blast** Is caused by the sudden decompression of highly pressurized magma by a volcano's flank or lava dome failure. At Mount St. Helens, on 8 May 1980, a northward-directed lateral blast of rock, ash, and hot gases occurred some seconds after a debris avalanche

was triggered by flank failure of the volcano. It began with an initial velocity probably exceeding supersonic speeds and rapidly overtook the avalanche and traveled up to 25 km, devastating an area of about 600 km<sup>2</sup> in a fan-shaped sector north of the volcano.

**plinian eruption** An eruption with a powerful, convecting column reaching up to 45 km high.

**pyroclastic flow** A flow of volcanic material ranging from vesiculated, low-density pumice to unvesiculated, dense lava and clasts which tends to follow topographic lows (i.e., valleys) as it moves.

**pyroclastic surge** A turbulent, low-density, high-velocity part of a pyroclastic flow. It is not so constrained by topography as a pyroclastic flow.

**vulcanian eruption** An explosive event of less than 1 km<sup>3</sup>, but with an eruption column often reaching 10–20 km high.

MANY OF THE largest historical volcanic disasters have involved pyroclastic flows or surges (29,000 killed at Mount Pelée, Martinique, in 1902; 12,000 at Tambora, Indonesia, in 1815; and 6000 at Santa María, Guatemala, in 1902). Even relatively small-scale events can have devastating human consequences. Pyroclastic flows contain massive mixtures of hot lava blocks, ash, pumice, and volcanic gas descending the slopes of volcanoes at very high speeds. Pyroclastic and base surges are constituents of pyroclastic flows, which

are characteristically diluted, lacking a high concentration of particles and containing a lot of gases. Surges can be generated directly by column collapse and by separation from the moving, relatively dense main body of the pyroclastic flow. Surges rarely have sufficient force to destroy buildings in their path and are short-lived compared with pyroclastic flows because of their lower momentum and density. Surges often run over topographic barriers, however, and have therefore also been called "hot hurricanes" or "blasts."

## I. INTRODUCTION

Pyroclastic flows can derive from gravitational collapse of Plinian eruption columns. In this case, the flows descend radially down the volcano's slopes. At Pinatubo, Philippines, on 15 June 1991, for example, more than 4 km<sup>3</sup> of ash and pumice moved radially down from the summit crater as several flows within a few hours. Column collapse and vulcanian explosions at Soufriere Hills volcano, Montserrat, in August 1997, also produced pyroclastic flows in multiple directions which traveled as far as 5 km from the vent.

Pyroclastic flows can also originate directly from the vent rather like a pot of rice boiling over. The 1980

explosive eruptions at Mount St. Helens produced pyroclastic flows of this type.

Lateral explosions directly from a summit dome or lava flow may produce small but explosive pyroclastic flows like those at Mount Pelée volcano, Martinique, in 1902, where the associated pyroclastic surges killed about 29,000 people, mainly in the city of St. Pierre. Finally, pyroclastic flows may also originate from gravitational collapse of lava domes or lava flows. These types of pyroclastic flows were frequently observed during the 1991–1995 eruption at Unzen, Japan (Figure 1), and in the 1995–1998 eruption at Soufriere Hills, Montserrat, West Indies. In both eruptions, several tens of people lost their lives as a direct consequence of being overwhelmed by pyroclastic flows and surges.

---

## II. PHYSICAL PROPERTIES OF PYROCLASTIC FLOWS AND SURGES

### A. Mobility

Driven by gravity, pyroclastic flows seek topographically low areas of the volcano and tend to be channeled into valleys. Large-scale pyroclastic flows associated with

**FIGURE 1** Ash cloud associated with the pyroclastic flows that descended the Oshigadani Valley at Unzen. The cloud grew vigorously from the valley mouth. (Taken by Kenji Ohkawa on 15 September 1991.)

caldera-forming ash flows can move distances of more than 100 km. The travel distance depends largely on the mass of pyroclastics thrown out from the source and the height at which pyroclastic flows start to descend (or collapse). The ratio of the height ( $H$ ) dropped over the travel distance ( $L$ ) is as small as 0.2–0.29 for large-scale pyroclastic flows and higher than 0.33–0.39 for small block-and-ash flows. This indicates that larger flows are more mobile than small flows. High-mobility pyroclastic flows may be fluidized by volcanic gases released from the interior of lava blocks and particles or by expansion of heated air trapped in the moving front. These gases may reduce friction between grains and the ground. It is not clear, however, that pyroclastic flows except for diluted pyroclastic surges have a significantly different emplacement mechanism from other flows such as debris avalanches. This is because the relationship between volume erupted and the  $H/L$  ratios, which is negative, is almost identical for pyroclastic flows and debris avalanches. Therefore, we can predict the travel

distance from the starting point of pyroclastic flows, assuming a constant apparent friction ( $H/L$ ) for the flow. The value of apparent friction can be estimated from field observations of pyroclastic flow deposits only when they did not result from column collapse. Measurements of  $H$  and  $L$  tend to produce underestimates of the actual values for column-collapse-type large and prehistoric pyroclastic flows, leading to low  $H/L$  ratios. It is very difficult to estimate the height of column collapse, even if the eruption can be observed.

Prehistoric large-scale pyroclastic flows sometimes traveled over the sea for distances of several tens of kilometers. This implies that at least the upper parts of the pyroclastic flow were less dense than water. Most pyroclastic flows are considered to consist of a clast-rich bottom portion (basal avalanche) and an overlying low-density cloud. Surges are relatively short-lived and the area impacted by them is limited around the source (vent or moving front of basal avalanche) to generally less than a few kilometers (Figure 2). However, although

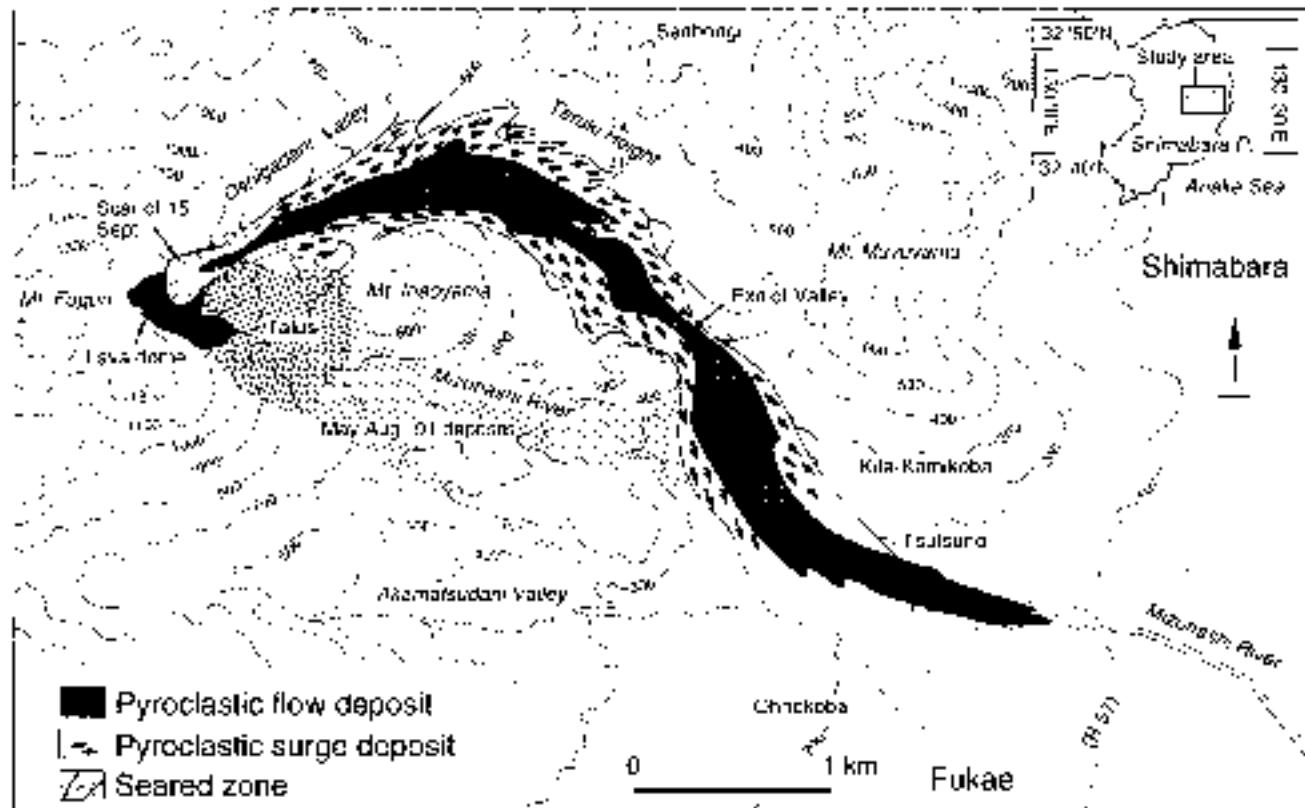

FIGURE 2. Map showing deposit distribution of the 15 September 1991 pyroclastic flow at Unzen and detachment of the pyroclastic (ash cloud) surges from the main stream (basal avalanche) of pyroclastic flows. Devastation by the surge in Kita-Kamikoba was such that a car was thrown about 120 m by the surge. In contrast, houses and an elementary school in the Ohnokoba District engulfed by the detached surges were burned but otherwise undamaged by the surges.

lateral blasts are also a short-lived diluted turbulent current, they may travel large distances (for example, at Mount St. Helens, the initial velocity was supersonic).

### B. Speed

Pyroclastic flow and surge travel speeds are generally greater than  $10 \text{ m s}^{-1}$  and sometimes reach more than  $100 \text{ m s}^{-1}$ . Speeds of recent pyroclastic flows have been measured using video footage and precise observations based on seismic signals. The 1980 Mount St. Helens lateral blast traveled up to  $150 \text{ m s}^{-1}$ , with an internal velocity of  $235 \text{ m s}^{-1}$ . Pyroclastic flows of 7 August 1986 at Mount St. Helens had a maximum speed of  $30 \text{ m s}^{-1}$ , and at Soufriere Hills volcano, Montserrat, small flows had an average speed of  $3\text{--}10 \text{ m s}^{-1}$ , while flows which traveled further were in the range  $15\text{--}30 \text{ m s}^{-1}$ .

### C. Temperature

Temperatures of pyroclastic flows may be estimated indirectly if carbonized wood or melted or deformed household materials can be found after a flow has passed. In the 1902 pyroclastic flows at Mount Pelée, glass materials were melted but gold coins were not; temperatures in the range of  $100\text{--}1100^\circ\text{C}$  have been suggested. However, melting can take place due to fires ignited by hot pyroclastic flows. The estimate of these temperatures is therefore ambiguous, as it is not clear whether they represent the condition of the ash cloud, ash particles drifting inside, or the deposit. Direct measurements of the temperature, pressure, and speed of pyroclastic flows can be made by placing devices in the expected path of a flow. On Montserrat, temperatures ranging from 99 to  $250^\circ\text{C}$  have been determined in this way. On Unzen volcano in 1992, maximum temperatures of over  $660^\circ\text{C}$  were found. The temperature of the ash cloud was as high as  $350^\circ\text{C}$ , and the pressure of the surge did not exceed 0.5 bar (a pressure of 0.1 bar corresponds to a moving pressure with strong wind of  $125 \text{ m s}^{-1}$ ). The velocity of ash particles ranged from several tens of meters per second to  $160 \text{ m s}^{-1}$ . The moving front of pyroclastic flows at Unzen had a velocity of  $6\text{--}50 \text{ m s}^{-1}$ ; however, since the surge moves turbulently, particle velocities are not necessarily the same as those of the whole flow.

## III. VOLCANIC DISASTERS INVOLVING PYROCLASTIC FLOWS AND SURGES

### A. Mount Pelée, Martinique

One of the most tragic volcanic disasters in the world took place at Mount Pelée, Martinique, West Indies, in May 1902. The city of St. Pierre, with a population of 28,000, was located only 7 km southwest of the volcano's summit. One month before the tragic event, phreatic eruptions began spewing ash and sulfurous gas. A large mudflow descended along the Riviere Blanche on 5 May, and during 7–8 May swept the mountain flanks, burying 23 people working at a sugar mill and 400 people in a coastal village. It is thought that explosions displaced the water of a summit lake into the head of the river. Then ash fell on the city of St. Pierre and birds fell dead onto the streets, suffocated by gases. Although many people wanted to leave the city, they were urged to stay in the city by the government because of an important forthcoming election.

A series of violent explosions took place on the morning of 8 May. A great black cloud of ash rose above the mountain top, and simultaneously another cloud shot southward from the crater. Pyroclastic flows descended along the Riviere Blanche and reached the coast, while pyroclastic surges spread south of the river (Figure 3) and engulfed the city within several minutes. Nearly every one of the 28,000 inhabitants was killed. The surge struck the city with tremendous force, such that 1-m-thick stone walls were knocked over and large trees toppled. Trees that remained standing were stripped of leaves and branches, and on many the bark was stripped away on the side toward the volcano. A few people survived the surges. One of them was a prisoner shut up in a well-sealed cell, and one was in a house located on the periphery of the surge cloud. Both were severely burned. The explosive eruptions were renewed on 20 May and 30 August 1902, and produced 1000 additional victims in two villages about 5 km southeast and 6 km northeast of the mountain.

### B. Pinatubo, Philippines

Mount Pinatubo in the Philippines became active suddenly in 1991. This volcano had been quiet for more than 500 years and more than 30,000 people lived in small villages on the volcano's flanks, with a much larger population in surrounding cities. Felt earthquakes began

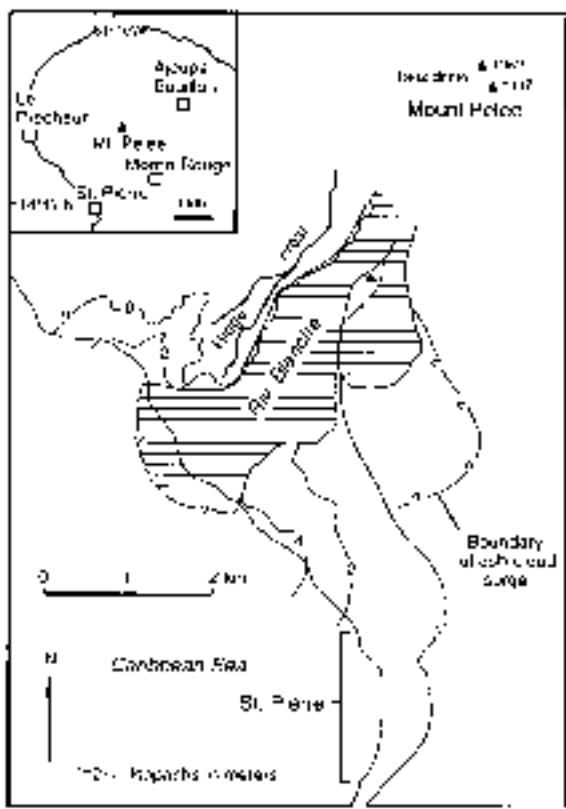

FIGURE 3 Distribution of block-and-ash flow deposits and the associated ash cloud surge deposits from the 8 and 20 May 1902 eruption of Mount Pelée, Martinique. The thickness of the surge deposits in most parts of St. Pierre was less than 1 m. [Simplified from Fisher and Heiken, 1982.]

3 months before the 15 June 1991 explosive eruption, and a phreatic eruption started a month before that. Release of seismic energy continued at a constant rate, while  $\text{SO}_2$  emissions increased. A lava dome appeared within the summit crater on 7 June and continued to grow. A series of vertical eruptions and long-period earthquakes occurred between the morning of 12 June and the early afternoon of 14 June. In addition a number of pyroclastic surge-producing eruptions occurred, and seismic activity evolved toward the climactic explosion on 15 June. The climactic explosion continued for about 9 hours after 1:42 P.M. This eruption caused the summit of the volcano to collapse and resulted in the formation of a caldera 2.5 km across.

This Plinian eruption sent ash into the stratosphere and pumice fell over an area of  $2000 \text{ km}^2$  with  $>10\text{-cm}$ -thick deposits. At the same time, voluminous pyroclastic flows were emplaced that extended 12–16 km from the vent down all sectors of the volcano and impacted an

area of approximately  $400 \text{ km}^2$ , stripping vegetation and dramatically modifying the preexisting topography. Massive deposits filled valleys to depths of up to 200 m, and the estimated volume of the whole pyroclastic flow deposits was  $4.2\text{--}4.5 \text{ km}^3$ .

After identification of precursory phenomena, volcanologists hurried to study volcanic rocks around the volcano and drew up a risk map of the area. By 14 June, officials had ordered the evacuation of more than 80,000 people from their land and homes. The next morning, Mount Pinatubo produced a large eruption. However, less than 300 lost their lives as roofs collapsed under the weight of heavy wet ash.

### C. Soufrière Hills, Montserrat

A lava-dome-forming eruption started in the Soufrière Hills volcano, Montserrat, West Indies, in December 1995, and continued until March 1998. As at Pinatubo, historic eruptions were not documented for this volcano, although the volcano contained old summit lava domes and pyroclastic flow deposits extensively distributed on the flanks. Partial collapse of the growing lava dome frequently generated pyroclastic flows together with vulcanian explosions during 1996–1998. At first, the dome grew inside the old English's crater and repeatedly collapsed to the east where the crater wall was lowest. The resultant pyroclastic flows descended eastward along the Tar River Valley and entered into the Caribbean Sea, making a delta of pyroclastics. As the lava dome size increased, it grew beyond the old crater rim and started to collapse northward in May 1997. The travel distance of pyroclastic flows extended in the northern flank day by day (Figure 4). A pyroclastic flow started from the lava dome at 12:55 P.M., 25 June 1997. In the following 20 minutes, a series of three devastating flows swept the northern flanks of the volcano, moving along Mosquito Ghaut and following the Paradise River close to the sea. The flows and associated surge clouds damaged or destroyed 100–150 houses, with villages being severely affected. Nineteen people died and another 9 were missing, presumed dead. An estimated  $5 \times 10^6 \text{ m}^3$  of lava dome collapsed during the event, and the resulting flow and surge deposits covered 4 km<sup>2</sup>.

A sequence of 13 vulcanian explosions occurred in early August 1997 with ash columns up to 15 km high. Column collapse resulted in the generation of radial pumiceous pyroclastic flows (Figure 5). Pyroclastic flows destroyed the capital city, Plymouth, located 4 km west of the summit, where all inhabitants had been evacuated.

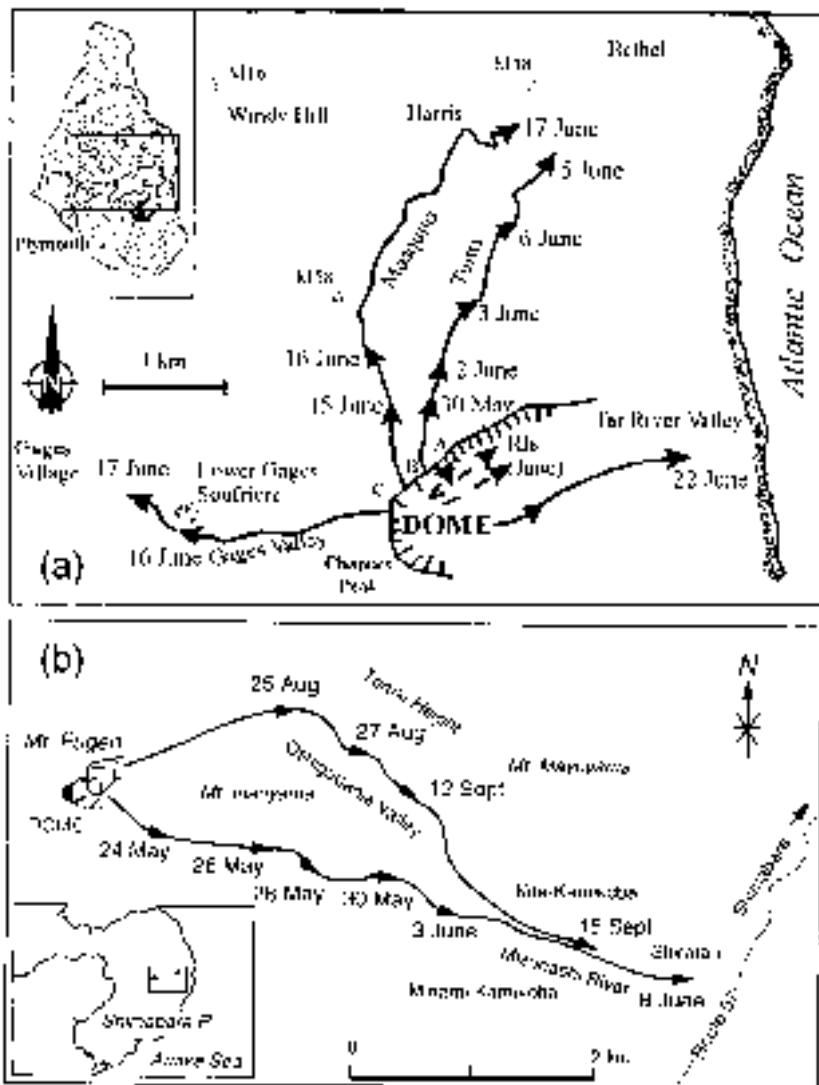

FIGURE 4 Time variations in travel distance of dome-collapse-type pyroclastic flows. (a) During May–June 1997 at Soufrière Hills volcano, Montserrat. [After (1997) Bull. Global Volcanism Network 22(6), 2.] (b) During May–June and August–September 1991 at Unzen volcano, Japan.

On Boxing Day, 26 December 1997, the largest sector collapse (landslide), including the dome and crater walls, took place. The total volume of collapsed materials reach  $6.4 \times 10^7 \text{ m}^3$  DRE (dense rock equivalent). As a result, extensive volumes of debris avalanches and pyroclastic flows (and surges) swept the whole area of the southwestern flanks and reached the southern coast. Deposits rushing into the Caribbean Sea caused a small tsunami, 1 m high. Fortunately, there were no casualties.

Periods of elevated productivity of pyroclastic flows and sustained dome collapse events are linked to pulses of high magma extrusion rates.

#### D. Unzen, Japan

Unzen began erupting in November 1990, and a lava dome grew between May 1991 and February 1995. Partial collapse of the dome generated frequent pyroclastic flows, and a total of 9500 pyroclastic-flow events were counted from seismographs. The active center of this eruption was 7 km from the center of Shimabara City. On the afternoon of 3 June 1991, pyroclastic flows reached the Kita-Kamikoba area, and the associated ash cloud surge swept 43 people away in the evacuated zone (Figure 6). The victims included volcanologists and

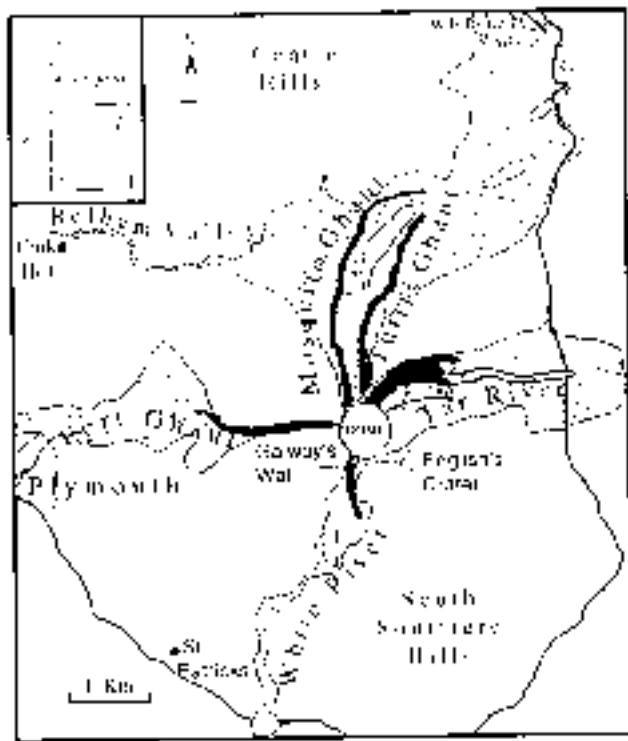

FIGURE 5 Map showing the distribution and extent of pyroclastic flow deposits during 1996–1997 eruption at Soufriere Hills volcano, Montserrat, West Indies. [Cole *et al.*, 1998.] The distributions expanded from the solid areas to the gray areas in each river.

journalists waiting to take images of descending pyroclastic flows.

The largest pyroclastic flow in this eruption occurred on the evening of 15 September 1991. This event consisted of a relatively large failure of the lava dome and underlying older rocks (total volume  $4 \times 10^6 \text{ m}^3$ ). As a result, four pyroclastic flows cascaded down the Oshigadani Valley, the largest one reaching the Mizunashi River after passing through a narrow gorge in the valley (Figure 2). The main pyroclastic flow followed the topographically lowest areas. In contrast, the surge moved separately and went directly from the exit of the Oshigadani Valley for 0.9 km into the Ohnokoba District (Figure 2). The surge climbed 10 m up the southern bank of the Akamatsudani River. In Kita-Kamikoba, most trees were swept away by the surge and a car was thrown 120 m. Contrasting with the devastation in Kita-Kamikoba, trees in the Ohnokoba District impacted only by the surges were not toppled, although most houses engulfed by the surge were burned. This indi-

cates that the surge had lost much of its force by the time it reached Ohnokoba, although it kept its high temperature.

When the lava effusion rate was high, frequent pyroclastic flow events were observed. The major pyroclastic flow events, including the 15 September 1991 flows, occurred during periods with high lava effusion rates.

#### IV. STORIES OF THE 3 JUNE 1991 EVENT AT UNZEN

When a man and his wife opened their front door a few minutes after the surge arrived at their house, a mass of hot ash rushed inside. They closed the door immediately, but breathed in some ash-laden air. Fortunately, this did not affect them significantly. A minute later, they decided to go outside and opened the door, and no more ash-laden air entered the house. Houses nearby were burning fiercely as the couple fled. Their house later also caught fire.

Another person opened his door soon after the surge hit his house. A hot mass of black smoke (ash) avalanched into the house. He suffered burns on his arms where he had no sleeves. Then glass in upstairs windows was broken and a mass of ash invaded the house. The hot ash caused burns to his stomach. Houses nearby were burning as he fled. He left the house without shoes, and felt intense heat as he stepped on the ash deposits. His house was still burning the next morning.

A man took refuge in a car as he was engulfed by the surge. He saw that small pebbles hit the windscreens, crackling and glowing in the darkness and he felt intense heat in the darkness. He suffered some burns on his neck and back and it was later found that the surges had melted the vinyl cover of the car seat.

French photographers Katia and Maurice Krafft and the American volcanologist Harry Glicken were engulfed by a pyroclastic surge during the 3 June 1991 event. A series of pyroclastic flows started at 16:08 (JST). They stood together with more than 10 Japanese journalists, facing the summit at a place called Teiten ("fixed point") within the evacuated zone (Figure 6). Although the summit area was covered with rain clouds, they were waiting for pyroclastic flows that were large and vigorous enough to film and photograph. The travel distance of pyroclastic flows extended day by day (Figure 4). Teiten was only 40 m higher than the river bottom, and the river curved to the south at that point. Teiten was engulfed by

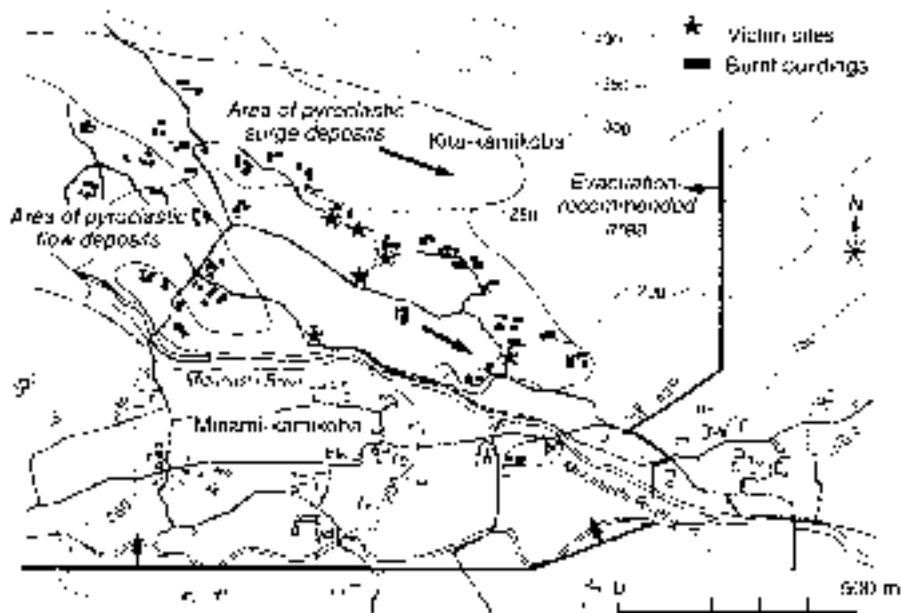

FIGURE 6 Map showing disaster area of a pyroclastic flow event at Unzen on 3 June 1991. Ash cloud surges associated with pyroclastic flows that stopped moving within the upper stream of the Mizunashi River swept higher parts in Kita-Kamikoba District (Teiten), where three volcanologists and journalists were engulfed in an instant. Arrows within the surge deposit area represent the direction of movement, which can be estimated from fallen trees. [Modified from the data by Shimabara Earthquake and Volcano Observatory, Kyushu University, and Prof. Kazuya Ohta.]

FIGURE 7 Crumpled cars and victims of ash cloud surge at Unzen volcano on 3 June 1991. They were thrown about 80 m from their original position. [Courtesy of Genji Maruta.]

a surge but not by the main stream of pyroclastic flows at 16:10. Trees and electric poles were toppled down and all wooden houses were knocked down. Cars together with dead bodies were also thrown as far as 80 m from Teiten, and landed in a tobacco field (Figure 7). A taxi was caught on a road, but inside, the completely carbonized bodies of journalists and a driver were found. They presumably rushed inside the car to take a refuge from the oncoming surge.

Dentists from the Dental Association of Minami Takaki District (Shimabara) examined the cause of death of the casualties. The bodies were described as showing rigor mortis and looking like sooty mannequins. Most

of the clothes and hair were burned away. Hands were set close to the face, suggesting that victims lay with their faces on the ground trying to escape the effects of the hot ash. They probably lost their lives due to dyspnea in hot ash. The tongues were hypertrophic and stuck out of the mouths. Ash and pebbles filled their mouths. Both mucous membranes and gums were decomposed.

Causes of death in pyroclastic flows and surges are believed to be mainly asphyxiation and thermal distress, except for victims who are first burned by the deposits. A further example comes from the A.D. 79 eruption of Vesuvius. Pompeii, an ancient city on the southeastern

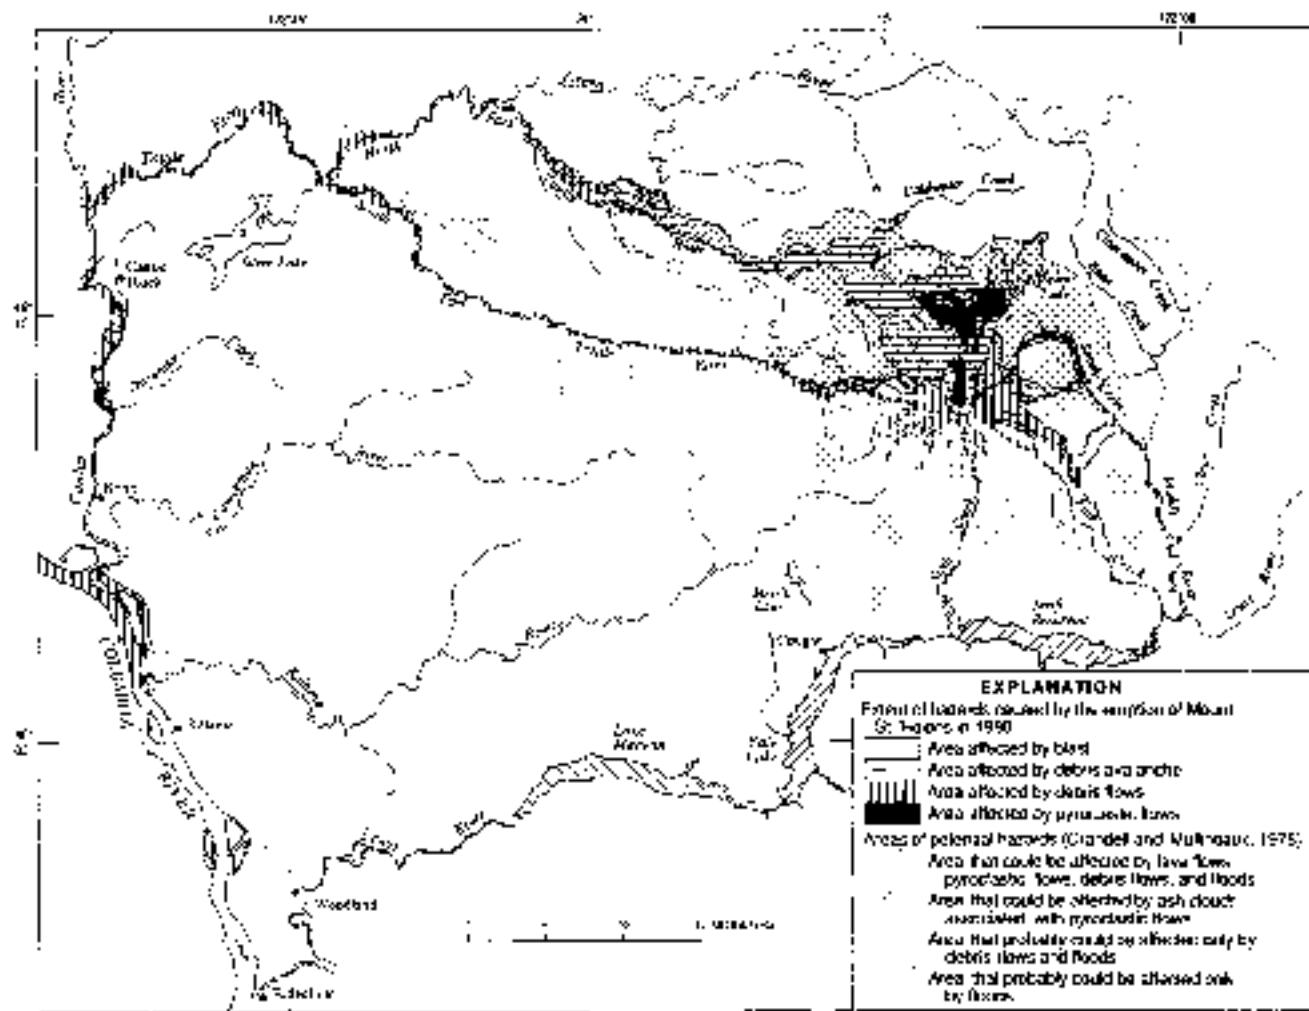

FIGURE 8 The actual extent of damage during the 18 May 1990 eruption of Mount St. Helens, Washington, USA, compared with that anticipated in the hazard zone map published 2 years earlier. Except for the lateral blast, the actual hazards by pyroclastic flows, debris avalanches, and flows occurred within the expected areas of potential hazards. [Reproduction from (1992) "Living with Volcanoes." U.S. Geological Survey's Volcano Hazards Program, U.S. Geological Survey Circular 1073.]

foot of Vesuvius, was impacted by pyroclastic surges, and deeply buried by pyroclastic flow deposits. Uneaten food laid out on tables was found in houses after the deposits were excavated. This shows that normal life continued in the town until the last moment. Many human fossils have been found as holes in the deposits (natural molds in ash). Plaster casts made from these molds clearly show hands covering the mouths, implying that the victims had difficulty in breathing.

---

## V. MITIGATION OF PYROCLASTIC FLOW AND SURGE HAZARDS

It is most likely that an eruption similar to previous eruptions will occur in the future. A comprehensive understanding of eruption phenomena and frequency is therefore needed for hazard mitigation. Areas impacted by pyroclastic flows previously are likely to be affected again in future eruptions. Hazard maps show the probability of pyroclastic flows, surges, and other hazards for different areas and provide guidelines for long-range land-use planning around volcanoes and for evacuation from pyroclastic flows and surges. Distribution of maps (where they exist) to local people and public education are essential for hazard mitigation.

When an explosive eruption occurred on a spring Sunday morning at Mount St. Helens, the tourist season had just started. After the beginning of volcanic activity there, regulation of entry into the volcano area was set according to the hazard map which had been drawn 2 years previously (Figure 8). Pyroclastic flows and surges swept the areas shown on the map. Less than 60 people became victims of a laterally directed blast, which resulted from a sudden collapse of the volcano, on 18 May. Lessons at Mount St. Helens and Unzen teach us that diluted pyroclastic surges or blasts are less influenced by the topography and may easily climb up topographic obstacles, though dense pyroclastic flows tend to descend along valleys.

Once an eruption with the potential for pyroclastic flows and surges starts, we can take steps to mitigate hazards from them using knowledge from recent eruptions at other volcanoes. Specifically, dome-collapse-induced pyroclastic flows can occur as successive events in a period ranging from days to weeks. During this period, the magnitude of pyroclastic flows increases generally with time (Figure 4). Since dome eruptions commonly last a few years or longer, the pyroclastic flow

hazards become modified. As a lava dome increases in volume and height with time, pyroclastic flows tend to travel larger distances due to the increase in  $H$ , increasing the risk of larger-scale dome collapse. As the valleys around a dome become filled, later pyroclastic flows are likely to descend further and to spread out more.

The degree of volcanic explosions primarily depends on the extrusion rate of lava from the vent and may be very variable. For example, at Soufrière Hills volcano, although small dome collapse pyroclastic flow events were dominant, column collapse pyroclastic flows often occurred following a long period of quiescent lava effusion.

Large-scale explosive eruptions ( $>10 \text{ km}^3$  in volume) like those producing caldera-forming eruptions are historically rare. Despite their low frequency, the associated pyroclastic flows tend to travel distances of several tens of kilometers in any direction from the crater. Identification of volcanoes with a high risk of such large-scale eruptions is required through field observations of old deposits and age determination studies. Evaluation of future eruptions is required through patient and continuous volcanological monitoring. When there is a high possibility of large explosions, people living around the volcano should be ordered to evacuate the area. This course of action has economic and political difficulties as well as volcanological uncertainties.

## GLOSSARY

**aspect ratio** The ratio of the mean thickness of a lava flow (or flow field) to the diameter of a circle with an area equal to the area covered by the flow.

**effusive eruption** A nonexplosive volcanic eruption in which coherent fluid molten rock is extruded from the vent to form lava flows.

**explosive eruption** A volcanic eruption powered by the abrupt release of dissolved gas which propels broken and torn solid and molten matter of all sizes upward and outward through the air that fall to form fragmental (pyroclastic) deposits.

**hazard** The existence of a condition under which a potentially dangerous volcanic process might occur.

**intermediate lava** Lava with a silica content (by weight) between about 55 and 62%.

**lava dome** A steep-sided rounded accumulation of lava extruded from a volcano to form a dome-shaped or bulbous mass of congealed lava above and around the vent.

**lava flow** An outpouring of molten rock from a vent or fissure spreading along the ground; also the body of solidified rock resulting from the outpouring.

**lava-flow field** The rock body made up of a succession of individual lava flows.

**littoral** An adjective used to describe features that lie, or processes that occur, along the shoreline of an ocean, sea, or lake.

**mafic lava** Lava with a silica content (by weight) less than about 55%.

**risk** The probability of a loss of life, property, or productive capacity within an area subject to volcanic hazard.

**silica** Silicon dioxide ( $\text{SiO}_2$ ).

**silicic lava** Lava with a silica content (by weight) more than about 62%; a close synonym, sometimes used, is felsic lava.

**A**T THE OUTSET it should be emphasized that, in theory at least, lava flows would pose no hazards or risks to society if people simply avoided regions with potential for active volcanism. Obviously, however, such a simplistic option is unrealistic, inasmuch as about three-quarters of the Earth's surface—above and below sea level—is composed of rocks of igneous (mostly volcanic) origin. It has been estimated that about 10% of the world's population lives near active and potentially active volcanoes and, therefore, cannot ignore the possi-

bility of eruptions and associated hazards. With continued increase in population growth and attendant economic development, the challenge to reduce volcano risk in the 21st century becomes even more critical.

### I. GENERAL NATURE OF LAVA-FLOW HAZARDS

Lava flows are inherently dangerous. Scenes of flows of molten rock advancing down the slopes of volcanoes occasionally enliven TV news broadcasts; these flows can consume trees and crops, and sometimes they bury or surround, push over, and burn houses and parts of villages and towns. Such events dramatically illustrate the destructive potential of lava flows, which are the products of effusive eruptions. A few examples of devastating lava flows in recent decades include those of Kilauea (Fig. 1) and Mauna Loa, Hawaii; Etna, Italy; Parícutin, Mexico; and Heimaey, Iceland. Most lava flows advance slowly enough to allow people to get out of harm's way, but everything left behind can be damaged or destroyed, and the land covered by lava is generally rendered uninhabitable and (or) unproductive for years, decades, or centuries.

In addition to the readily recognized hazards posed by lava flows, other less-obvious hazardous processes

often accompany and (or) follow the emplacement of lava flows that may have even more serious social consequences than the immediate damage caused by lava inundation. Some of these processes and results include landslides caused by the increasing weight of new lava on unstable slopes, people being displaced owing to losses of homes, farms, and livelihood, and disease and starvation resulting from damage to vital stocks of supplies and from disruption of communication and transportation networks.

The focus of this article is to describe and explain the character of the hazardous processes associated with lava flows and to discuss the methods that have been utilized and proposed for mitigating their risks.

#### A. Hazard and Risk

In everyday usage, the terms *hazard* and *risk* are commonly treated as interchangeable. However, in some disciplines, including studies of volcanoes, it has been useful to distinguish between these two terms and define each of them more narrowly. In volcanology, hazard can be thought of as the existence of a condition under which a potentially dangerous process might occur. Risk, in contrast, is the degree of probability of a loss of life, property, or productive capacity if the hazardous process does occur. The relation between the terms can be expressed in the equation,  $\text{risk} = (\text{value}) \times (\text{vulnerability})$ .

**FIGURE 1** Aerial view of fluid lava flows advancing great distances from the Pu'u 'O'o vent on the east rift zone of Kilauea volcano, Island of Hawaii, in 1983. Some of these flows traveled more than 12 km to reach the south coast of the island and destroyed many dwellings. (Photograph, J. D. Griggs, USGS.)

ity)  $\times$  (hazard). Value is a measure of the number of people, amount of property, and productive capacity in the potentially affected area, and vulnerability is a measure of the proportion of this value that might be lost if a hazardous process should occur. In this more strict sense, hazard is just one of the elements that constitute risk.

For example, a particular volcano in an unpopulated area would present a certain degree of hazard, but its risk to people and property on the ground would be relatively small. As people move into the area near the volcano and establish farms, towns, and cities, the hazard would remain unchanged, but the risk would be proportionately increased. Further, different methods are used for determining the two factors. The hazard posed by a potentially active volcano can be investigated by systematic observation and monitoring and by studying the history of the volcano and analyzing its past behavior. When the hazard is assessed in this way and applied to the societal and economic framework of the surroundings, the degree of risk can be evaluated.

The hazard of a dormant volcano is determined by its past behavior as revealed by its geological record, which explains the character and products of its past activity. However, hazard can also be expressed in a more immediate sense by describing the threat posed to land in the path of lava flows while an eruption is in progress. While the term is properly used in both senses, in this article we emphasize the first sense because sev-

eral of the articles on effusive volcanism emphasize hazards in the second sense.

---

## II. GENERAL CHARACTER AND BEHAVIOR OF LAVA FLOWS

Lava flows are outpourings of molten rock from vents or fissures that spread across the ground. The vast majority of lava flows are composed of silicate rocks whose compositions range from basalt to andesite and dacite to rhyolite, as well as basanite, latite, trachyte, phonolite, and others. The volumes of individual flows vary widely; historically they have ranged from small ponds to widespread bodies approaching a cubic kilometer. Flow fields are formed by a succession of individual flows, erupted through time, which cumulatively build a larger and thicker topographic feature. Flow fields can aggregate several cubic kilometers; the largest historical flow field of Lakagígar, Iceland, was about 12 km<sup>3</sup>.

The prehistoric worldwide geologic record includes several immense lava-flow fields that have volumes of hundreds and even thousands of cubic kilometers; two good examples are the massive plateau basalts of Tertiary age that form the Columbia River Plateau of the northwestern United States (Fig. 2) and the Deccan Plateau of western India. These flow fields were emplaced by

FIGURE 2 Columbia River Plateau, Washington State (USA), showing a high cliff exposing a series of thick lava flows (plateau basalts). A car on the highway at the base of the cliff (lower left) gives scale. (Photograph, D. A. Swanson, USGS)

huge, mobile flows that would have obliterated everything in their paths. Because of the vast time span since the eruptions of the most recent plateau basalts, the probability of renewed eruptions of this type is regarded as too low to be practical or useful, and their hazards are not considered in the present discussion.

Historical flow fields may reach tens of kilometers long, a few kilometers wide, and hundreds of meters thick, although most are smaller and more typically range from hundreds of meters to a few kilometers long, tens to hundreds of meters wide, and a few to tens of meters thick. Lengths of individual flows generally range from a few tens of meters to a few kilometers, and, depending on their properties and ground-surface controls, thicknesses may vary from a few centimeters to tens of meters. Historical lava effusions have lasted from just a few minutes to several decades, although commonly their durations range from days to a few years.

The consequences of the largest known historical effusive eruption, that of Lakagígar (Laki Fissure), Iceland, 1783–1784, illustrate well the kinds of hazards associated with a large effusive emplacement of a lava-flow field. Although the lava flows covered more than 500 km<sup>2</sup> during an 8-month period, the human casualties ( $\approx 9000$ ) were not caused from engulfment by lava but instead by starvation and disease resulting from the loss

of crops and livestock. The Lakagígar eruption ranks among the world's six deadliest eruptions since 1600 A.D. (Fig. 3).

To describe the relationship between the thickness and the area covered by a lava flow or flow field, the term *aspect ratio* has recently come into common use. The term, regrettably, has not been used consistently throughout the literature, so the definition used here needs to be explained. In accord with most of the recent literature, aspect ratio is here used as the ratio of the mean thickness of a flow to the diameter of a circle having an area equal to the area of the flow (or flow field). By this definition, a flow with low viscosity would tend to have a low aspect ratio because it would have a small thickness in comparison to its area. A flow of viscous lava would have a higher aspect ratio because its thickness would be larger in comparison to its area. The majority of mafic lava flows have low aspect ratios, and most, but not all, silicic lava flows have relatively higher aspect ratios.

The specific behavior of a lava flow is controlled by a number of factors, the most important of which include the rate of discharge of lava from the vent, the duration of the effusion, the slope of the ground and other details of topography, and the viscosity of the lava, which in turn is governed by its chemical composition, crystal and gas content, and temperature. Diverse combinations

FIGURE 3 Aerial view of cinder cones along fissure vent of the Lakagigar (Laki), Iceland, eruption of 1783, the largest known effusive outpouring of lava in recorded history. (Photograph by R. W. Decker.)

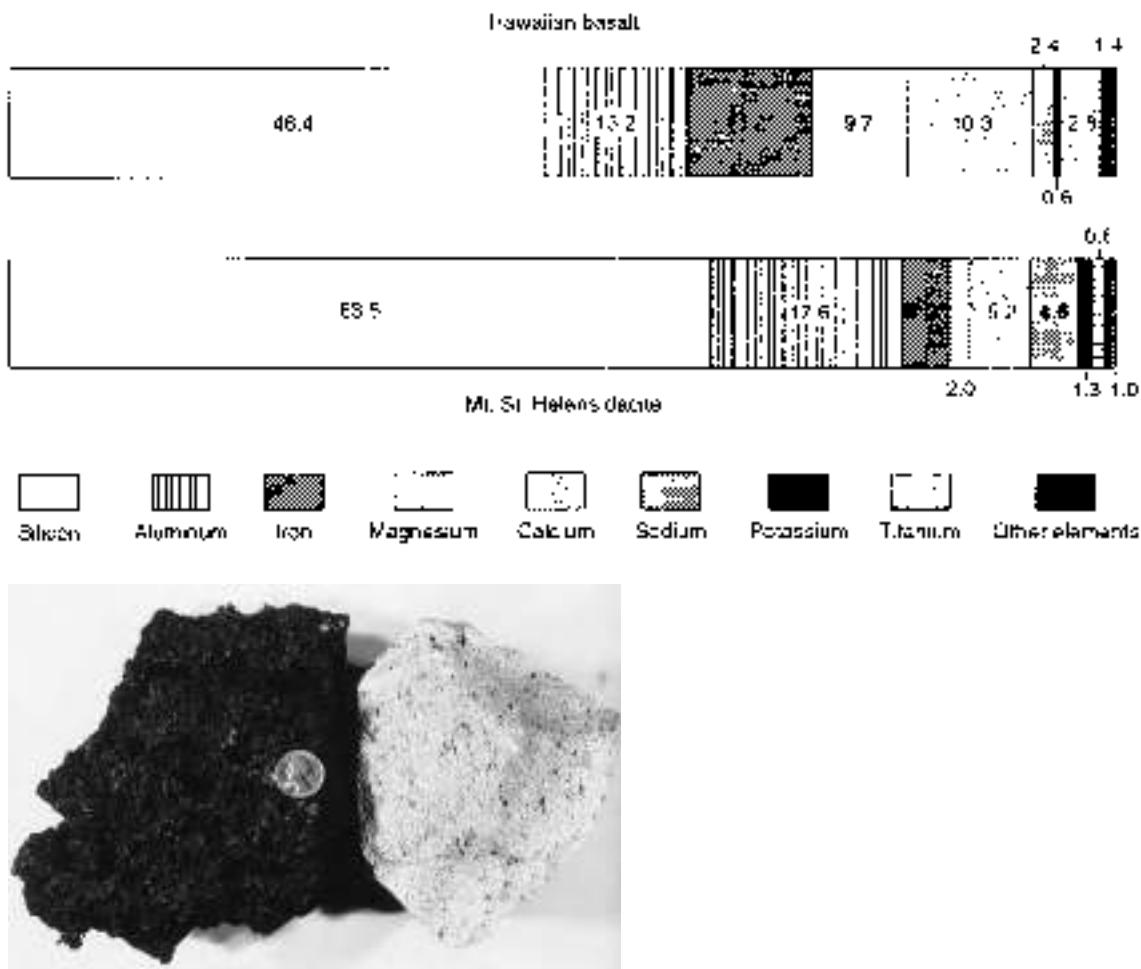

FIGURE 4 Differences in color and average chemical composition between Hawaiian basalt (dark) and Mount St. Helens dacite (light). The number given for each chemical element gives the amount (in weight percent) of that element (expressed as oxide) contained in the lava.

of all these factors influence such matters as the speed of advance of the flow, both forward and laterally, the thickness of the flow and size of the area covered (which in turn determine the aspect ratio), and the physical nature of the lava during flow (such as pahoehoe, aa, or block lava). All of these parameters are involved in helping to understand and explain the nature of the lava-flow hazards.

Chemical composition is a major determinant in the behavior of lava during its eruption and flow. Magmas of mafic composition (those with silica content less than about 55%) tend to have lower viscosity at typical eruption temperatures than magmas of intermediate and silicic compositions. Thus mafic lavas, which chiefly include basalts of various types and some basaltic andesites, tend to have low viscosity, flow readily, and spread out

easily and rapidly from their vents to form flows with low aspect ratios. With progressive increase of silica content of lava from basalt to andesite, dacite, and rhyolite, lava viscosity increases (Fig. 4); in general the more silicic lava does not spread as fast or as far from the vent, but instead builds shorter, thicker lobes or blankets with higher aspect ratios than those of mafic lava. The silicic end members of this progression may form lava domes, built by multiple extrusions of viscous lava that pile up as steep-sided edifices with even higher aspect ratios. In recent years, however, a few exceptions to the thick, stubby shape of silicic lava flows have been recognized. Extensive silicic lava flows have been identified in several regions of the world that have relatively low aspect ratios, approaching those of plateau basalts. Well-studied examples include widespread (as much as

3000 km<sup>2</sup>) rhyolite flows in southwestern Idaho and in Trans-Pecos Texas. Like the plateau basalts, these voluminous flows are chiefly of Tertiary age or older, so the hazard posed by their possible recurrence is negligibly small, although recurrence is geologically possible.

Another characteristic of increasingly viscous lava is that the gas dissolved in the magma cannot escape easily, so the exsolving gases build up to high internal pressures that are more likely to be released abruptly instead of gradually. The sudden release of pent-up pressure results in an explosion which produces broken fragments (pyroclastic deposits) instead of lava flows. Explosive behavior constitutes a completely different, and more dangerous, type of hazard, not covered in this article. Eruptions of intermediate and silicic magmas commonly include a progressively higher proportion of explosive events, along with a lower proportion of effusions, as silica content increases. While many eruptions of mafic magmas may include explosive events, they are proportionately less common.

The differences in form and behavior between mafic, low-viscosity flows and intermediate and silicic, higher viscosity flows provide a convenient basis for organizing the discussion to follow. Nonetheless, it must be emphasized that the distinctions made between types of lava-flow behavior are gradational throughout the entire compositional range of lavas, owing to the gradational nature of all of the factors that influence flow behavior. (Additional information about the characteristics, properties, behavior, and variations in the different kinds of lava and their resulting bodies is provided in the articles on Effusive Volcanism.)

---

### III. HAZARDS FROM MAFIC LAVA FLOWS

The principal hazards of effusive mafic eruptions are, of course, the lava flows themselves, which can damage or destroy whatever lies in their paths. However, other, generally less destructive hazards are also associated with mafic lava flows, the most common of which involve the fall of fragments from lava fountains, explosive interactions sometimes triggered when hot lava enters the ocean, and explosions when lava flows advance into vegetated areas. For a well-illustrated summary of the volcanic hazards associated with mafic lava flows, as typified by the basaltic eruptions of Hawaiian volcanoes, the interested reader is referred to the website of the U.S.

Geological Survey's (USGS's) Hawaiian Volcano Observatory, currently located at: (<http://www.hvo.wr.usgs.gov/hazards/>).

#### A. Primary Hazards

A typical eruption of mafic lava is commonly preceded by a period of increasing seismicity concentrated near the site, almost always accompanied by cracking and (or) swelling of the ground and increased emission of volcanic gases. If these associated activities intensify, they commonly lead to the eruption of lava, which may range from quiet welling out from the vent, to low to moderate fountains of lava, to spectacular fountains that can shoot upward to heights as great as several hundreds of meters. The lava moving along the ground away from the vent(s) constitutes the lava flow; its behavior and characteristics are determined by the combination of all the factors governing lava behavior. During vigorous fountaining, lava is disrupted into discrete irregularly shaped masses (variously described as blobs, shreds, drops, etc.), and those that remain fluid coalesce upon falling to form, or add to, a lava flow issuing directly from a vent. Airborne lava masses that solidify during their flight and fall within the flow are incorporated into it, and those that fall beyond the margins of the flow form spatter or cinder deposits. The falling pieces of lava constitute a separate hazard from that of the flow itself; they are among the several kinds of hazards associated with, but distinct from, the hazards directly caused by the flows.

If the eruption issues from a vent in an area of nearly flat topography, or from a line of fountains (popularly termed a "curtain of fire"), the lava may spread across the land as a sheet flow. The lava in a moving sheet soon tends to coalesce into discrete channels of flowing lava, while the lava remaining within the sheet proper (i.e., exclusive of the channels) gradually cools, slows, and solidifies. Whether originating from a single vent or a sheet flow, much mafic lava is ultimately transported by discrete lobes and by channels, and the characteristics and behavior of the flows are determined by the discharge rate, total volume, topography, and temperature and lava composition, which, in turn, determine the viscosity. Mafic lava is commonly erupted and transported as either pahoehoe or aa, and rarely as block lava. Under particular conditions determined chiefly by viscosity, rate of shear strain, and yield strength, during flow pahoehoe may change to aa, but not the reverse (Fig. 5). Large flows with high discharge rates show a

FIGURE 5 Dark, rough-surfaced aa lava flows (left) that have advanced across older smoother-surfaced, shiny pahoehoe lava flows (right); volcanologist (center) gives scale. Both the aa and the pahoehoe lava shown were erupted in 1973 during the Mauna Ulu eruption on the east rift zone of Kilauea volcano, Hawaii. (Photograph by Barbara Decker.)

strong tendency to form aa as they cool and become more viscous during the advance of the flow, but aa can also form in smaller and slower flows under appropriate conditions.

Pahoehoe flows in well-established channels with stable, moderate discharge tend to have crusts develop across their surface, and as the crusts grow laterally and in thickness, they merge to form the roofs of lava tubes. Lava flowing beneath the crust in tubes is better thermally insulated than lava flowing in the open, and thus it better retains its heat and fluidity. As the tubes extend themselves downslope, the lava travels progressively greater distances before emerging from the tube to eventually cool and solidify. Even moderate-sized flows fed by lava tubes can extend to distances many kilometers from their source. Some of the most systematic observations of the behavior of mafic lava flows, both open-channel and tube-fed, have been made at Kilauea and Mauna Loa volcanoes in Hawaii and at Mount Etna in Sicily, and the principles deduced from these studies

seem to apply generally to most mafic effusions throughout the world.

Advancing lava flows, whether large or small, and whether aa or pahoehoe, pose obvious hazards to the land in their paths, principally involving the possibility of surrounding and overrunning both natural and man-made features and structures (Fig. 6). Depending on their character and size, these features may be burned, buried, crushed, and rendered agriculturally unproductive, with consequences ranging from partial damage to total loss. In turn, the valuation of economic development on this land, its agricultural worth, and the size of the population it supports determine the degree of risk in the path of the lava flow.

Although most lava flows travel slowly enough for people to move out of harm's way, a tragic exception occurred at Nyiragongo volcano, Zaire, in 1977. A long-lived lava lake at the summit of the volcano drained abruptly when fissures on the flank opened and highly fluid fast-moving lava emerged and rapidly advanced

**FIGURE 6** Aerial view of San Juan Parangaricutiro church surrounded by 1944 lava of the 1943–1952 eruption of Parícutin volcano, Michoacán, Mexico. [Photograph in 1981 by Katia Krafft, provided courtesy of Agence Hoa-Qui, Paris, France.]

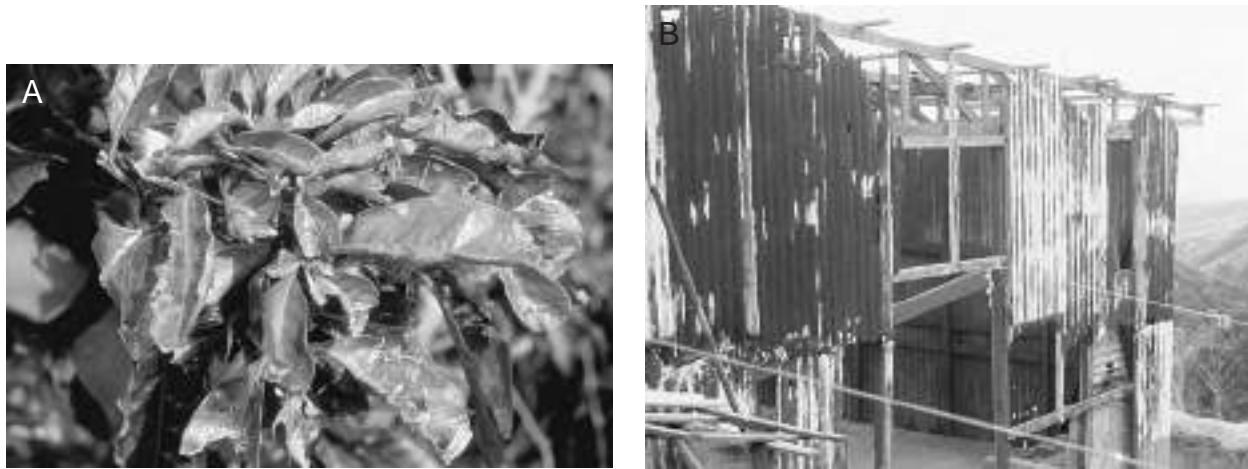

downslope. The entire lake drained in less than an hour, and speeds of some parts of the flows were estimated as high as 100 km per hour. The lava had an exceptionally low silica content (about 42%), which, along with high temperature, accounted for its very high fluidity. Several villages on the flanks of the volcano were engulfed before the inhabitants could flee, and resulting deaths were variously reported from 60 to 300 people. Other examples of fast-moving voluminous lava flows have been observed at some eruptions of Mauna Loa, Hawaii, at which speeds reached a few tens of kilometers per hour. More customary rates of advance of Hawaiian flows on moderate slopes are only a few kilometers per hour, whereas flows spreading over relatively flat terrain advance much more slowly.

## B. Other Hazards

Several types of hazards beyond those caused directly by lava flows commonly accompany effusive eruptions. The most ubiquitous are from the volcanic gases that are dissolved in the magma and escape from it at various rates as the ascending magma encounters progressively lower confining pressures as it approaches the surface. Expansion of the escaping volcanic gas propels the expulsion of liquid and solid material during any eruption; the rate of gas release is the predominant factor in determining the style of the eruption, which varies from violent explosions to quiet effusions. Upon escaping the magma, however, the volcanic gases may pose several types of additional hazards. Their effects are most intense near the vents and active lava flows, particularly on the downwind side, but they become less severe at increasing distances from active areas. Volcanic gases include some components that are toxic and (or) corrosive; in dilute concentrations they generally cause unpleasant odors and other sensory irritations, but even when dilute they can affect the health of people, corrode and cause other damage to structures and machinery, and adversely affect the growth of plants and agricultural productivity (Fig. 7). At higher concentrations volcanic gases can cause serious health problems and even be lethal. Another serious hazard from gases is confined to areas that include enclosed depressions. Several of the gaseous components are heavier than air (e.g., carbon dioxide), and during times of gentle or no wind, drifting heavy gases can collect within the depressions in dangerous concentrations. Unwary people and animals entering such depressions can suffer asphyxiation.

Flows that are accompanied by vigorous lava fountaining cause the additional hazard of hot, falling material. This hazard, distinct from those caused directly by lava flows, is generally restricted to areas within a few hundred meters downwind of the vent. Stronger explosive activity is unusual during many eruptions of mafic lava, such as most of those at Hawaiian volcanoes, but at many other mafic volcanoes, such as Mount Etna, Sicily, volcanoes in Iceland, and during the 9-year-long eruption of Parícutin, Mexico (1943–1952), large explosions often have accompanied or were interspersed with lava effusions. While the hazards of explosions are not covered here, it must be remembered that mafic lava flows are often punctuated by explosive activity.

Another type of explosion is fairly common when mafic lava flows advance into vegetated areas. When plants are engulfed by the lava without being completely burned, organic gases distilled from the buried plants can travel through the pores and cracks in the ground

**FIGURE 7** Damage sustained by a coffee plantation more than 15 km downwind from vents at the summit of Poás volcano, Costa Rica. Frequent rainfall in the region mixes with volcanic gas to form acid rain. (A) Severe damage to leaves of a coffee plant by acid rain. (B) Extensive corrosion of corrugated metal by acid rain on a plantation building. [Photographs by R. I. Tilling, USGS.]

beneath. When this gas blends with atmospheric oxygen, a highly volatile mixture is created, and if heat from the lava ignites it, an explosion results. Such explosions can occur directly beneath the lava flow, and molten spatter is thrust upward and outward, sometimes falling beyond the flow margins. If the volatile gas mixture, while still underground, migrates outward beyond the margin of the lava flow, a confined explosion may rapidly travel within the ground both below the flow and beyond it, and it sometimes reaches as much as tens of meters outside the flow margin before the explosion breaks through to the surface. Such explosions are random, unpredictable, and sometimes quite violent, hurling dirt, rocks, shrubs, and even trees high into the air. Because of this hazard, the areas along the edges of new lava flows advancing through heavy vegetation should be regarded as extremely dangerous. This type of explosion has been common in Hawaii during long-lived activity on the east rift zone of Kilauea both during the Mauna Ulu eruptions of the 1970s and the Pu'u 'O'o eruptions of the 1980s and 1990s.

Still another type of explosion may occur during eruptions when mafic lava flows enter the ocean or other bodies of water. For these explosions to take place, some sort of special configuration must exist among the flowing molten lava, a confining channel or tube, and proximity to the shoreline. Perhaps the most common configuration is when the mouth of a lava tube lies right at the shoreline and discharges lava directly into the water. When the surging surf submerges the mouth of the tube, a large amount of water enters the tube into the confined space and is abruptly converted to steam by

the intense heat of the flowing lava. A steam explosion results that hurls shreds of molten lava and broken solidified lava in various directions, both out the mouth of the tube and through any nearby openings in the tube roof. Another configuration is when lava in an open channel drains into the entry of a littoral lava tube near the shoreline in the surf zone. Such tubes enable lava to pass undisturbed beneath the vigorous surf to emerge later as a submarine lava flow. However, when an occasional extra strong wave floods the entry to the tube, water is carried into the tube and is transformed instantly to steam, which explodes out of the tube entrance and propels shreds of molten lava and fragments of broken solidified lava high into the air. When such explosions are repeated frequently over a sustained period of lava entry into the sea, the ejecta accumulate to form a littoral cone. Such cones are common along the shorelines of Kilauea and Mauna Loa volcanoes in Hawaii, as well as on other volcanic islands and coastal volcanic areas. The possibility of littoral explosions is a distinct hazard to persons attempting to make close-up observations of the dynamics of molten lava flowing into the sea.

A different variety of hazard results when flowing lava encounters snow and (or) ice on volcanoes at high latitudes or on high mountains. Lava flows with high discharge rates can quickly thaw large amounts of snow and ice, leading to floods, lahars, and debris flows. A unique variety of this process occurs at intervals in Iceland, where frequently active volcanoes lie beneath large glaciers. Lava from an eruption melts overlying ice, and meltwater collects beneath and may be temporarily dammed by the ice. If the eruption is large or continues

**FIGURE 8** Destruction of older brick structures in Pozzuoli (Bay of Naples), Italy, caused by earthquakes during the volcanic unrest at Campi Flegrei caldera during 1982–1984; although involving increased seismicity and 1.8 m of ground uplift, the unrest did not culminate in eruption. (Photograph by David Chester.)

for a sustained period, the water may break through the dam and descend the drainage as a massive and devastating flood, termed in English a “glacier burst,” and commonly known by its Icelandic term, *jökulblau*.

Still other hazards sometimes precede, accompany, and (or) follow effusions of mafic lava, and, indeed, they are commonly associated with all types of volcanic eruptions. These hazards include shifting ground, opening of cracks, and sudden ground subsidence. Although most volcanic earthquakes are relatively mild, shaking caused by them, especially during swarms precursory to new eruptions, can be damaging (Fig. 8). A potential hazard develops when deposits of new lava accumulate on or above sloping ground with appreciable gradients. The increasing load being added to the deposit may exceed the limit of stability, and the entire block of ground may give way as a landslide. Such collapse events also may occur along shorelines when new flows advance into the ocean. The offshore gradient is generally steeper than that inboard from the shore, and large blocks of “new” land, built over formerly offshore areas, may suddenly fail and collapse into the sea. A shoreline landslide in April 1993, involving part of a growing lava bench, resulted in the first fatality caused by the volcanic activity of Kilauea in seven decades when a visitor was swept into the sea (Fig. 9). Earthquakes may trigger landslides of fresh, unstable lava long after an eruption has finished. Landslides related to slope instability have caused dam-

age and casualties in Hawaii, on Mount Etna, and at many other volcanoes throughout the world.

---

#### IV. HAZARDS FROM INTERMEDIATE AND SILICIC LAVA FLOWS

Lava flows of intermediate and silicic composition have higher viscosity than mafic lavas, and so, as mentioned earlier, they generally flow more sluggishly, travel shorter distances, spread less widely, and tend to build higher edifices in comparison with area covered (higher aspect ratios). They have a greater tendency to erupt explosively, and even during effusive activity, eruptions are frequently punctuated by explosive activity.

The higher viscosity of the lava results in other differences in the character of intermediate and silicic flows. For example, block lava is the common surface form of many of these flows, in contrast to the pahoehoe and aa surfaces characteristic of mafic flows. Some highly viscous lava of rhyolitic and dacitic composition piles up above and around its vent to form steep-sided lava domes; andesitic domes are less common. If a silicic magma is erupted with high total volume, or with rapid effusion rates, or in long sustained eruptions, the resulting lava may spread downslope away from a dome

**FIGURE 9** Large lava block hurled 30 m inland by explosions caused by the interaction of still-hot lava with seawater during a collapse of a lava bench in January 1988 on the south coast of Hawaii. This bench was one of many that have formed—then subsequently collapsed or was covered by new lava—during the eruption on Kilauea volcano's east rift zone that began in 1983 and has continued essentially nonstop to the present. (Photograph by Christina Heliker, USGS.)

or other vent to form thick, stubby lava flows, which are commonly termed coulees; examples include those of the rhyolitic Mono Craters and of the Medicine Lake Highlands in, respectively, eastern and northern California. But in spite of the differences in behavior between silicic and mafic lava flows, some of their hazards are the same, for advancing flows can obliterate cropland and can bury, burn, and crush everything that lies in their paths. But the additional hazards of silicic volcanism, inherent with its greater potential for explosive activity, require that additional precautions be taken by those who venture near the flows. The hazards associated with andesitic and other intermediate effusions, however, are somewhat less severe, being gradational between those of silicic and mafic lava flows.

Although severe or total damage can be the result when flows and domes of silicic and intermediate lava overwhelm what lies in their path, and although injuries and loss of life can be high during explosive episodes of silicic volcanism, the lava flows themselves rarely are the direct cause of casualties. The viscous lava of these flows typically advances much more slowly than mafic lavas and, with rare exceptions, generally does not spread widely, so people and animals can easily get away from the flow itself. Furthermore, people are probably warned away by the explosions that commonly herald the new activity before the lava flows even begin, so people are rarely if ever caught by advancing lava. The principal hazards to life associated with intermediate and silicic flows are from the primary explosions and other phenomena that precede and accompany the viscous flows.

The flanks of lava domes and the sides and advancing fronts of highly viscous lava flows are typically steep and unstable, and the block lava breaks to form loose piles of broken lava (talus) that constantly falls and results in hazardous conditions all around the margins of flows and domes. The blocks form talus aprons that accumulate at the base of the slopes; in advancing flows these are overrun and incorporated as basal breccias. A hazard much more severe and widespread than falling talus is the possibility of landslides and debris avalanches spalling from the unstable slopes. Depending on the volume of material and the topographic gradient, landslides and avalanches may travel rapidly for considerable distances; for example, avalanches spawned from the lava dome in the crater of Soufriere Hills volcano on Montserrat traveled for several kilometers at rates of tens of kilometers per hour at temperatures exceeding 700°C. This illustrates that this hazard extends to areas well beyond the immediate vicinity of a dome or flow.

If gas pressure, confined by the solidified crust within the dome or flow, has not yet equilibrated with the atmosphere, the abrupt release of pent-up gas pressure by a landslide or avalanche may trigger an explosion, which can range from jets of gas blasting forth from the newly exposed surface to the escaping gas hurling both solidified and fluid lava upward and outward from the flow. Some of these events spawn pyroclastic flows that can travel many kilometers from the source. All these events are dangerous, especially the pyroclastic flows, and small events of each type occurred during the growth of the dacitic dome at Mount St. Helens between 1980 and 1986. In addition, during the decade of the 1990s, larger pyroclastic and debris flows of this origin caused multiple casualties downslope from the growing lava domes at Unzen, Japan, and Merapi, Indonesia.

Phreatic explosions blasting from a dome or flow re-

sult in a similar kind of hazard but are rooted in a different cause than those resulting from volcanic gas explosions. When rainwater or groundwater seeps through fractures in the outer solidified crust and meets the high-temperature zone around the still-molten core of the dome of flow, it generally boils off and escapes through cracks and pores in the overlying carapace of solidified lava as clouds of vapor. However, in some circumstances, the water may become trapped, and as it turns to steam the pressure increases within the confined space until steam explodes through the crust, carrying pulverized ash and fragments with it. Such explosions were common during the growth of the lava dome in the crater at Mount St. Helens, which required constant vigilance by the volcanologists who were monitoring the growth of the dome. An additional series of phreatic explosions occurred from the dome in the early 1990s, several years after the cessation of the major period of intermittent growth that ended in 1986.

Along with these special hazards accompanying silicic and intermediate lava flows, all of the hazards associated with mafic flows, such as ground movement, cracking, and collapse, and shaking from earthquakes, also accompany silicic and intermediate lava flows and are prevalent in their vicinity. Additionally, toxic gases pose a pervasive potential hazard, especially when they accumulate in topographic depressions.

---

#### V. MITIGATION OF RISKS FROM LAVA-FLOW HAZARDS

More than 1500 volcanoes have erupted during the last 10,000 years, and more than 500 of these have erupted during the span of recorded human history. The volcanoes with recorded historical eruptions must be regarded as most likely to erupt again and are those for which mitigation efforts are most needed. However, even in the industrialized countries, scientific and economic resources are not sufficient to study all high-risk volcanoes. Thus, priority must be given to those in populated and developed areas that are known to erupt frequently and to those that erupt less frequently but have had major eruptions in historical time. Several times in recent decades, however, strong unrest has begun at volcanoes that have had no record of historical activity but which culminated in catastrophic explosive eruptions; examples include Lamington (1951), El Chichón (1982), and Pinatubo (1991). No advance mitigation had been instituted at Lamington or El Chichón, but emergency mitigation efforts of several kinds were quickly organized at Pinatubo, which led to saving thousands of lives and to reducing economic loss.

Although these explosive eruptions involved hazards much more serious than those anticipated for lava flows, mitigation efforts for hazards from lava flows depend on many of the same techniques and practices as those used in attempts to mitigate volcano risk in general. Details of the techniques, however, differ from one volcano to another and must be adapted as needed to the individual characteristics of each volcano. Efforts to reduce volcano risk can be grouped into four broad categories: (1) identify, (2) monitor, (3) control, and (4) inform. Categories 1, 2, and 4 are applicable for volcanic hazards of all types, but category 3 is only sometimes attempted in favorable situations for flowage processes of different kinds, including lava flows.

##### A. Category 1: Identify the Types of Hazard at the Volcano

An essential prerequisite for mitigation of volcanic risk at any volcano is to determine its history of eruptive activity and associated hazardous processes. This can only be accomplished by studying the geology of both the volcanic edifice and the region around the volcano. These studies, especially geologic mapping and dating of the volcanic deposits, are aimed chiefly at determining the rock types that have been erupted and their distribution and relations between one another in time and space. Such data are used to interpret the kinds of eruptions that have occurred at the volcano and their frequency, size, and impacts. Experience has shown that past activity of a volcano is generally a reliable indicator of the kinds of activity that can be expected in the future, so the results of the geological studies can provide an indication of what and where the hazards are likely to be. This information can guide plans for appropriate use of land in potentially hazardous areas, can indicate recurrence intervals between past eruptions, can provide estimates for timing of future eruptions, and can serve as a guide for organizing the other elements of risk reduction. If the population has grown and economic development has expanded since earlier eruptions, hazard zone maps can form the basis for estimating the risk to these newly developed areas. The geological studies, while essential to a complete mitigation program, should not be expected to reveal every type of activity that might occur in the future. For example, the geological

studies of Mount St. Helens, completed several years prior to 1980, served as an excellent guide to most of the types of potential activity and hazards, and even indicated the time frame in which renewed activity might take place, but they did not foresee the immense landslide that carried away much of the north flank of the volcano nor the magnitude of the resulting powerful laterally directed density currents that were the chief agents of destruction. Even so, the precautions that the geological studies had prompted were a key factor in reducing the casualty toll.

### B. Category 2: Monitor and Observe the Current Status of the Volcano

The objective is to determine current volcanic behavior and to detect and interpret significant changes that might signal impending activity. Regular observations and systematic monitoring, utilizing techniques tested and proven worldwide, operated continuously through periods of both quiescence and unrest, will provide a background database that enables meaningful changes to be recognized and interpreted promptly. Some of the most common and useful monitoring techniques include seismic monitoring to detect movement of magma or hydrothermal pressurization, along with geodetic monitoring to detect ground displacements, detecting the types and amounts of gas emissions, and regular field observations of important sites on the volcano. When resources permit, other monitoring tools can be added, such as gravity and electromagnetic monitoring, ground- and satellite-based infrared sensing, space geodesy (e.g., global positioning system, interferometric synthetic aperture radar), and utilization of digital telemetry and computer-controlled data management systems. Improvements in electronics and computer technology and miniaturization have led to the development of rugged, lightweight equipment with real-time and telemetry capabilities that have been used to develop a mobile monitoring system that has many of the capabilities of a complete volcano observatory. Such a system can be quickly established at volcanoes which lack adequate monitoring capabilities during volcano emergencies to provide vital data during crises. This type of system has been deployed several times in recent years by the USGS at restless volcanoes in Latin America and elsewhere. During increasing restlessness at Pinatubo volcano (Luzon, Philippines) in 1991, the system was used collaboratively by the Philippine Institute of Volcanology and Seismology and the USGS, enabling data

to be gathered, in near real time, that played a key role in convincing officials that evacuation of vulnerable areas was necessary, which saved tens of thousands of lives when the restlessness culminated in a catastrophic eruption on June 15.

### C. Category 3: Control of Lava Flows by Diversion or by Slowing Their Advance

When geologic studies or historical events have shown evidence of repeated flows from a volcano (such as lava flows, debris flows, lahars, and volcano-generated floods), it may be feasible in some circumstances to consider attempts to hamper or divert future flows by erecting barriers, by clearing channels to provide alternative paths, and (or) by disrupting their source of supply. Under special and favorable conditions, such attempts can be launched after flows are in progress. In this chapter, the focus is limited to attempts to control lava flows. Very large flows with high discharge rates cannot be controlled by any methods now known, but, by flow-modeling studies, estimates can be made of their likely ultimate distance and area to be covered. Several methods have been attempted to control smaller and slower lava flows at different volcanoes, and these have had varying degrees of success.

An early example was an effort in 1669 when a flow from Etna was advancing toward the city of Catania. Residents of the city tried a diversion tactic by attacking the crust on the side of the flow with picks and shovels, but they were later prevented from doing so by people from a neighboring village that would have lain in the path of the diverted flow. Later the flow advanced to breach the city wall of Catania and destroyed part of the city.

Three centuries later, a large-scale effort was again made to divert lava at Etna, during the 1991–1993 eruption, to protect the village of Zafferana Etnea. The construction of several earthen barriers during January–April 1992 achieved temporary, limited success in delaying the advance of the flow front before the barriers were successively overtapped. However, the barriers gained time to attempt—by means of explosives—to breach the natural lava channel (at a point about 8 km from the village) and divert the lava into an artificial channel (Fig. 10). The explosive “intervention” in May 1992, when the flow front was only 850 m from Zafferana, successfully diverted about two-thirds of the lava flow into the artificial channel. Shortly thereafter, the effusion rate about halved, and ultimately the eruption

FIGURE 10 Scene showing the engineering preparations to attempt diversion of the natural lava channel (lower right) into an artificial channel (foreground) during the 1991–1992 eruption of Mount Etna, Italy. On 27 May 1992, the detonation of explosives carefully placed in the thin natural separation wall (center) did divert about two-thirds of the lava into the artificial channel (see text); two people (center) give scale of the operations. (Photograph by Franco Barberi.)

ceased on March 31, 1993, with the front of the diverted lava flow stopping about 6 km from Zafferana. The 1992 lava diversion at Etna, while involving substantial expenditure of resources, is generally regarded as being successful in saving the village from lava inundation. Even so, the lava diversion tactics became controversial as serious questions were raised regarding their cost-benefit effectiveness.

Various efforts have been made in Hawaii to change the course of lava flows or to block their paths. In 1935 and 1942, attempts were made to divert the source of supply from Mauna Loa flows advancing toward the city of Hilo by bombing critical segments of the flow by aircraft. Each of these attempts showed promise of success, but both of the eruptions stopped by natural processes before the results could be fully evaluated. Diversion barriers were hastily constructed during eruptions in 1955 and 1960 in attempts to protect villages and other structures from flows issuing from the lower east rift zone of Kilauea. Most of the barriers were eventually overrun, but they succeeded in gaining time. For example, an eastward-moving flow, delayed by a barrier, resumed its advance and was just reaching the base of the lighthouse at the eastern tip of the island when the eruption stopped and the lighthouse was spared. Diver-

sion tactics, however, have been controversial, for complex legal problems can arise when property, which otherwise would have escaped, is overrun by the diverted lava. Further, in Hawaii, many residents are deeply offended when attempts are made to subvert the intentions of Pele, the Hawaiian goddess of volcanoes; they believe, instead, that her mischief should either be accepted with no resistance or be appeased by offerings and ceremonies.

On the island of Heimaey, south of Iceland, an eruption producing massive, slow-moving flows of aa and blocky lava in 1973 destroyed part of the town of Vestmannaeyjar and was threatening to flood the harbor, which was and still remains Iceland's most important fishing port. Initial small-scale trials to cool and hamper progress of the flow by water sprayed from fire hoses showed promise, so the effort was quickly expanded, and finally dozens of high-capacity pumps, mounted on barges in the harbor, pumped as much as a cubic meter of seawater per second through a system of movable plastic pipes, and water was conveyed to strategic areas of the advancing flows and sprayed onto the lava. These efforts succeeded in reducing damage to the town, and, even more importantly, deflected parts of the flow toward the broad mouth of the harbor and into the sea,

narrowing the harbor entrance. Fortunately, the eruption stopped after 5 months, which halted further damage, and at the end of the eruption the newly added land provided the harbor with greatly improved protection from storm waves.

#### D. Category 4: Inform and Educate Public Officials, Community Leaders, the News Media, and the General Public

A vital element of effective risk reduction is for the population at large to gain an adequate understanding of the current status of neighboring volcanoes, the types of behavior and nature of the hazards characteristic of these volcanoes, and the kinds of work being done by the volcanologists. Scientists should work closely with officials so that each will gain understanding and appreciation of the type of work and responsibilities of the other and of the functions that each must carry out during times of crisis. Good relations with members of the news media should also be fostered, so that news stories about the volcano will be as reliable and informative as possible and will avoid sensationalistic exaggeration. The population at large can be informed by illustrated talks to clubs, service organizations, civic groups, and schools. A well-informed populace is more likely to be willing to promote support for the geological studies, monitoring activities, and efforts at control because they understand the reasons behind the needs for such efforts. Good relations need to be cultivated among all elements of the local population so that officials will understand the need for planning for emergency-management procedures, so the public will be willing to accept them, and so that the scientists will have already established credibility and support for times when it is necessary to declare emergencies.

Mitigation capabilities are still far from being able to stop or control the actual source of lava flows, that is, the volcanic eruptions themselves. However, by making diligent and wise use of resources now available, and the combined procedures summarized above, it should be possible to reduce the loss of life and the damaging

effects of many eruptions. By learning to avoid expanding developments into the most vulnerable areas, by planning economic growth in ways that will reduce the risk from volcanoes, by making plans for effective emergency management, and by developing and maintaining monitoring networks aimed at learning the characteristic background behavior of volcanoes and recognizing unrest when it begins, much can be accomplished toward protecting life and property from avoidable losses from volcanic eruptions.

## GLOSSARY

**debris flow** Viscous, flowing slurry of rock fragments containing 10 to 25 wt% water. Unlike normal streamflows, in which water carries sediment, in debris flows the solid material carries water, which lubricates the flow. Debris flows commonly move as fairly coherent "plugs" with laminar flow, but they also may display pronounced turbulence and standing waves. Debris flows are not restricted to volcanoes; they occur in any environment with abundant soil or rock debris that experiences intense rains or sudden floods.

**hyperconcentrated streamflow** Turbulent flow of water mixed with enough sediment (60–75 wt%) to possess some yield strength. Such flows look little different from normal sediment-laden stream floods, but flow faster and with greater energy, and commonly display large standing waves that may break like surf in the upstream

direction. They display a spectacular tendency to erode stream banks laterally.

**jökulhláup** An Icelandic term that refers without distinction to both water floods and lahars that are generated when a volcano erupts under a glacier.

**lahar** An Indonesian term meaning a stream of water mixed with more rock than normal streams carry that roars as it flows rapidly down a volcano, and commonly reaches the surrounding plains. Most scientists reserve the term for the *process* and not to the deposit it leaves, but this distinction is ignored in much popular usage. Lahars closely associated with eruptions sometimes are called "primary lahars" to distinguish them from the "secondary lahars" that are not induced by eruptions. Some pre-1980s scientific literature uses "lahar" and "volcanic debris flow" synonymously, or refers to laharic debris flows as "true lahars." This usage incorrectly ignores the more fluid lahars (the hyperconcentrated transitions from normal, turbid streamflow to debris flow), and the fact that a single lahar can consist of multiple, alternating hyperconcentrated and debris flow phases. Many lahars are composed chiefly of sand and coarser materials, and thus should not be called "mudflows." The rock content of a lahar deposit is usually, but not exclusively, volcanic, because a lahar can flow through nonvolcanic terrain from which it can erode and incorporate enough rock to increase its load several times.

**mudflow** A flowing mixture of water and sediment composed dominantly of mud. They occur in both volcanic

and nonvolcanic terrains. Mudflows can entrain and buoy along boulders and equivalently sized artifacts like vehicles. The term is popularly and even scientifically used as a synonym for lahar—incorrectly for many lahars that are coarser than mud, and therefore flow much differently and leave different deposits. To avoid confusion that may worsen the lahar hazard, the term should be used exclusively for flows that genuinely are composed mostly of mud. Genuine laharic mudflows, if their fine components are powders of glass and feldspar instead of phyllosilicate minerals, also do not behave like mudflows in well-weathered terrains.

**muds** Admixtures of silt (particle diameters of 2–62  $\mu\text{m}$ ) and clay (grains finer than 2  $\mu\text{m}$ ), regardless of mineralogy. The most common clays in muds are weathering products, phyllosilicates (“leaf silicates”) with platy or fibrous crystal structures that can assimilate and release water molecules and carry electrostatic charges, and thus strongly influence the properties and behavior of the mud. All tephra grains finer than 2  $\mu\text{m}$  are technically clay, but ground glass and feldspar, such as compose the fine content of fresh volcanic debris and lahars, do not have phyllosilicate properties, and even when abundant do not affect the properties of slurries in the same way.

**A** SLURRY OF water and volcanic debris that roars loudly as it flows down a volcano is what Indonesians call a *lahar*, and it rivals the pyroclastic flow for the distinction of being the most deadly and destructive volcanic phenomenon. In terms of deaths from individual 20th century disasters, the lahars generated by the 1985 eruption of the Colombian volcano Nevado del Ruiz that buried more than 23,000 people in the town of Armero are outranked only by the pyroclastic flows that destroyed the town of St. Pierre and killed 29,000 people during the 1902 eruption of Mount Pelée on the Caribbean island of Martinique.

## I. INTRODUCTION

In terms of the cumulative fatalities they have caused, lahars are more devastating than pyroclastic flows for several reasons. They flow farther down volcanic slopes to the more heavily populated plains. Requiring only the sudden admixture of large amounts of water with abundant, loose or easily eroded debris on a volcano

slope, they can be formed in a remarkable variety of ways (Table I). Thus they occur more frequently, at many more volcanoes, and over longer periods of time than pyroclastic flows.

Unlike any other volcanic hazard, lahars do not require an eruption to occur. They can be triggered by bad weather or by edifice failure long after an eruption—a timing that can worsen the hazard, because the people in harm’s way have become less alert. For example, during a hurricane in October 1998, an avalanche and lahars on Casita volcano in Nicaragua killed an estimated 1600 people. Only one of five volcanoes in a complex that is dominated by the frequently active San Cristobal volcano, Casita itself has no historic record of eruption. Similarly, during the 4 centuries that records have been kept at Mount Mayon in the Philippines, the most lethal of all events, including eruptions, was a lahar that killed 1500 people in 1875. It was generated by typhoon rains 3 years after an eruption, and thus is excluded from most catalogs of volcanic disasters. Many other lahars that occur during volcanic quiescence in remote wilderness, lethal or not, go unobserved and unreported because, unlike an eruption, a lahar descending a single valley is not visible from afar.

The laharic aftermath of the 1902 eruption of Santa María volcano in Guatemala lasted at least 22 years. A comparable period of lahar activity is well underway following the 1991 eruption of Mount Pinatubo in the Philippines. In that developing country, poor people cannot avoid the hazard, and must learn to live with it.

Death and devastation from a natural hazard very often have been compounded by societal inadequacies. By unfortunate coincidence, the Earth’s tropical belt holds more than its share of rainstorms; explosive, debris-generating volcanoes; and developing countries with exploding populations. Lahars can be triggered by the strongest normal monsoon rains, which can be intensified and sustained greatly by passing typhoons or hurricanes. The warm, moist climate immediately attacks and weathers fresh lahar deposits into fertility, and so farmers resettle volcano aprons in increasing numbers, forced by poverty, population pressure, and custom to accept natural risks in exchange for livelihood.

The theoretical and physical bases for laharic flow are treated in detail elsewhere in this volume; here, lahar characteristics are reviewed insofar as they impinge directly on the lahar hazard. Then, to illustrate the variety and behaviors of lahars, and how the hazards they pose may be mitigated, we examine those that have occurred at three volcanoes: Gunung Kelut in Indonesia, where lahars were first described; the Colombian volcano Nevado del Ruiz; and Mount Pinatubo in the Philippines, where lahars began to flow during the 1991

TABLE I Notable Examples of Lahars and Their Triggering Mechanisms

Mechanism	Volcano, occurrences	Fatalities	Remarks
<b>Penecontemporaneous with eruption</b>			
Crater lake expulsion	Galunggung, Indonesia, 1822 Kelut, Indonesia, 1919 Ruapehu, New Zealand, 1975	3,600 5,110	$10^8 \text{ m}^3$ of deposits 130 km <sup>2</sup> covered
Crater lake breakout (wall failure)	Pelée, Martinique, 1902	25	
Subglacial eruption (jökulhlaups)	Öraefajökull, 1727 Katla, Iceland, 1918 Gjálp, Iceland, 1996	3	Peak discharge $3-4 \times 10^5 \text{ m}^3/\text{s}$
Snowmelt	St. Helens, USA, 1980 <sup>a</sup> Nevado del Ruiz, Colombia, 1985 Ruapehu, New Zealand, 1975	6 <sup>a</sup> 23,000	
Pyroclastic flows entering streams	Asama, Japan, 1783 Santa María, Guatemala, 1929 St. Helens, USA, 1980 <sup>a</sup>	550 6 <sup>a</sup>	Lahars traveled 100 km
Landslide	White Island, New Zealand, 1914	11	
Avalanches into lakes and streams	St. Helens, USA, 1980 <sup>a</sup>	6 <sup>a</sup>	
Rain during eruption	Agung, Indonesia, 1963	200	
<b>During volcanic quiescence</b>			
Avalanche	White Island, New Zealand, 1914		
Crater lake failure	Ruapehu, New Zealand, 1953	151	Peak discharge $850 \text{ m}^3/\text{s}$ ; $1.9 \times 10^6 \text{ m}^3$
Crater lake failure (man-made?)	Parker, Philippines, 1995	100–500	
Heavy posteruptive rain	Irazu, Costa Rica, post-1964 Mayon, Philippines, post-1984 Pinatubo, Philippines, post-1991 Semeru, Indonesia, 1981		Peak discharge $497 \text{ m}^3/\text{s}$
Lake breakouts	Santa María, Guatemala, post-1902 Pinatubo, Philippines, post-1991		
Earthquake-induced avalanche on extinct volcano	Ontake, Japan, 1984		

<sup>a</sup> Multiple triggering mechanisms.

eruption and likely will continue to be generated into the 21st century.

amounts of meltwater that are suddenly released as great “glacier bursts” called *jökulhlaups* in Iceland, where they have been best studied. Jökulhlaups include water floods as well as the dilute and viscous lahars that, by definition, carry more sediment than normal floods do.

Meltwater from subglacial eruptions collects in calderas, forming lakes that can be entirely covered by ice, as at Katla volcano in Iceland, or partly visible at the surface, as at Grimsvötn volcano. In either case, when meltwater has accumulated deeply enough to float the ice off its base, it can suddenly escape in large volumes— $7 \text{ km}^3$  during the 1937 Grimsvötn eruption. Discharge rates are enormous, estimated at 300,000 to

## II. LAHAR CHARACTERISTICS AND HAZARD IMPLICATIONS

### A. Jökulhlaups

In Antarctica, arctic North America, and Iceland, eruptions of volcanoes under glacial ice generate large

400,000 m<sup>3</sup> per second during the 1918 Katla eruption—on the order of 20 times the discharge of the Mississippi River. Huge blocks of ice, fresh volcanic debris including hyaloclastites or shattered volcanic glass, and large boulders incorporated by the floods along the way can be carried large distances, forming, for example, the extensive “sand plains” of southern Iceland.

A subglacial fissure eruption in October 1996 at a new site between the subglacial Grimsvötn and Bárdarbunga calderas under the Vatnajökull icecap (Figure 1) gives a sense of the duration and magnitude of a large jökulhlaup. Gjálp, the new volcano, erupted for 13 days, melting 3 km<sup>3</sup> of ice, at peak rates of 0.4 to 0.6 km<sup>3</sup> per day. An additional ice volume of 1.2 km<sup>3</sup> was melted during the first 3 posteruption months. Much of the water, with temperatures of 15 to 20°C, drained south

into the Grimsvötn caldera, from which a jökulhlaup with a volume of 3.5 km<sup>3</sup> was discharged on November 4–7, at peak discharges of 45,000 m<sup>3</sup> per second, carrying large volumes of sediment and blocks of ice up to 15 m in diameter and weighing up to 2000 tons.

Given the intense scientific and media scrutiny before the Gjálp event, it is no surprise that no casualties were incurred. Curiously, historical records of casualties from jökulhlaups are very rare, possibly due to low population densities. The only fatalities mentioned in the literature are of two women and a boy swept off a roof by the Öraefajökull jökulhlaup in 1727, which also killed 600 sheep and 150 horses. Only one woman was recovered; the mud had been hot enough to parboil her corpse.

## B. Dilute Lahars (Hyperconcentrated Streamflows)

The more dilute lahars are called hyperconcentrated streamflows because their sediment loads are greater than those of the most turbid normal streams. Apart from displaying prominent standing waves, dilute lahars look deceptively little different from normal, dirty floodwaters (Figure 2). But more than half of the slurry—anywhere from 60 to 75% by weight—is solid material, and velocities of 20 km per hour are not uncommon. People or even trucks and buses trying to cross dilute lahars have often been carried downstream.

Even while flowing vigorously, a hyperconcentrated lahar can deposit sediment, raising its bed several centimeters in an hour. Thus the lahar may force itself to shift sideways and vigorously erode its bank. Lateral erosion rates of 6 m per minute have been documented at Pinatubo volcano. If the flow persists, a stream bank can retreat as much as a kilometer in a few hours, and if houses are in the way, they fall in and are washed away (Figure 3). The least intense lahar events consist entirely of hyperconcentrated streamflows.

## C. Channelized Debris Flows

In the larger and most powerful lahars, hyperconcentrated flows are merely the dilute advance warning of approaching debris flows, the most spectacularly sediment-laden and destructive variety of lahar. In a debris flow, the water is no more than about 25 wt%, and as low as 10%—barely enough to mobilize the debris. Being viscous, debris flows tend to move in a fairly straight-line or laminar fashion, or even as coherent “rigid plugs”

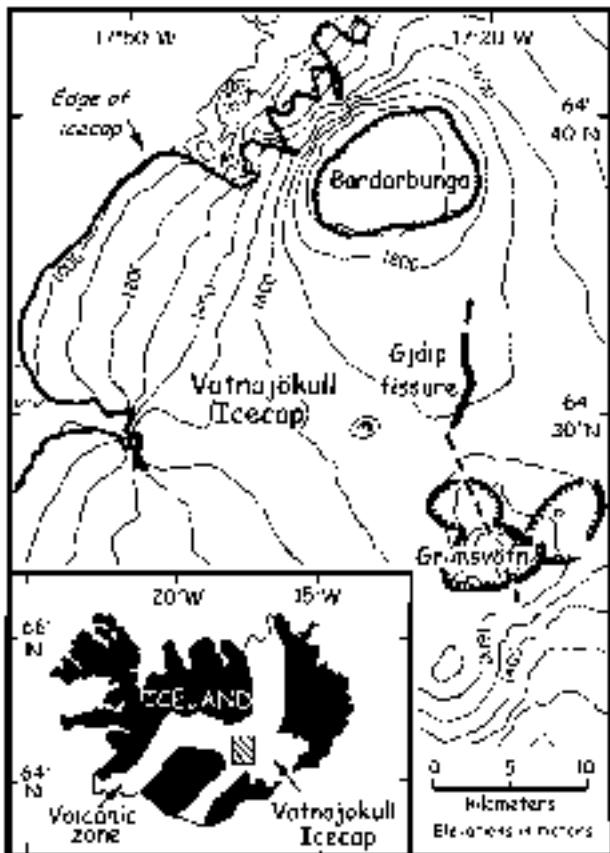

FIGURE 1 Map of the northwest part of the Vatnajökull icecap, showing the Grimsvötn and Bárdarbunga calderas and the Gjálp fissure volcano between them. [Modified from Gudmundsson, M. T. et al. (1998). Ice-volcano interaction of the 1996 Gjálp subglacial eruption, Vatnajökull, Iceland. *Nature* **389**, 954–957.]

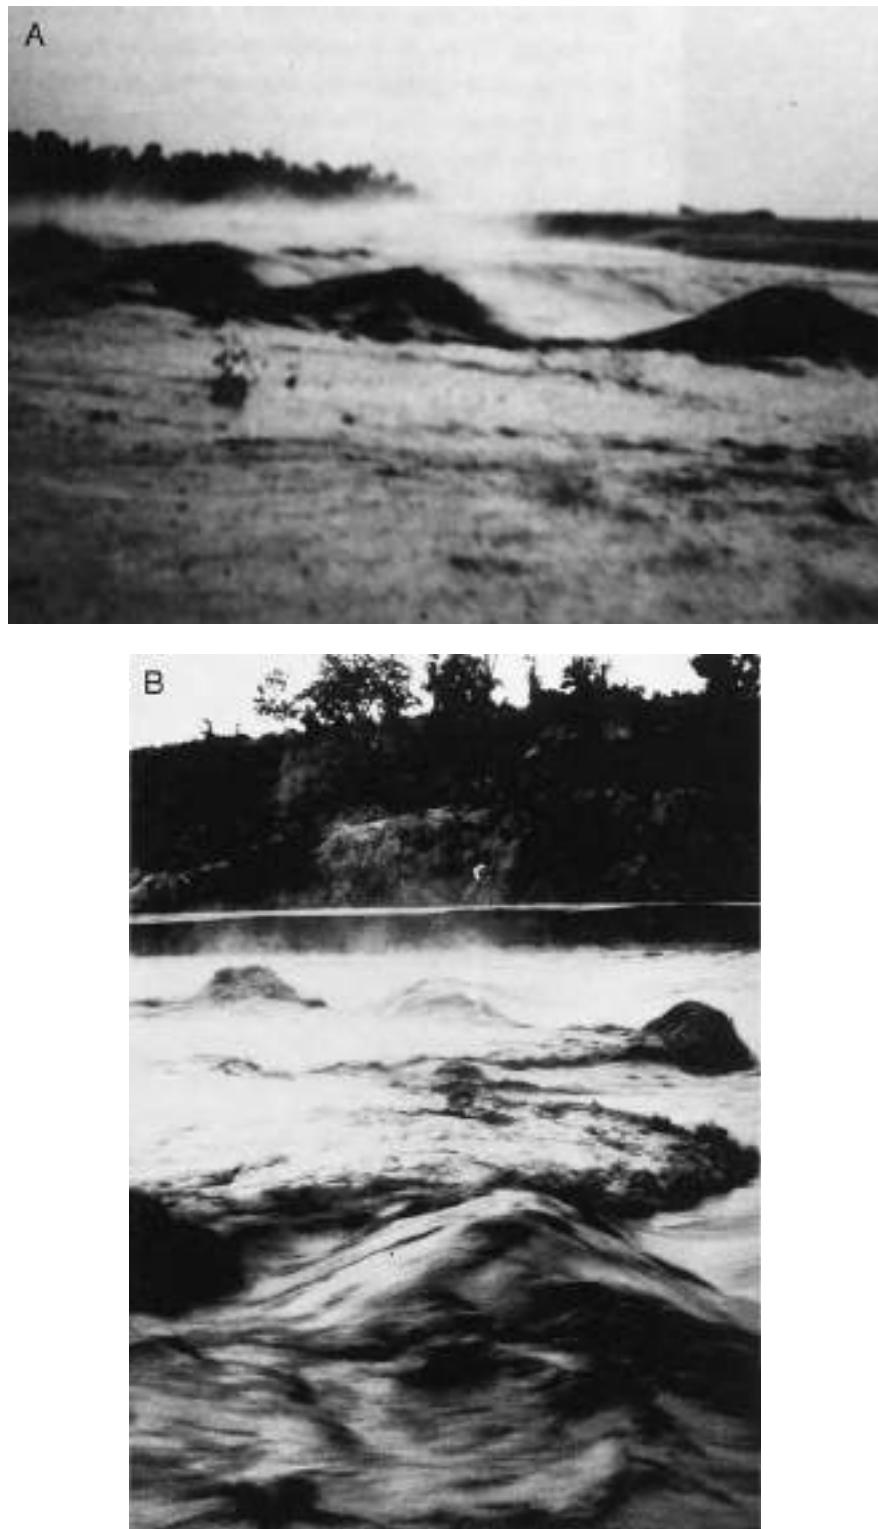

FIGURE 2 Hyperconcentrated lahars along the Santo Tomas River, southwestern sector of Mount Pinatubo. (A) Standing waves 6 m long and 1.5 m high. (B) Waves breaking in the upstream (right) direction during transition from hyperconcentrated to debris flow. [Reproduced with permission from Rodolfo et al. (1996). **FIGURE 3** Damage to houses caused on June 15, 1991, by lateral bank erosion along the Abacan River, eastern sector of Mount Pinatubo. Also see Figure 7. [Reproduced with permission from Major, J. J., et al. (1996). Page 909 in "Fire and Mud: Eruptions and Lahars of Mount Pinatubo, Philippines" (C. G. Newhall and R. S. Punongbayan, eds.). Univ. Washington Press, Seattle.]

(Figure 4A). Unlike floodwaters, however, they have the curious property of being less viscous at higher speeds, and can display remarkable turbulence (Figure 4B). Flow velocities of 15 to 30 km per hour (4–8 m/s) are common on the slopes of typical composite volcanoes. At Nevado del Ruiz in 1985, laharic debris flows confined in long, steep, narrow valleys attained velocities of over 60 km per hour (17 m/s). Lahar speeds of 140 km per hour were reported at Mount St. Helens in the United States in 1980, and 180 km per hour at the Japanese volcano Tokachi in 1926.

Owing to their high densities, thicknesses, and velocities, debris flows exert powerful shear stresses on their channels and especially on their bases. Thus, they feed on their own success—"bulking up" or swelling to a remarkable degree as they travel by eroding and incorporating an even more remarkable amount of rock along the way. If, for example, the average specific gravity of the rock is twice that of water, a debris flow starting out with 25% of its weight as water can bulk up to twice its original volume by eroding enough rock from its channel to triple its weight of solid load. The potential to bulk up is limited only by the need for the minimum 10% water necessary to lubricate the flow. Lahars that flowed down Irazu volcano in Costa Rica after its 1964 eruption reportedly swelled sixfold in volume.

The hazard implication of bulking is that reports of

lahar size and consistency from an upstream observer may greatly underrepresent the lahar that reaches the plains below. For example, at Pinatubo in 1995, when typhoon floodwaters began arriving at an upstream observation post, lahar watchers on the Pasig-Potrero River radioed the authorities below. Being used to floods, the people were reassured and went about their business. However, as the floods continued descending along 22 km of channel, they bulked up enormously and with shocking speed into debris flows that entirely buried Barangay Cabalantian, a village with 2000 houses, in debris up to 9 m thick (Figure 5), killing hundreds of people.

It is difficult to determine the maximum depth of scour attained during the peak debris flow stages of a lahar, because as it wanes, hyperconcentrated streamflows usually fill up the channel again to an unknown degree that depends on the size of the lahar and on other factors that vary from site to site. A lahar-containment structure with an appropriately deep foundation cannot be built until the maximum possible scour depth at that site can be estimated, because debris flows also migrate laterally and could undermine footings that are too shallow. One lahar at Mount Pinatubo in 1997 first deposited about 12 m of debris, and then eroded through it and continued scouring downward an additional 25 m. At this site, then, an effective dike would be much too

FIGURE 4 Steaming debris flows at adjacent sites along the Sacobia River, northeastern sector of Mount Pinatubo, Philippines, in August 1991, 2 months after the paroxysmal eruption. The fluid temperatures were 50–60°C, and sediment contents were 85% by weight and 70% by volume. The flows were 15 m wide and about 2 m deep. Velocities were 17 to 21 km per hour (4.8–5.9 m/s). (A) The flow here, toward the camera, appears to be a “rigid plud” in its center. (B) Here, downstream from (A), the channel was locally steeper and more constricted. Flowing from left to right, the turbulent debris flow formed standing waves about 1 to 2 m high that broke violently in the upstream direction. [From Pierson et al. (1996). Page 942 in “Fire and Mud: Eruption and Lahars of Mount Pinatubo, Philippines” (C. G. Newhall and R. S. Punongbayan, eds.). Univ. Washington Press, Seattle.]

FIGURE 5 A house in the village of Cabalantian, 30 km from the caldera of Pinatubo volcano (A) before and (B) after the lahar disaster of October 1, 1995. Previously untouched by lahars, the entire village was buried in the deposits of lahars that flowed for 4 to 6 hours. [Photographs collected and taken by the Philippine Institute of Volcanology and Seismology. Modified with permission.]

expensive to construct because it would have to be seated too deeply.

Debris flow densities can be twice that of water, and buoyancy effects cause flow behaviors that are spectacularly different from stream floods. Even the strongest of mountain torrents preferentially transport finer sedi-

ment and leave the boulders behind. In many debris flows, however, the boulders immersed in the slurry have lost much of their effective weight, and jostle each other so strongly that they may be bounced and lifted toward the surface and center of the lahar. There, the flow is smoothest and velocities are greatest, and bob-

bing boulders weighing up to 200 tonnes can be rafted 10 km or more to the front of the lahar (Figure 6). A moving, rapidly evolving dam consisting of boulders that have reached the front maintains the thickness of the flow behind it that is pushing it along.

A lahar can fling boulders and logs against a bridge or dam, exerting impact forces of 10 to 1000 tonnes per square meter—forces that few structures can withstand. In addition, most engineering edifices are designed to withstand gravity, not the opposite buoyant forces exerted by the higher densities of debris flows that reduce their effective weights, lifting them and making them even more susceptible to the lateral battering. Furthermore, lahars triggered by protracted rains can flow for several days as alternating dilute flows and debris flows, each in turn testing a structure with its own destructive behaviors (Figure 7).

#### D. Lahar Noise

To Indonesians who have experienced lahars, the very term evokes the roaring of clashing and tumbling boulders, “like a thousand stampeding water buffalo.” Mount Pinatubo tephra contains few boulders, and so when it is mobilized into flowing lahars the frequencies of the noise are higher, “like a giant’s sandpaper.” The

sound, if not drowned out by eruption or storm noise, is commonly loud enough to precede the arrival of the lahar by as much as half an hour—a precious interval during which people can escape to safety on high ground.

#### E. Debris Flow Temperatures

Being volcanic debris admixed with water, lahars cannot have bulk temperatures above that of boiling water, although individual boulders or cobbles may have internal temperatures of several hundred degrees. If the tephra are pumiceous and thus are poor thermal conductors, as at Mount Pinatubo, they may insulate the deposits on volcano flanks and keep temperatures only a few meters below the surface at several hundred degrees for many years after an eruption. During that period, the flood from a strong rainstorm or the sudden breaching of a crater lake wall can incise quickly into the hot debris, generating large steam explosions and hot lahars.

Although common, scalding is not the main cause of injury and death from either eruption or posteruptive lahars. Most trauma and fatalities are effected by suffocation, resulting from rapid burial, because rates of deposition are typically meters per hour or minute or, exceptionally, per second.

FIGURE 6 Boulder front of a laharic debris flow overtopping a sediment-retention structure. The largest boulder is 2 m in diameter. [Reproduced with permission from the Ministry of Construction, Japan.]

**FIGURE 7** Bridge across the Abacan River in Angeles City destroyed by debris flows during the 1991 eruption of Mount Pinatubo. The channel bank to the left has been severely eroded by hyperconcentrated streams. [Reproduced with permission from Major et al., 1996, p. 910.]

Hot debris can continually release heat into a debris flow, generating water vapor that may decrease its viscosity, lubricate it, and increase its speed. In that sense, lahar temperature may enhance the hazard.

#### F. Overbank Debris Flows

The slope down which a debris flow moves is a primary factor in determining its speed, and so it must eventually slow down and stop. Emerging from a mountain canyon and spreading out over gentler slopes, or bulking up so much that it overflows its banks, a debris flow is rarely more than several meters thick, and so any low hill or slope can serve as safe refuge. As a debris flow spreads, basal area and frictional resistance increase, slowing it down. Debris flows are more viscous at lower speeds; this causes them to slow down even more quickly. As a consequence, spreading lahars are not powerful enough to topple even fragile structures such as thatched huts, and merely flow around and into them, and bury their bases (Figure 8). People trapped in the path of an overbank lahar can escape by climbing to the roofs of the tallest buildings or trees in their vicinity.

Owing to the rapid rates at which lahars can lay down their sediments, fresh deposits may remain loose and

water-saturated for days to weeks. Debris flows possess strength even while they flow, and leave lobate deposits with abrupt edges. If the sediment masses contain little silt and clay, the water can drain out of their higher portions fairly quickly. Draped over a high-standing road, new deposits can harden enough to take the weight of vehicles in only a few hours. The deposits drain less rapidly if they contain substantial clay. If they are deposited in topographic lows, especially river channels, they can remain saturated and have the consistency of quicksand for weeks or months. People and vehicles bogged down in such deposits can be extricated only with difficulty, and entrapped animals often starve to death.

---

#### III. CRATER LAKE EXPULSIONS: THE LAHARS OF GUNONG KELUT

Lahars have been generated on many volcanoes that contain crater lakes, including 16 in Indonesia alone. Of these, Mount Kelut on the island of Java (Figure 9) is the most famous, for its crater expulsion in 1919 holds the record for the number of people killed by lahars generated in that manner. Kelut also offers one of the more spectacular examples of lahar mitigation by engi-

FIGURE 8 Thatched huts buried by lahars during the 1991 eruption of Mount Pinatubo. [Reproduced with permission from Major et al., 1996, p. 909.]

neering. (J. B. Scrivenor's 1929 description of that event also introduced the term *lahar* to the scientific literature.)

The summit crater of Kelut contains a lake elevated about 1700 m (more than a mile) above sea level. As is characteristic of composite volcanoes in the tropics where fresh tephra weathers quickly into fertility, the area surrounding the volcano is intensively cultivated and densely populated by more than 500 people per square kilometer. Kelut erupted without warning in 1919, suddenly disgorging 40 million m<sup>3</sup> of lake water. Escaping from the lowest portions of the crater rim, the water rushed down three sides of the volcano. The floods were so strong and turbulent that they quickly picked up large amounts of rock debris along the way, bulking up into lahars. Carrying huge numbers of boulders and trees, the three lahar tongues raced down the flanks of the volcano at speeds up to 64 km per hour. In less than an hour, the longest flow had extended 38 km from the summit. Spreading out over an area of 131 km<sup>2</sup>, the lahars buried many villages, killing more than 5000 people. Especially hard hit was the southwestern sector of the volcano, where coalescing flows overwhelmed the adjacent drainages of the Temas and Ngoglik rivers.

The Dutch colonial government recognized that the volumes and distances reached by Kelut's eruption lahars depend on the volume of crater lake water released.

In 1923 engineers began to tap the crater lake with a series of drainage tunnels in order to reduce its volume in stages from 38.5 to 1.8 million m<sup>3</sup> (Figure 10). Continuous crumbling of the inner crater wall raised the bottom of the crater, further reducing the lake volume. In 1951, when a minor eruption occurred, the lake contained only about 1 million m<sup>3</sup> of water, and so no major lahars were generated. The eruption, however, deepened the crater floor and restored the original capacity of the lake.

Mount Kelut erupted again on April 24, 1966, again with little warning. Only about 20 million m<sup>3</sup> of water was expelled—about half the volume of the 1919 event—and thus the lahars were much smaller. As anticipated, they followed the same general paths of the 1919 flows. Fortunately, even though the inhabitants had little warning, most had experienced lahars in the past, and were alerted by their roaring approach. Overtopping the river banks about 500 m above sea level, the lahars fanned out, burying 45 km<sup>2</sup> of farmland and several villages. Most of the people had fled to designated safe areas, but 282 people were killed, mostly the aged, women, and children.

A new tunnel to drain the crater lake, completed in 1967, has kept the lake at low levels. Three successive eruptions have since shown that destructive eruption lahars are not generated if the volume of the crater lake is kept below 1 million m<sup>3</sup>.

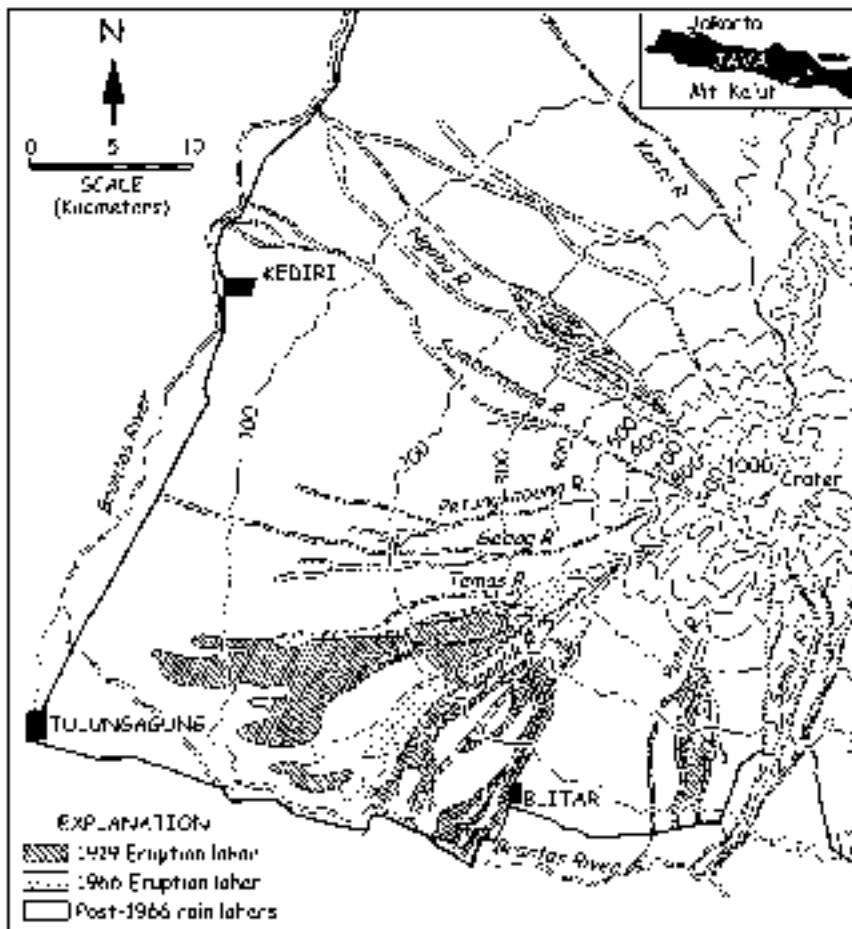

FIGURE 9 Map of Mount Kelut. [Modified from an unpublished monograph of the Japan International Cooperation Agency.]

#### A. Containing Rain Lahars at Kelut

Lahars in the years of quiescence following the 1951 eruption raised the bed of the Brantas River by 2 m or more, causing flooding of the lower reaches of the river and its tributaries during rainy seasons. Pyroclastic flows of the 1966 eruption filled the summit valleys, and the downstream valleys were choked with the deposits of eruption lahars. Much of this loose material was remobilized and transported downslope during subsequent rainy seasons, dramatically increasing the load of the Brantas River (Figure 9). Massive lahar deposits in the lower reaches caused the river to overflow its banks and to create new courses, and so new areas were successively buried, and seasonal flooding increased in the industrial city of Kederi.

To minimize the volume of loose volcanic material entering the river, a series of check dams and sand pockets with a total storage capacity of 40 million m<sup>3</sup> were

constructed. To contain the rain lahars, the depositional area was bounded by dikes, but by 1994 the continuous deposition had raised the river bed 1.5 m above the surrounding paddy fields. Such a situation itself constitutes a hazard, because major lahars can be produced if the dikes are breached and the escaping waters remobilize the previously trapped debris.

---

#### IV. ERUPTION SNOWMELT: THE 1985 “WORST-CASE” ARMERO DISASTER

Nevado del Ruiz is a volcano in the Central Cordillera of Colombia (Figure 11). *Nevado* means “snowy”; although the volcano is situated near the equator (lat. 4°54' N), it stands more than 5 km above sea level, and thus has a permanent cap of snow and ice. On November 13,

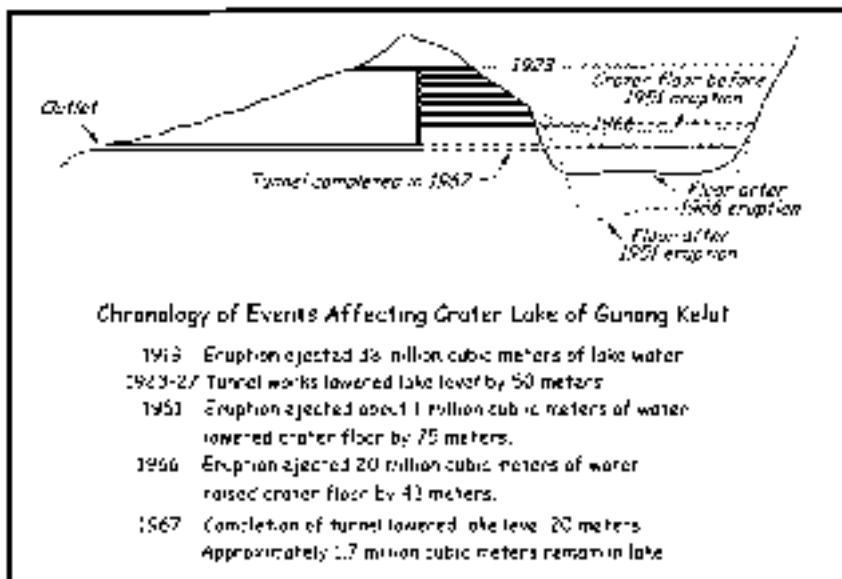

FIGURE 10 Cross-sectional sketch of Mount Kelut showing drainage-tunnel system and modifications of crater lake level and floor due to tunnel drainage and eruptions. [Modified from an unpublished monograph of the Japan International Cooperation Agency.]

1985, shortly after 9 P.M., hot tephra from a relatively small series of pyroclastic flows and surges swept across the snowpack, generating an estimated 20 million m<sup>3</sup> of meltwater. Mixed with tephra into dilute slurries, the discharge descended along three major valley systems that drain the volcano. Coursing down the narrow valleys, the flows eroded great quantities of rock from their

channels, and bulked up into huge lahars, with peak discharges of 48,000 m<sup>3</sup> per second and maximum velocities of over 60 km per hour (17 m/s). Only 4 hours after the eruption, the flows had descended 5100 m, wreaking havoc as far as 104 km away from the summit crater and burying more than 2100 km<sup>2</sup> of volcano apron and adjacent plains in 90 million m<sup>3</sup> of slurry.

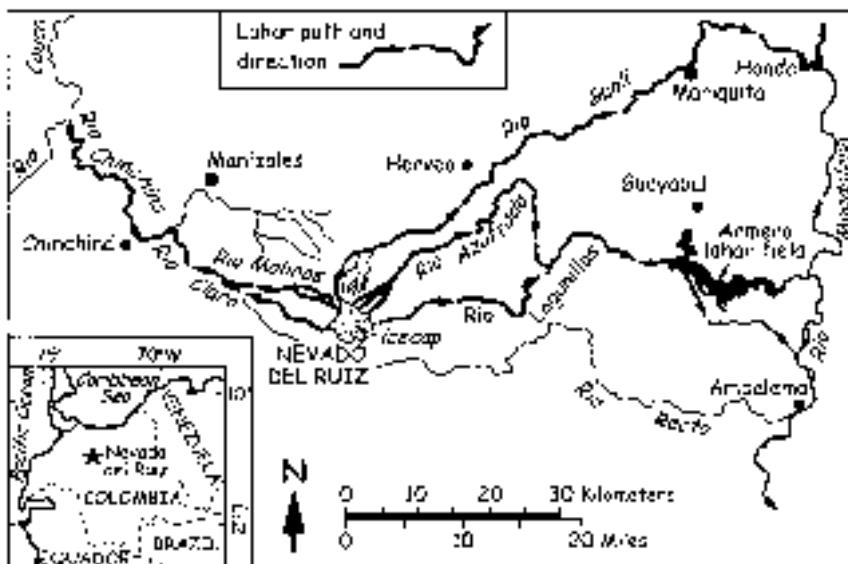

FIGURE 11 Map of Nevado del Ruiz volcano showing routes followed by the lahars of the 1985 eruption of Nevado del Ruiz volcano.

The Rio Azufrado, the principal lahar conduit, enters the Rio Lagunillas about 20 km upstream of the town of Armero, which lay 74 km from the summit crater along the more circuitous Azufrado route. The first and strongest Azufrado lahar emerged from the Lagunillas Valley and arrived at Armero at about 11:35 P.M. with a frontal velocity of about 43 km per hour (12 m/s). Lasting 10 to 20 minutes, it inundated the town in slurry 2 to 5 m thick (Figure 12). At 11:50 P.M., before the first lahar could recede, a second pulse with about half the velocity arrived and lasted approximately a half hour. Six to eight smaller pulses ensued in the next hour. Finally, a smaller lahar from the upper Lagunillas arrived shortly after 1 A.M. and, lasting about 15 minutes, ended the catastrophe. Armero had been virtually wiped out, and more than 23,000 of its citizens had been killed.

The Armero event is the “worst-case” lahar event of record in terms of many parameters: the sheer volume of slurry, distances of transport, peak velocities, size of the devastated areas, and number of fatalities. Its occurrence at night worsened the disaster by making warning and evacuation difficult. An even greater contributing factor was that, although the hazard had been thoroughly studied, life-saving information had not been disseminated among the threatened populace. The legacy of Armero is the important lesson that understanding a hazardous phenomenon is not enough to avert its threat—scientific information has little life-

saving value if it is not shared in timely fashion with those in harm’s way.

#### A. Sociopolitical Enhancement of Catastrophe

The first social circumstance that paved the way to the disaster was the total lack of land-use planning in the location and growth of Armero. The town was built on deposits left by lahars that killed 600 people in 1595 and 1000 in 1845—events that were both larger than the lahars of 1985.

Authorities had an entire year of warning that Nevado del Ruiz was restless, after mountain climbers reported heavy steaming at the summit in November 1984. By February 1985, Colombian geologists had visited the volcano several times. Scientific teams from several countries began working on the volcano in March. A preliminary hazard map that proved to be tragically accurate had already been published in newspapers before the eruption, and its final version had been scheduled to be released on the day after the eruption. Ironically, one of the problems was that there were too many scientific teams to coordinate well, and too much inconclusive argument among them. Scientists later also complained that it was hard to work because of the numerous

FIGURE 12 Aerial view of Armero after the 13 November 1984 lahar. [From Pierson et al., (1990) with permission from Elsevier Science.]

"briefings" they had to provide to various government officials who, unfortunately, did not pass the information on to the threatened population.

Shortly before the Armero catastrophe, leftist rebels took over the Palace of Justice in Bogotá and held the Supreme Court justices hostage. On November 6, a week before the eruption, the President of Colombia ordered the army to attack the Palace, and a hundred people, including 10 of the judges, were killed. Officials responsible for managing the Nevado del Ruiz emergency were distracted from their duties by the continuing political crisis.

But the worst problem of all was the lack of communication. To avoid disaster, scientists and decision makers must communicate often and well, and the information must be passed on to the people at risk. Neither happened at Nevado del Ruiz. Shortly after 3 P.M. on the day of the tragedy, a minor phreatic eruption lasting about 15 minutes caused a small landslide into the upper Rio Azufrado. Mixing with the river water, this mass movement was liquified into a lahar that destroyed a bridge 4.5 km downstream from the crater. This should have been a clear signal for increased vigilance. But in the evening, as tephra from explosions began falling in Armero, the town mayor spoke on the radio, telling the people that nothing had been reported from Nevado, and instructing them not to worry and to stay in their houses. The radio transmission ended abruptly as the lahar arrived.

---

#### V. MOUNT PINATUBO: THE LONG AFTERMATH OF RAIN LAHARS

The 1985 lahar of Nevado del Ruiz is the single-event worst-case lahar in recorded history, but, together, the lahars that ensued in the years after the 1991 eruption of Mount Pinatubo constitute the most voluminous, the most devastatingly widespread, and one of the longest-lasting laharic episodes of record. Its occurrence in an area inhabited by people with no previous experience of volcanoes and lahars has brought about socioeconomic and political responses that have aggravated the continuing calamity.

The 1991 eruption deposited about  $5.5 \text{ km}^3$  of pyroclastic flow debris on the volcano (Figure 13). Since the last, prehistoric eruption 5 centuries earlier, torrential runoff on Pinatubo had cut deep canyons into the mountain. After the eruption, large areas of the gullied terrain were smoothed into sloping surfaces by the new pyro-

clastic deposits that completely filled pre-eruption valleys, some as deep as 200 m.

Lahars began to flow shortly before the paroxysm because, by unfortunate coincidence, a minor typhoon passed within a hundred kilometers of the volcano and caused locally heavy rains that destroyed bridges and roads on all sides of the volcano. The channels draining Pinatubo were still unclogged, and so the lahars did not overflow the river banks. Except for the bridges, the lahars caused little damage to land and property and few casualties.

The eruption killed over 900 people, most from malnutrition and disease in refugee camps. About 200 people died when roofs collapsed under the weight of rain-soaked tephra, and a smaller but indeterminate number who did not evacuate from the volcano slopes were killed by pyroclastic flows. Lahars generated by the monsoonal rains that followed on the heels of the eruption claimed an estimated hundred lives. Some wide river valleys received sediment 15 m or more thick (Figure 14). More than  $350 \text{ km}^2$  of farmlands on river plains were buried or eroded away by lahars in 1991. But the devastated area and the number of casualties were increased greatly in the following years during the seasons of monsoonal and typhoon rains. The affected area eventually may be double or triple that of 1991.

#### A. Lake Breakouts

Some of the largest and most lethal lahars are produced by outbreaks from temporary or permanent lakes that form when a lahar channel is blocked by a landslide or by a steam explosion. Other lakes, for example, Mapanuepe Lake at Pinatubo, can form where a lahar channel is joined by a tributary that drains an area on the volcano, or even outside it. Lahars can deposit so rapidly at the junction that the tributary is dammed, and a lake forms behind it (Figure 15). After the landslide, or when the damming lahars stop flowing, water can continue to rise in the lake, eventually overtopping and breaching the natural dam. The large volumes of water released then erode the channel and bulk up into new lahars. Although cold, such so-called lake-breakout lahars can be as large and destructive as hot lahars. They can be even more dangerous if the lake is breached during good weather, several days after the lahars have stopped coming down from the volcano, and the threatened populations have relaxed their guard. Communities below the lake should monitor the temperature of arriving flow. Cold water means that the lake is draining, and hot lahars mean the

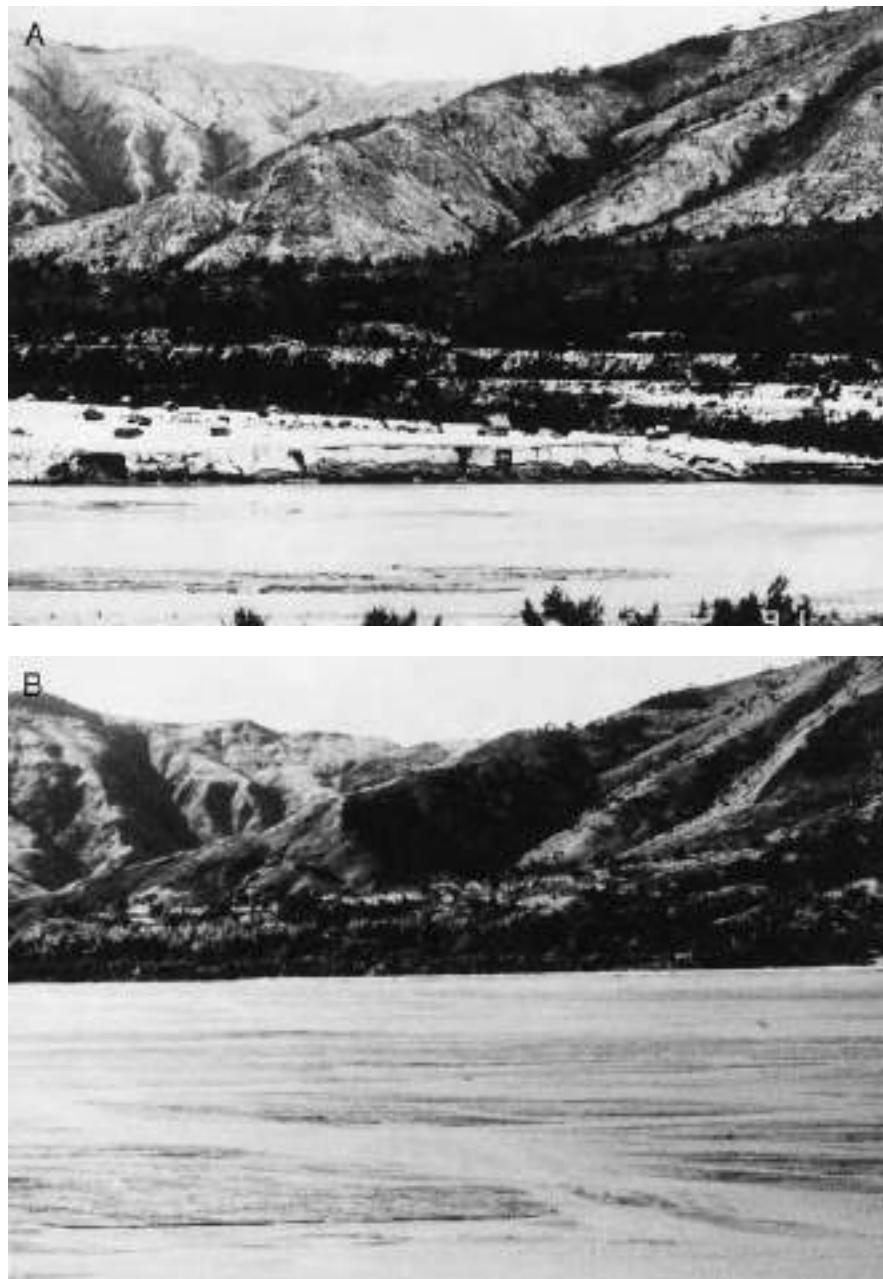

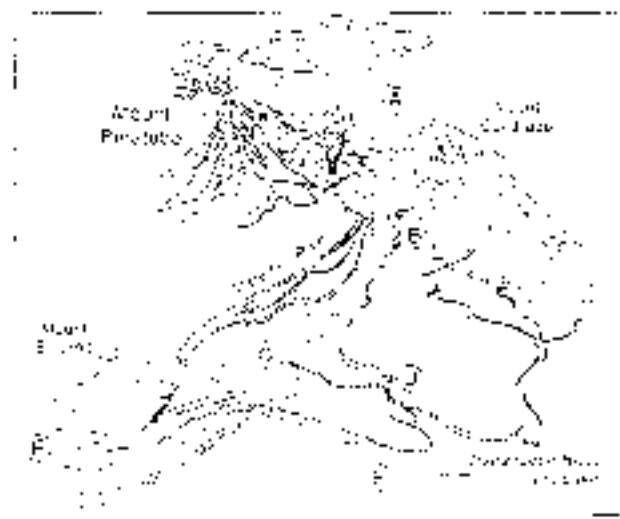

FIGURE 14 A portion of the terraced south bank of the Bucao River. (A) June 1991, before lahars began to flow. For scale, the largest hut on the lowest terrace is about 3 m tall. (B) The same area in January 1992, after the deposition of about 15 m of lahar sediment.

lake has been blocked and may be accumulating toward a breakout.

#### B. Mitigation Engineering

Soon after the 1991 Pinatubo eruption, the government decided that abandoning doomed towns and resettling

their populations would be more expensive than building structures to protect the towns. This judgment was made in circumstances of crisis and emergency, and before proper feasibility studies could be conducted to determine the power and behaviors of lahars, the necessary designs to contain them, and what such structures would cost. Confronted by the threat of huge and imminent lahars, the government and communities alike

**FIGURE 15** Diagram of the generation of lake-breakout lahars at the Santo Tomas River southwest of Pinatubo. (A) Heavy rain on the pyroclastic field generate steam explosions and hot lahars. (B) Lahars cascade down the Marella River. (C) Marella lahars spread and deposit along the wide channel reach and choke the constriction at the Mapanuepe junction. (D) At the confluence, Marella lahars invade upstream along the Mapanuepe River, damming it. (E) After Marella lahars cease, rising Mapanuepe Lake waters breach the dam. (F) Breakout waters remobilize deposits of previous lahars along the Santo Tomas River and erode its banks as they descend toward the sea.

stampeded into building costly structures that did not work, and even enhanced the danger by encouraging an unjustified sense of security. Every year, the government has built structures without proper planning, employing floodwater techniques in attempts to contain and deflect lahars, and the structures have failed.

Perhaps the biggest mistake persistently made was to use lahar deposits for the bulk of dikes. The only advantages this material offered were its abundant availability and that quarrying it out of lahar channels helped to restore their capacity. But lahar material is almost exclusively pumice—porous, low-density sand and gravel—that provides minimal mass and inertia against impact. Its laharic history already attests to its ease of remobilization. In large part this is because it lacks silt and clay to bind it together. Moreover, without these fines to clog the pores between the grains of sand and gravel, it is very porous and permeable. Expensive structures, even some armored in concrete, have failed not only from lahars, but also from the mere passive pressure of impounded water that, seeping rapidly through and under them, erodes large, natural pipes that riddle and undermine them.

Intelligent, surgical engineering with explosives was applied successfully to mitigate breakout lahars from Mapanuepe Lake. An engineering scheme devised by a Filipino volcanologist to cut an artificial outlet to the lake and keep its level stable has eliminated dangerous buildups and breakouts. The lake itself has also served as a natural trap for large volumes of laharic sediment.

### C. Predicting the End of the Pinatubo Lahar Crisis

Rehabilitation of the area surrounding Pinatubo urgently requires sound predictions of the rates at which lahars will occur, and the duration of the laharic aftermath. Data gathered from 1991 to 1994 indicate that the volumes of debris on the volcano flanks that were

**TABLE II** Predicting the Continuing Sediment Yield of Pinatubo Lahars

Year	Actual	Best fit	Low	High
1991	805	801	725	925
1992	555	596	539	688
1993	505	444	401	512

2007		7	6	8
2008		5	5	6
2009		4	4	5
2010		3	3	3
Total	2175	3122	2864	3604

Note. See Figure 16. From Umbal, J. V. (1997). Five years of lahars at Pinatubo Volcano: Declining but still potentially lethal hazards. *Geological Soc. Philippines Bull.* **52**, 1–19.

mobilized into lahars roughly followed an exponential decay rate. Extrapolated into the future, this predictive model projects another decade of significant lahar activity (Table II and Figure 16). However, the model has several serious drawbacks. First, it cannot be used to predict lahar activity along any individual channel, because all are unpredictably subject to major reorganization. In February 1992 a large secondary explosion blocked the Abacan River and rerouted its lahars into the Sacobia River, worsening the lahars there, but greatly diminishing the threat to Angeles City. After the 1991 eruption, the Pasig-Potrero River had few lahars for 2 years, but in 1993 virtually all flow on the eastern half of the volcano was rerouted into it by another secondary explosion. The years 1994 and 1995 were catastrophic ones along this river.

The second drawback to the exponential decay model is that it presumes a fairly constant supply of lahar-triggering rain, and so a pronounced dry spell such as the years from 1996 to 1998, enhanced by a major El Niño episode, temporarily stopped the clock on the decay curve. The model also does not take into consideration the very real possibility of a “50-year” or “100-year” rainstorm, which would certainly produce catastrophic lahars greatly exceeding any “high” estimate of sediment yield based on normal rainfall.

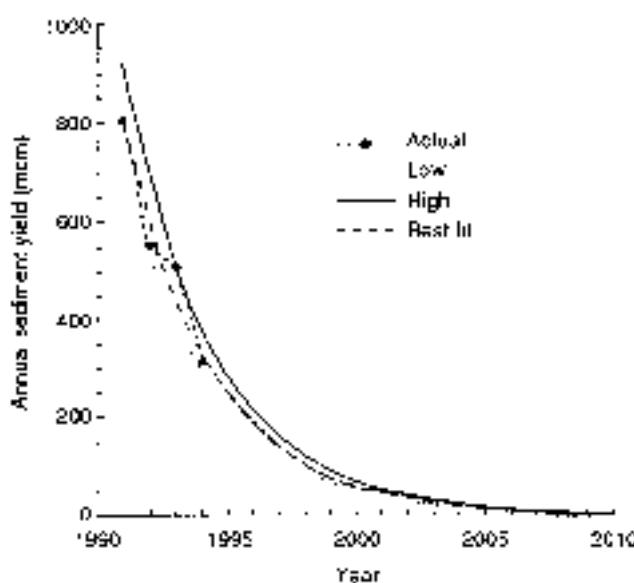

FIGURE 16 Three predictive curves for continuing sediment yield of Pinatubo lahars, based on the data of Table II. [Modified from Umbal, J. V. (1997). Five years of lahars at Pinatubo volcano: Declining but still potentially lethal hazards. *J. Geol. Soc. Philippines* 52, 1–19.]

Perhaps the most serious drawback is that the model does not take into consideration the fact that lahar deposits can be remobilized in large volumes. In 1994, a large breakout from a lahar-dammed lake sent floods down the Pasig-Potrero River, carving a prominent new channel by remobilizing much sediment that had been deposited since 1991 (Figure 17). The resulting lahars inundated the municipality of Bacolor in lahar deposits several meters thick (Figure 18). The following year, water floods from a typhoon followed the new channel, greatly enlarging it, cutting it deeply into centuries-old, hardened lahar deposits left by earlier eruptions. Huge debris flows carrying many boulder-sized pieces of the ancient materials buried the previously untouched Bacolor village of Cabalantian (Figures 5 and 19). In short, none of the hundreds of millions of cubic meters of lahar deposited on Bacolor in 1994 and 1995 came from the fresh debris perched on the volcano. Scientists continue to grapple with the problem of properly estimating how much fresh and ancient material will be remobilized before lahars finally stop flowing.

## VI. MITIGATING THE LAHAR HAZARD

### A. Recognizing Old Lahar Deposits

The first step in minimizing death and damage by lahars is to recognize the danger and its extent. Eruptions and lahars can occur at intervals of thousands of years, and so any inhabited area within the possible reach of lahars needs to be examined closely for evidence of past flows. Debris flow deposits consist of very poorly sorted rock fragments that range in size from clay to boulders. They are difficult to distinguish from the deposits of pyroclastic flows, but tend to have a wider range of the coarser sizes. Larger fragments in the deposits of both pyroclastic flows and hot lahars, unlike those of cold lahars, may share a common magnetic alignment adopted when they cooled down enough to regain their magnetism.

Layers left by debris flows characteristically are chaotically mixed, but their bases may be finer grained than the middle and upper portions, in which boulders may be found. More dilute lahars leave layers that are finer-grained and crudely bedded. Commonly, finer material in small vertical zones in lahar deposits show where water escaped upward after deposition.

Inasmuch as lahars were not well recognized and understood before the 20th century, many areas have only recently been discovered to be lahar terrain. The area

FIGURE 17 House in Porac town, buried by lahars in 1991, exhumed and exposed in the wall of a new canyon that was incised when these deposits, as well as pre-eruption materials, were remobilized by the lahars of 1994 and 1995 that buried Bacolor and Barangay Cabalantian.

FIGURE 18 Aerial view of the town of Bacolor after the disastrous lahars of 1994 and 1995. Note the large San Guillermo Church in the center of the picture. Its basal portion was buried to a depth of 6.5 m (21 ft.).

**FIGURE 19** Debris flows in Cabalantian village after the 1995 disaster. The high-tension cable touching the ground is a measure of the thickness of the deposits, which was 9 m in some places. The boulders are coherent pieces of lahar deposits from ancient eruptions and illustrate that an unknown but substantial percentage of the later Pinatubo lahars are derived not only from debris of the 1991 eruption, but from older material as well.

around Mount Rainier in the northwestern United States has received enormous prehistoric lahars (Figure 20). A single series of flows called the Osceola Mudflow occurred 5700 years ago when a huge portion of the northwestern sector of the volcano collapsed. Incorporating glacial ice and stream waters of the White, Green, and Puyallup rivers, the debris became lahars that traveled 100 km and covered more than 500 km<sup>2</sup>.

Hundreds of thousands of people live in five towns built on the Osceola deposits. Even larger prehistoric lahars spread their debris farther away from Mount Rainier, over the areas where millions of Seattle and Tacoma citizens now live. If such an event occurring today were to flow at typical lahar speeds, it could reach Tacoma in only an hour. Given the enormous financial investment that the communities in this area represent, and the fact that the most recent of the large lahar events took place millennia ago, it simply is not feasible for the towns and cities to be evacuated and resettled elsewhere. Little can be done to mitigate such a disaster, other than closely monitoring the volcano and local seismicity, familiarizing the threatened populaces with the hazard, and encouraging individual families and neighborhoods to make contingency plans.

### B. Delineating Lahar Paths

Lahars flow in obedience to gravity, and so any drainage channel on a volcano can funnel lahars downslope, given the necessary water and debris ingredients. Using topographic maps, it is a fairly simple matter to trace the avenues that lahars may follow. If lahars have occurred several times in the past along a channel, they will have left a conical fan of deposits spreading outward from an apex at the valley mouth.

On volcanoes that have a continuing lahar threat, such as those that experience seasonal rain lahars, active lahar channels need to be mapped in microtopographic detail between events. This is because each lahar modifies its conduit and the topography of its depositional area, thereby helping to determine the path the next lahar will take.

### C. Monitoring

At volcanoes where lahars have been triggered only during eruptions, monitoring for lahars is inseparable

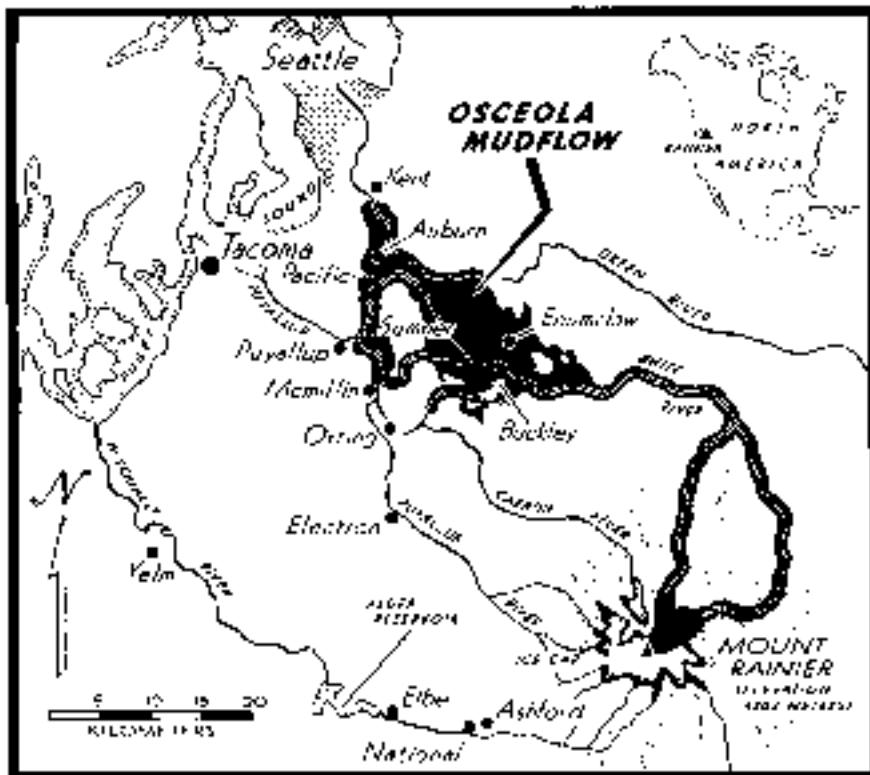

FIGURE 20 Areas north and west of Mount Rainier, including the sites of the cities of Seattle and Tacoma, are underlain by the deposits of enormous prehistoric lahars. [From Fisher et al., 1997, p. 131, reprinted by permission of Princeton University Press.]

from that for eruption, using standard seismographic, ground-tilt, and other equipment. At a volcano that experiences recurring rain lahars, the regional weather must be watched closely as it develops. Evolving storms can be tracked using satellite imagery for days or even weeks before their arrival. When rain actually begins to fall, its intensity and duration can be monitored in real time with unmanned, telemetered rain gauges on the volcano, and if the combinations of intensities and durations that trigger lahars are known for a particular site, warnings of imminent danger can be issued when these thresholds are approached. Observers can be stationed as high as possible along known lahar channels to warn the communities below when lahars actually start to flow. At Gunung Kelut, alarms are given by striking tong-tong, large wooden drums. Bells, flares, and cannons can also be used, but none of these are of much use in the noise of a howling gale or heavy downpour. Two-way radios are inexpensive and have been successfully used to transmit lahar warnings at Pinatubo.

In Japan, wires are stretched across lahar channels high up volcanoes to trigger warning devices when broken by lahars. To avoid false alarms from animals or

falling trees, the devices are designed to be activated only after several wires are broken in the proper downstream succession. At Pinatubo, volcanologists from Mount St. Helens have developed and installed seismic equipment that detects and transmits the low-frequency vibrations of lahars shaking the ground. These work well, but, as can be expected in an impoverished area, the unmanned rain gauges and flow sensors at Pinatubo have been decimated by theft. In developing countries, manned observation stations may be cheaper and more effective.

#### D. Structural Measures

Engineering technology to contain debris flows in non-volcanic terrain has been adapted with varying degrees of success to trap or divert lahars. Not surprisingly, Japanese engineers have been at the forefront of such efforts, their country being both volcanic and technologically advanced. Check dams across lahar channels, called "sabo," are meant to trap lahar sediment. Their use, singly or in series, is feasible only if lahar volumes

are not too great. They may actually make a single catastrophic event out of a succession of small flows when they are filled and breached. "Training dikes" and deflection dams have been built at Kelut, Pinatubo, and elsewhere to divert lahars away from towns and cities. Such an approach is more appropriate for water floods, which eventually subside, leaving only a minor amount of silt in their wakes. A single debris flow can leave meters of impounded sediment, thereby transforming a dike into a dam that is subjected not only to the pressure of the accumulated sediment, but to undermining seepage driven gravitationally through and under the dike by the difference in elevation across it. To maintain its efficacy, and prevent it from becoming a man-made hazard, any such structure needs to be cleaned out whenever it has acquired substantial fill. Such cleaning may not be feasible in areas that receive lahar sediment very rapidly.

Like any major engineering undertaking, a structure meant to deflect and contain lahars must be designed with careful attention to the strength and behavior of lahars, and to topographic factors such as channel slope and width, and abutment height. The rock types and joints or other structures within the abutment and foundation need to be known. Dimensional elements of the structure, such as crestal thickness, gradients of front and back slopes, wing slopes and penetration, and footing depths, need to be appropriate to withstand the powers of debris flows. The rock used to fill the structure must be of high density to withstand the high density of lahars and the resulting buoyant forces they exert, and its porosity and permeability must be too low to allow damage by seepage and piping.

Theoretically, artificially widening a channel might retard a debris flow by decreasing its depth, thereby stranding large boulders and increasing basal friction to decrease flow velocity. The feasibility of such a measure depends on the rates with which the debris descends and can be removed. At the Pasig-Potrero channel of Mount Pinatubo, the work of removing a thousand truckloads of lahar deposits every day for 3 months can be undone by 1 hour of lahar flow.

## E. Temporary Refuges

People anywhere in the world are loath to abandon their homes in any circumstance, and this is especially true for rural areas in developing countries. Coupled with warning systems that give at least a half to 1 hour of warning, the construction of temporary refuges on high

ground, and easy access paths to them, is one of the simplest and least expensive ways to save lives from lahars. At some Indonesian volcanoes where lahars are fairly common events, high ground is too distant from some villages, and so artificial hillocks are built. The hillocks have flat tops that can be used as marketplaces and soccer fields. Such artificial havens should have bases deep and strong enough to withstand the lateral scour of lahars. If the area experiences protracted rains, and if fresh lahar deposits may isolate the hill for some time, it should have shelters to prevent illness and death due to prolonged exposure.

---

## GLOSSARY

**aerosol** A colloidal dispersion of liquid particles in a gas, for example, SO<sub>2</sub>, which will react with the OH radical in the atmosphere to form tiny droplets of sulfuric acid (H<sub>2</sub>SO<sub>4</sub>).

**COSPEC** An ultraviolet correlation spectrometer used to detect the concentration and emission rate of SO<sub>2</sub> from degassing volcanoes.

$\delta_{\text{gas}}$  The vapor density of a gas relative to air (density = 1), measured in g/liter.

**gas solubility** The maximum amount of a gas which can be dissolved in a given amount of water at 20°C. Measured in g/liter.

**Giggenbach bottle** An evacuated alkaline-solution-filled bottle (e.g., sodium hydroxide, NaOH) generally connected to a titanium or silica tube which is inserted into a fumarole. The gases bubble through the solution, condense, and are absorbed by the solution, which can then be analyzed.

**hazard** In a volcanic context, hazard refers to the phenom-

ena produced by an eruption and is directly related to risk, where  $(\text{risk}) = (\text{hazard}) \times (\text{vulnerability})$ , with vulnerability referring to the consequences for population and infrastructure.

**PEL** The recommended permissible exposure limit to a given chemical compound above which health risks may occur. The exposure limit is generally averaged over an 8-hour day, 40-hour week. It is measured in parts of compound (e.g., CO<sub>2</sub>) per million parts of air (ppm).

**GASES ARE THE** invisible yet often continuous products of volcanic activity. Even volcanoes in a state of quiescence, not actually erupting lava or showing signs of unrest through seismic activity, are able to degas continuously. Eruptions can produce lethal quantities of toxic gases, but long-term exposure to a lower dose also can pose a significant hazard. Although volcanic gases are only directly responsible for ~3% of volcano-related deaths (1900–1986), they are nevertheless hazardous and responsible for deaths every year, including volcanologists such as Werner Giggenbach. They have an important effect on the regional and global environment and may contribute greenhouse gases to the atmosphere. Indirectly, through the destruction of crops, volcanic gas emissions have resulted in starvation and disease (40% of volcano-related deaths between 1600 and 1982).

The composition of volcanic gases depends on the type of volcano and its eruptive state. However, the most common volcanic gases in order of abundance are water ( $H_2O$ , 30–90 mol%), carbon dioxide ( $CO_2$ , 5–40 mol%), sulfur dioxide ( $SO_2$ , 5–50 mol%), hydrogen ( $H_2$ , <2mol%), hydrogen sulfide ( $H_2S$ , <2mol%), and carbon monoxide ( $CO$ , <0.5mol%). Some of these, when emitted from active vents (Figure 1), react in the atmosphere or volcanic plume to form aerosols, the most important being hydrochloric acid (HCl), hydrofluoric acid (HF), and sulfuric acid ( $H_2SO_4$ ).

### I. TOXICITY OF VOLCANIC GAS SPECIES

It is difficult to determine accurately the contribution of gases to volcano-related deaths since much of the data reflect deaths during eruptive periods, whereas the majority of gas-related deaths have occurred during noneruptive periods. The long-term health effects of volcanic gases are poorly understood; they may be responsible for or accelerate epidemic diseases because of their irritant and depressing effects, which reduce the resistance of ocular, respiratory, and digestive systems to microbial attack. From a health perspective, the most important volcanic gases and aerosols are  $CO_2$ ,  $SO_2$ , Rn,  $H_2S$ , HCl, HF, and  $H_2SO_4$  (Table I). Exposure to these has been the cause of the majority of volcanic-gas-related fatalities.

FIGURE 1 Degassing vent at Santiago crater at Masaya volcano, Nicaragua.

### II. HAZARDS TO THE POPULATION AND ENVIRONMENT: CASE STUDIES

The relative degree of hazard from volcanic gases is also dependent upon the type of gas emitted. Some gases are poisonous while others are dangerous only if present in such high concentrations that they block oxygen respiration. The dispersion of a given gas species is also directly related to the hazard. Ejection of gases at high elevations (e.g., Mount Etna) will have less direct impact on population than low-level gas plumes (e.g., Masaya). Relatively short-lived eruptions may eject significant amounts of gases into the stratosphere with short-term global consequences. Persistently active volcanoes, however, degas continuously and may present a long-term hazard. In some instances, even dormant volcanoes can pose a threat to human health and the local environment.

#### A. $CO_2$ Hazards

The most lethal  $CO_2$ -related events have been those in which  $CO_2$ , which is colorless, odorless, and denser than air, flowed downhill as a density current, collecting in low-lying areas and asphyxiating all life in its path. The first recorded incident of this occurred in the Dieng Volcanic Complex (or Dieng Plateau), Indonesia, a complex of volcanic centers forming a large depression approximately 14 km long and 6 km wide. On the morning of February 20, 1979, the inhabitants of the village of Batur felt three seismic shocks at 2:00 A.M., 3:30 A.M., and 4:00 A.M., and then observed a phreatic eruption at 5:15 A.M. which ejected a dark gray cloud from the Sinila crater (a small water-filled vent, 3 km northeast of the village). This eruption, which formed a 90-m wide and 100-m deep crater, was accompanied by the ejection of blocks, mud, steam, and gas, and by a hot lahar that flowed 3.5 km downslope. At 6:45 A.M., a second minor eruption occurred 300 m west of Sinila that resulted in the formation of a new crater, Sigludung. Many of the villagers from Koputjukan fled west toward Batur and were killed by a gravity current of gas (probably  $CO_2$  and  $H_2S$ ) which was emitted from multiple small vents and fissures to the south and west of the two craters. Others, having witnessed the deaths along the Koputjukan–Batur road, retreated to a nearby elementary school where they were also killed. In total, the gas killed at least 149 people and injured over 1000 people.

The crater lakes of Monoun and Nyos, located along the Cameroon Volcanic Line, a great fracture consisting

of a chain of alkalic volcanoes, are the only two recorded examples of rapid free-CO<sub>2</sub> release from lakes. The CO<sub>2</sub> is believed to have originated from cold springs degassing below the lakes, which being thermally stratified, allowed for the gas accumulation. Although still controversial, it is generally believed that these two events may have been triggered by landslides which caused the deep gas-rich layer to rise to a point in the lakes where the hydrostatic pressure was insufficient to keep the CO<sub>2</sub> in solution. Being denser than air, the CO<sub>2</sub> gas which was released formed a large density current that flowed over the crater rim and downslope.

On August 15, 1984, at approximately 11:30 P.M. local time, a lethal cloud of CO<sub>2</sub> burst from the crater in Lake Monoun and flowed down the valley several hundred meters where it settled along the Panke River depression. The emission was heralded by an explosion heard by the people in Njindoun village (1 km north of the lake), and by seismic shocks felt 6 km to the north in the village of Mbakouop. At approximately 3 A.M., the majority of the victims (39 in total) had left the village of Njindoun and were heading south toward the Foumbot market. The location of the bodies indicated that the victims encountered and succumbed to the dense gas cloud near the bridges over the Panke River. When police arrived at the scene (~6:30 A.M.), a whitish smoky cloud still covered the area, drifting with the wind off Lake Monoun. They were only able to enter the area when the cloud was finally dissipated at approximately 10:30 A.M.. It was then that they noted that the bodies of the victims were covered with reddish first-degree burns and blisters and that mucus and blood had frothed from their noses and mouths. The surrounding vegetation was bleached yellowish and withered, yet the victims' clothes were unaffected. The carcasses of domestic and wild animals were also found nearby.

Between 9 and 10 P.M. (local time) on August 21, 1986, almost 2 years after the Lake Monoun event, a cloud of concentrated CO<sub>2</sub> was emitted from the lowest point of the Nyos crater lake and spread into the surrounding valleys, affecting an area approximately 20 km long and 15 km wide. The gas emission appears to have been preceded by the rise of a gas column at 4 P.M. and a weak explosion at 8 P.M., and then by two or three violent explosions between 9 and 10 P.M. No seismic events were recorded. There was little or no damage to vegetation or housing although taller vegetation was flattened in some areas between the lake and Lower Nyos. As with the Lake Monoun event, the carcasses of many domestic and wild animals were found in the affected area (Figure 2). The exact number of casualties is unknown, but according to government sources, at

least 1700 people died while approximately 5000 people in the affected area escaped exposure or survived its effects.

Another type of CO<sub>2</sub>-related hazard is that seen at Mammoth Mountain, California, a large dacitic volcano located on the southwestern rim of the 760,000-year-old Long Valley caldera. Beginning in 1990, extremely high levels of CO<sub>2</sub> soil degassing (20–90% CO<sub>2</sub>) on the flanks of Mammoth Mountain have resulted in tree kill areas which cover >500,000 m<sup>2</sup>. The CO<sub>2</sub>, which probably kills the trees during the winter by inhibition of root function and oxygen deprivation, most likely originates from the degassing of an intruded magma and gas release from magmatically heated carbonate metasedimentary rocks beneath the caldera. The CO<sub>2</sub> flux from Mammoth Mountain was estimated at 1200 metric tonnes/day (t/d) in 1995 and 500 (t/d) in 1998, occurring principally in the tree kill areas. This diffuse degassing may also be producing catastrophic acidification of the soil and mobilization of toxic Al<sup>3+</sup> into local aquatic ecosystems.

Although CO<sub>2</sub> generally dissipates when it leaves the ground, its relatively high density causes it to collect in hollows, wells, and confined places where it creates a serious asphyxia hazard. During the winter months, the relatively impermeable snow prevents CO<sub>2</sub> from escaping, dramatically increasing the hazard; a number of cases of near-asphyxia were reported by people entering small snow-covered cabins.

Global CO<sub>2</sub> emission from subaerial volcanoes has been calculated, using CO<sub>2</sub>/SO<sub>2</sub> ratios and SO<sub>2</sub> flux estimates, to be approximately 6500 metric kilotonnes of CO<sub>2</sub> per year, with over half of that coming from passively degassing volcanoes. Although only 0.2% of anthropogenic emissions, volcanoes nevertheless contribute large amounts of CO<sub>2</sub> to the atmosphere. In earlier geologic times, catastrophic volcanic events such as the eruption of the Deccan Traps may have added significant amounts of CO<sub>2</sub> to the atmosphere and therefore may be partially responsible for increased global warming.

## B. SO<sub>2</sub> Hazards

When sulfur dioxide is released to the atmosphere, it oxidizes with the OH radical in air to form sulfurous acid (SO<sub>3</sub>), which then reacts with water to produce sulfuric acid particles. At Masaya volcano, a basaltic complex of nested calderas and craters located in northwestern Nicaragua, the long-term degassing activity from the currently active crater, Santiago, has had a significant impact on the surrounding vegetation; high

TABLE I Toxicology of Volcanic Gases and Aerosols

		<b>Carbon dioxide (CO<sub>2</sub>)</b>
Characteristics		Colorless, odorless gas. Irritation of eyes, nose, and throat only at high concentrations. Vapor density relative to air ( $\delta_{\text{gas}}$ ) = 1.52 g/liter. Gas solubility in water at 20°C = 0.04 g/liter. Permissible exposure limit (PEL) averaged over 8 hours = 5000 ppm in air; 9000 mg/m <sup>3</sup> of air.
Effects of overexposure		
Short-term		A simple asphyxiant, symptoms appear only when such high concentrations are reached that there is insufficient oxygen to support life. Inhalation may cause rapid breathing, increased heart rate (at >7.5%), headaches, sweating, dizziness, shortness of breath, muscular weakness, mental depression, drowsiness, and ringing in the ears. Concentrations at >11% result in unconsciousness in a minute or less. Convulsions may occur at concentrations of >25%. Rapid recovery occurs on removal from exposure.
Long-term		Prolonged exposure to concentrations of >10% may result in unconsciousness.
		<b>Sulfur dioxide (SO<sub>2</sub>)</b>
Characteristics		Colorless gas or liquid (<-10°C) with characteristic pungent odor. Perceptible odor at 0.3–1.0 ppm and easily noticeable at 3 ppm. $\delta_{\text{gas}} = 2.26$ g/liter. Gas solubility = 10 g/liter. PEL = 5 ppm in air; 13 mg/m <sup>3</sup> of air.
Effects of overexposure		
Short-term		Inflammation and irritation of the eyes and respiratory tract resulting in burning of the eyes, coughing, and difficulty in breathing. Approximately 90% of inhaled SO <sub>2</sub> is absorbed in the upper respiratory tract where it forms sulfurous acid, which then oxidizes to form sulfuric acid. Concentrations of 6–12 ppm cause immediate irritation of nose and throat. Exposure to >20 ppm causes irritation of the eyes, while concentrations of 10,000 ppm irritate moist skin within minutes.
Long-term		Prolonged exposure to low concentrations may be dangerous for persons with preexisting cardiopulmonary diseases.
		<b>Hydrogen sulfide (H<sub>2</sub>S)</b>
Characteristics		Colorless, flammable gas with offensive odor (rotten eggs). Characteristic odor perceptible at 0.77 ppm and easily noticeable at 4.6 ppm. $\delta_{\text{gas}} = 1.19$ g/liter. Gas solubility = 2.9 g/liter. PEL (averaged over 10 min) = 20 ppm in air; 28 mg/m <sup>3</sup> of air.
Effects of overexposure		
Short-term		Inhalation of 20–150 ppm may cause eye irritation while slightly higher concentrations cause irritation of upper respiratory tract. In low concentrations, exposure may result in headache, fatigue, dizziness, excitement, staggering gait, and diarrhea, followed sometimes by bronchitis and bronchopneumonia. In small amounts the gas acts as a depressant, and is a stimulant in larger amounts. Very large amounts result in paralysis of the respiratory center and death; exposure to 1000–2000 ppm may cause coma after a single breath.
Long-term		Prolonged exposure to concentrations as low as 50 ppm may cause pharyngitis and bronchitis while concentrations > 250 ppm may result in pulmonary edema.
		<b>Radon (Rn)</b>
Characteristics		Colorless, odorless, tasteless, radioactive gas, formed from the radioactive decay of uranium. $\delta_{\text{gas}} = 9.73$ g/liter. Gas solubility = 51 g/liter. PEL = 200 Bq/m <sup>3</sup> .
Effects of overexposure		
Short-term		There is no information on the acute noncancer effects of radionuclides in humans; however, animal studies have reported inflammation in the nasal passages and kidney damage from acute inhalation exposure to uranium.
Long-term		Chronic exposure by inhalation has been linked to respiratory disorders, such as lung disease and lung cancer, in humans. Smokers exposed to radon are at ~10–20 times greater risk for lung cancer than nonsmokers.

*continues*

*Continued*

---

		<b>Hydrochloric acid (HCl)</b>
Characteristics		Colorless gas or colorless fuming liquid with an irritating pungent odor. Detectable odor by most people between 1 and 5 ppm. $\delta_{\text{gas}} = 1.27 \text{ g/liter}$ . Gas solubility = 62 g/liter. PEL = 5 ppm in air; 7 mg/m <sup>3</sup> of air.
Effects of overexposure		
Short-term		Irritation of the mucus membranes of the eyes and respiratory tract with burning, choking, and coughing. At concentrations > 35 ppm, there is irritation of the throat after only short exposure. Severe breathing difficulties may occur along with skin inflammation or burns. Concentrations > 100 ppm will result in pulmonary edema, and often laryngeal spasm.
Long-term		Repeated or prolonged exposure may lead to erosion of the teeth and skin rash.
		<b>Hydrofluoric acid (HF)</b>
Characteristics		Clear, colorless, fuming corrosive liquid or gas with strong irritating odor. Irritation of nose and eyes at <5 ppm. $\delta_{\text{gas}} = 0.7 \text{ g/liter}$ . Gas solubility = miscible in all proportions. PEL = 3 ppm in air; 2 mg/m <sup>3</sup> of air.
Effects of overexposure		
Short-term		Extreme irritation and corrosion of the skin and mucus membranes. Contact with the eyes will cause deep-seated burns, and if the chemical is not removed immediately, permanent visual impairment or blindness may result. Skin exposure produces severe burns which are slow to heal. Subcutaneous tissues may be affected, becoming blanched and bloodless, which may result in gangrene. A severe irritant to the nose, throat, and lungs, inhalation of the vapor may cause ulcers of the upper respiratory tract; concentrations at 50–250 ppm are dangerous even for brief exposures.
Long-term		Repeated or prolonged exposure to lower concentrations may cause changes in the bones as well as chronic irritation of the nose, throat, and lungs.
		<b>Sulfuric acid (H<sub>2</sub>SO<sub>4</sub>)</b>
Characteristics		Colorless to dark brown, oily, odorless liquid. Irritation of nose and eyes at low concentrations. $\delta_{\text{gas}} = 3.4 \text{ g/liter}$ . Gas solubility = miscible in all proportions. PEL = 20 ppm in air; 1 mg/m <sup>3</sup> of air.
Effects of overexposure		
Short-term		Irritation of eyes, nose, and throat. Severe burns with rapid destruction of tissue and erosion of teeth may occur. Inhalation may also lead to difficulty in breathing and inflammation of upper respiratory tract.
Long-term		Repeated or prolonged exposure to the vapor may cause erosion of the teeth, and chronic irritation of the eyes, nose, throat, and lungs.

---

concentrations of SO<sub>2</sub> disturb stomatal respiration and cause necrosis. Sulfur dioxide fluxes from the crater have been measured at as much as 2500 (t/d) (Figure 3). The presence of this gas, as well HCl and HF, has led to extensive fumigation and destruction of most of the vegetation to the west of the volcano. Concrete and metal fences, telephone wires, and other metal equipment are also severely damaged in the effected areas (Figure 4). Since the 19th century, the significant economic impact from the degassing has led local coffee farmers to even demand the capping or destruction (by aerial bombardment) of the degassing vent; none of these attempts proved successful. Mixing of rain from Hurricane Mitch (late 1998) with the volcanic gas plume produced concentrated acid rain which local farmers blamed for the damage to young palm trees and even the complete destruction of a soya field during a single afternoon.

On June 6, 1912, Novarupta, a dacitic volcano located on the Alaska Peninsula, explosively erupted ~15 km<sup>3</sup> of magma and triggered the collapse of Mount Katmai volcano. The Katmai-Novarupta eruption released substantial amounts of gas which created acid rains that appear to have greatly impacted the local environment. As with Masaya, acid rain was reported to have dissolved metal work of buildings 400 km northeast at Seaward, while polished brass was tarnished 1100 km away at Cape Spencer. A month after the eruption, housewives in Vancouver, Canada (2400 km south), reported that clothes left out to dry had “turned to shreds” upon being ironed.

The conversion of volcanic sulfur dioxide into aerosol particles is often responsible for formation of an acid smog or “vog” (e.g., Kilauea volcano, Hawaii). This acid vog is slowly neutralized by NH<sub>3</sub> in the atmosphere to form a haze which may block solar ultraviolet rays from

FIGURE 2 One of the domestic animals asphyxiated by the dense  $\text{CO}_2$  cloud emitted from Lake Nyos, Cameroon. [Photo by Jack Lockwood.]

reaching the lower atmosphere, which in turn may lead to a global cooling effect (e.g., Mount Pinatubo, Philippines). The volcanic haze may also act as cloud condensation nuclei and perhaps even as sites for the catalytic destruction of ozone, with obvious global implications.

### C. $\text{H}_2\text{S}$ Hazards

Hydrogen sulfide is an extremely toxic gas which has been responsible for numerous fatalities, and in the case of Japan it is believed to be the most common cause of volcanic gas accidents (at least 10 incidents since the early 20th century). This has led many volcano observatories in Japan to install  $\text{H}_2\text{S}$  detectors and automated warning systems.

One such incident occurred in 1971 on the flanks of

FIGURE 3 A continuous gas plume rises from Masaya volcano, Nicaragua. The volcano currently emits approximately 2000 metric tonnes per day of  $\text{SO}_2$ , resulting in considerable damage downwind.

Kusatsu-Shirana volcano, Honshu, when six downhill skiers died almost instantly after passing through a depression filled with  $\text{H}_2\text{S}$ . Being denser than air, the gas may accumulate in snow-covered depressions or caves which are breached from time to time, releasing lethal concentrations to the surface. Another more recent accident occurred on Adatara volcano, Honshu, a basaltic to andesitic volcano which forms part of the volcanic front of northeastern Japan. On September 15, 1997, 4 hikers, from a party of 14, were killed after inhaling volcanic gases on the floor of the Numano-taira crater. The group had become disoriented because of fog and left the trail, which had signs warning of volcanic gas hazards in the area. Three of the hikers fell into the crater where they succumbed to noxious gases that had

FIGURE 4 A metal gate damaged by prolonged exposure to acid gases emanating from Masaya volcano, Nicaragua [photo by Pierre Delmelle].

accumulated on the crater floor due to calm wind conditions. The fourth hiker killed also succumbed to the gases while attempting a rescue. Scientists from the Ku-satsu-Shirane Volcano Observatory reported that the fumarolic gas from the southwest rim of the crater was composed of 0.5% SO<sub>2</sub>, 33–37% CO<sub>2</sub>, and 60–65% H<sub>2</sub>S.

#### D. HCl Hazards

Although there are few cases of hydrochloric acid being solely and directly responsible for volcano-related fatalities, it is nevertheless an important component because of its effects on the environment. HCl is highly soluble in water and is therefore easily removed by rain from a volcanic plume, resulting in low-pH acid rains (e.g., Kilauea, Masaya). Significant amounts of HCl may also have been injected into the stratosphere during the cataclysmic eruption of El Chichon in 1982 with potentially serious environmental implications. In Hawaii, clouds of lava haze or “laze” are formed from the boiling and vaporization of seawater when lava flows enter the sea. These large white laze plumes contain a mixture of HCl (up to 10–15 ppm) and seawater and produce acid rains (pH 1.5–2) which pose a hazard to the local population.

#### E. HF Hazards

Hydrogen fluoride is an aerosol which is indirectly responsible for the most lethal gas-related volcanic event. The Laki fissure, a northeast-trending 27-km-long row of cones and craters, was the source of the Grímsvötn caldera eruption which lasted from June 8, 1783, to May 26, 1785. The second largest historic basaltic fissure eruption since the ~935 A.D. Eldgja eruption, it was preceded by tremors and earthquakes starting on May 15. The eruption involved at least 18–20 km<sup>3</sup> of basaltic magma, of which 15 km<sup>3</sup> was erupted as lava and tephra covering 565 km<sup>2</sup>. Fire fountains are thought to have risen as high as 1400 m and were accompanied by convecting eruption columns which rose to a maximum altitude of 15 km, resulting in an atmospheric loading of 122 MT of SO<sub>2</sub>, ~7.0 MT of HCl, and 15.0 MT of HF over an 8-month period. A low-altitude gas haze caused grasses contaminated by fluorine to be stunted, leading to the loss of over 50% of Iceland’s grazing livestock. This consequently led to the “Haze Famine” which, in combination with various diseases and two severe winters, caused the death of 10,521 people, 22%

of Iceland’s population. The injection of ash, gases, and aerosols into the lower stratosphere also affected parts of western Europe, north Africa, and western Asia, and resulted in cooling of the northern hemisphere by 1–2°C.

A similar hazard, also in Iceland, occurred with the Plinian eruptions of Hekla volcano. HF gas can be adsorbed on tephra and transported hundreds of kilometers from the active vent. Populated areas around the volcano have been heavily impacted due to significant tephra fall, but also by the lethal fluorosis of livestock. As with the Laki fires, grazing livestock were affected after eating fluorine-contaminated grasses, even outside the areas of major tephra deposition.

---

### III. GAS HAZARD MITIGATION

Volcanic gases may be monitored and studied using a variety of techniques ranging from direct sampling of fumaroles (e.g., Giggenbach bottles) to remote sensing techniques (e.g., COSPEC). Ideally, gas monitoring is carried out sufficiently frequently by volcano observatories in order to develop an idea of the baseline or background activity for each volcano. Following the example of those working on industrial-related gas emissions, volcanologists have begun to develop and apply models of gas dispersion and deposition downwind from the

FIGURE 5 Example of a typical gas mask worn by the authors during work in the gas cloud at Masaya volcano.

volcanic source (e.g., Vulcano, Masaya). Based on this information, alert levels and hazard maps can then be developed and used for risk management. However, it is often the case that areas at risk lack the necessary funding and infrastructure to support such studies.

In only a few instances, such as the artificial degassing being carried out at Lake Nyos, is it possible to reduce or eliminate the gas hazard physically. In most cases, monitoring of the volcano and limitation of access by the public to affected areas are the only means of reducing the risk. On an immediate level, the impact of volcanic gases can be reduced by limiting exposure time, not overexerting oneself, and resting frequently. One should try to keep to the windward side of the gas source and wear full or half-face gas masks (respirators) with appropriate absorbers/filters (Figure 5). In the case where masks are unavailable, a wet cloth held over the face can greatly reduce the amount of water-soluble gases entering the lungs.

In some cases, evacuation is necessary, but for extended long-term activity such as at Masaya volcano, it is clearly not feasible. Education of the population at risk is therefore critical, and some excellent public information is now available on video. Produced by the International Association of Volcanology and Chemistry of the Earth's Interior (IAVCEI), "Understanding Volcanic Hazards" and "Reducing Volcanic Hazards" are available in Spanish or English from Northwest Interpretative Association, 3029 Spirit Lake Highway, Castle Rock, WA 9861360-27402101, USA.

#### IV. SUMMARY

Volcanic gases, although a relatively minor hazard in comparison with other volcanic phenomena, can have an important long-term impact on people and the environment. Gases and resulting acid rains may sometimes be detected over 1000 km from the volcanic source, but are generally directly responsible for relatively few deaths. Their effects on buildings are rarely totally destructive except in the case of long-term exposure (e.g., Masaya). Sulfur dioxide emissions from the 1783 Laki fires were responsible in part for global temperature

decreases while CO<sub>2</sub> from subaerial volcanoes may contribute to global warming. Although some attempts have been made to physically reduce gas hazards (e.g., artificial degassing), gas monitoring and education of the public are likely the most effective means of reducing the hazard from volcanic gases.

## GLOSSARY

**bore** A high wall-like wave of water caused by the meeting of two bodies of water. Displacement of water by volcanic processes can produce bores, although they are more usually generated by tidal action in narrow channels.

**hydromagmatic** Hydromagmatic eruptions involve interactions between magma and water, and can result in the production and explosive expansion of steam. Hydromagmatic eruptions in oceans and lakes often produce tsunamis.

**impulse wave** A wave generated by energy and momentum transfer from a rapidly moving debris avalanche, lahar, or pyroclastic flow to water.

**run up** The maximum vertical height which a wave attains as it floods the shore. The run-up height may be somewhat greater than the actual height of the wave as it is affected by both the potential energy (height) and the kinetic energy (velocity) of the shoaling tsunami wave. Run-up heights may also be increased if wave energy is focused or channeled at the shore.

**seiche** An oscillating wave in an enclosed or semienclosed basin (i.e., a lake, bay, or harbor) with a period of minutes to hours. Seiches in volcanic areas are typically initiated by earthquakes and may continue for some time after the triggering event.

**tsunami** Japanese term which can be directly translated as "long wave in a harbor." The term was originally applied to seismic sea waves, but its usage has been expanded to include waves of volcanic origin generated in the ocean or in lakes.

**volcanic explosivity index (VEI)** A measure of the magnitude and energy of volcanic eruptions based on several basic parameters, including eruption duration and style, volume of eruptive products, and the eruption column height.

**A** VOLCANIC TSUNAMI is a high wave or surge of water produced by a variety of eruptive and noneruptive processes at volcanoes. Tsunami waves are generated when some of the tremendous amounts of energy produced during volcanic eruptions are transferred to ocean water or nearby large lakes. At least nine different mechanisms have been documented by which volcanoes produce tsunamis, including volcanic earthquakes, eruptions of undersea volcanoes, travel of pyroclastic flows into the sea, caldera collapse, debris avalanches and landslides, large lahars entering the sea, phreatomagmatic explosions, coupling between water

and turbulent air waves traveling from an explosive eruption, and collapse of lava benches during effusive lava eruptions.

Volcanic tsunamis can transmit the energy of volcanic eruptions to great distances from the volcano, producing much more devastation than would occur from the direct effects of the volcanic eruption alone. Volcanic tsunami waves are comparable in height to those produced by the largest known earthquakes, and waves 1–30 m high have inundated low-lying coastal areas at distances of tens or even hundreds of kilometers from source volcanoes. Most volcanic tsunami waves have been produced by extremely energetic explosive volcanic eruptions in or near water, or by flow of voluminous pyroclastic flows or debris avalanches into the sea. The most devastating volcanic tsunami known was produced by the eruption of Krakatoa in 1883, which resulted in more than 36,000 casualties, some at distances of up to 800 km from the eruption. The volcanic tsunamis at Krakatoa produced more fatalities than any other historic volcanic eruption. Altogether, about 25% of all fatalities directly attributable to volcanic eruptions during the last 250 years have been caused by tsunamis.

The height of volcanic tsunami waves is strongly influenced by the morphology of the coastline on which they impinge. In some cases, waves can more than double in height where the wave energy is focused and amplified into bays and coves. The velocity of volcanic tsunamis is directly proportional to water depth, reaching typical speeds of between 10–100 km/hour in shallow, coastal areas, and up to 800 km/hour when crossing deeper waters.

## I. INTRODUCTION

Tsunamis (also called tidal waves) are sometimes thought to be produced only by large seismic events. However, about 5% of all historic tsunamis, including some of the most destructive tsunami waves ever seen on Earth, were produced at volcanoes by eruptions or other volcanic processes. More than 90 tsunamis of volcanic origin have been produced in the world's oceans during the last 250 years. Destructive waves have also been produced by eruptions which occurred within caldera lakes and other lakes, or at volcanoes adjacent to lakes.

Numerous mechanisms exist by which volcanoes can generate tsunamis. In general, volcanic tsunamis are

produced when part of the tremendous energy released during volcanic eruptions is directly or indirectly transmitted to the sea. One of the simplest mechanisms involves the generation of impulse waves by the displacement of water when debris avalanches and pyroclastic flows enter the sea or a lake and rapidly displace huge volumes of seawater. Water is also displaced and waves generated during explosive eruptions which occur in underwater environments, as may occur during eruption of undersea volcanoes, eruptions through crater lakes, and phreatomagmatic eruptions from shallowly submerged, near-shore vents. Processes which can transfer volcanic energy to water, including volcanic earthquakes and wave coupling with explosive atmospheric waves, have occasionally produced tsunamis during large eruptions. More rarely, small tsunamis have been produced when large lahars enter the sea, or when avalanches of recent tephra or collapse of lava benches displace water.

While relatively rare, volcanic tsunamis are of great concern because they typically occur with little warning and can devastate populated coastal areas at considerable distances from the volcano. Some of the most significant volcanic disasters in human history were caused by volcanic tsunamis (Table I). Indeed, about a quarter of all volcano-related deaths in historic time are attributable to the direct effects of volcanic tsunamis. Over 36,000 fatalities resulted from volcanic tsunamis produced during the 1883 eruption of Krakatoa alone, marking the single most catastrophic volcanic event in recent history.

Volcanic tsunamis have probably affected the development of human societies around the world. One of the earliest known carvings from archaeological sites in North America illustrates an erupting volcano (Figure 1). This carving, dating to about 500 years ago, was excavated at a paleo-Aleut archaeological site on Kodiak Island in Alaska, and appears to show a volcanic eruption associated with a tsunami wave (Figure 1). This carving is about the same age as an eruption at Augustine volcano on Augustine Island which sent a large debris avalanche into the waters of Cook Inlet. In Europe, a large tsunami is thought to have been produced circa 1628 B.C. by the Bronze Age eruption of Santorini volcano on the Greek island of Thera in the Mediterranean. The explosive eruption destroyed the original volcanic island, buried a thriving Bronze Age Minoan-style city, Akrotiri, and left a partly submerged caldera, perhaps accounting for the origin of the legend of Atlantis. A tsunami as much as 30 m high produced by the eruption is thought to have destroyed coastal areas near the Cretan Bronze Age city of Knosses, contributing to the collapse of

**TABLE I** Characteristics of Selected Volcanic Tsunamis

<i>Location</i>	<i>Age</i>	<i>Volcano type</i>	<i>Cause of tsunami</i>	<i>Wave height</i>	<i>Travel distance</i>	<i>Impact of tsunami</i>
Santorini Mediterranean Sea	1638 B.C. (?)	Island	Explosive eruption, caldera formation Pyroclastic flows into sea	10–50 m <sup>a</sup>	150–500 km ? <sup>a</sup>	Destruction of Minoan civilization on Crete <sup>a</sup>
Unzen, Japan Ariake Sea	1782 A.D.	Coastal	Debris avalanche into sea	10–55 m	20–50 km	More than 10,000 fatalities
Tamboro, Indonesia Java Sea	1815 A.D.	Island	Pyroclastic flows into sea	>10 m	>100 km	More than 10,000 fatalities
Krakatoa, Indonesia Sunda Straits	1838 A.D.	Island	Explosive eruption, caldera formation Pyroclastic flows into sea	5–35 m	800 km	More than 36,000 fatalities
Augustine, Alaska Cook Inlet	1883 A.D.	Island	Debris avalanche into sea	7–9 m	>100 km	Damage to coastal villages, no known fatalities
Ritter Island, New Guinea Bismarck Sea	1888 A.D.	Island	Debris avalanche into sea	4–12 m	450 km	Numerous fatalities
Paluweh Island, Indonesia Java Sea	1928 A.D.	Island	Debris avalanche into sea	5–10 m	>100 km	More than 150 fatalities
Iliwerung, Indonesia Java Sea	1979 A.D.	Coastal	Debris avalanche into sea	9 m	>100 km	More than 500 fatalities
Mt. St. Helens, Washington Spirit Lake	1980 A.D.	Mainland	Debris avalanche into lake	260 m	4 km	No known fatalities
Lake Nyos, Cameroon	1986 A.D.	Mainland	Exhalative emission of CO <sub>2</sub>	25–75 m	5 km <sup>b</sup>	No known fatalities from tsunami
Kick 'em Jenny Caribbean Sea	Numerous	Submarine	Submarine eruptions	1–5 m	1–10 km	No known fatalities
Karymskoye, Kamchatka Karymskoye Lake	1996 A.D.	Caldera lake	Phreatomagmatic eruptions	30 m	5 km <sup>b</sup>	No known fatalities

<sup>a</sup>The size, travel distance, and impact of a tsunami wave from the eruption of Santorini are inferred from the magnitude of the eruption and the elevation of tsunami deposits.

<sup>b</sup>Tsunami waves at Karymskoye caldera caused flooding for many kilometers downstream from the caldera.

the advanced Minoan civilization which dominated the Mediterranean at the time.

## II. EXAMPLES OF DIFFERENT VOLCANIC PROCESSES WHICH CAN PRODUCE TSUNAMIS

### A. Submarine Eruptions (Kick 'em Jenny, Caribbean Sea)

Although there are many more submarine than terrestrial volcanoes, there are very few instances in which tsunamis can be confidently attributed to individual submarine eruptions. The best known and studied examples involve the Kick 'em Jenny submarine volcano in the Caribbean Sea. While not all of the processes by which volcanoes produce tsunamis are well understood, direct observations have clearly linked submarine volcanic eruptions and small tsunamis at Kick 'em Jenny.

The tsunami waves at Kick 'em Jenny submarine volcano are apparently generated by multiple mechanisms. Direct transfer of seismic and explosive energy produced

during hydromagmatic eruptions to the ocean appears to produce most tsunamis. Less frequently, large steam bubbles form above the vent and generate waves either by submarine cavitation and collapse or by rapid ascent to the surface. Also, masses of ocean water can be heated near the vent and rise convectively to the surface, pro-

FIGURE 1 Reproduction of a carving on a circa 500-year-old wooden box excavated from an archaeological site on Kodiak Island, Alaska, showing an erupting volcano and a large wave. This carving is virtually identical in age to a large eruption of Augustine volcano that sent a debris avalanche into the waters of Cook Inlet (see Figure 2). This paleo-Aleut carving is the oldest known illustration of a volcanic eruption and volcanic tsunami in the western hemisphere.

ducing waves. On one occasion a scientific submersible vessel became trapped in a rapidly rising hot water mass, and only narrowly escaped.

In recent years, eruptions of Kick 'em Jenny have occurred approximately every 5–10 years. These eruptions were typically quite small (VEI = 0–1), and eruption columns rarely rose through the water to the atmosphere. Waves as much as several meters high have been produced and constitute a significant and well-known hazard to local shipping and yacht traffic among the Windward Islands of the southeastern Caribbean Sea.

The size of hydromagmatic eruptions at Kick 'em Jenny is limited because the summit of the volcano lies at a depth approximately 150 m below sea level, where hydrostatic pressures inhibit the occurrence of large hydromagmatic explosions. The energy of these explosions may also be minimized because of high water-to-magma ratios during the submarine eruptions. The volcano currently rises about 500 m above the surrounding seafloor and has been increasing in height by ~4 m/year. If Kick 'em Jenny volcano continues to erupt and grow in height, its submarine explosive eruptions are likely to become more energetic as it approaches the ocean surface and hydrostatic pressures decrease, and the local tsunami hazard may increase.

The documentation of submarine eruptions and a concomitant tsunami hazard at Kick 'em Jenny raises questions about the number, distribution, and eruptive style of other submarine volcanoes around the world, as well as the possibility of associated tsunami hazards. The number and distribution of active submarine volcanoes are poorly known, but are probably at least comparable to the total number of terrestrial volcanoes. In the Kurile arc south of Kamchatka, detailed surveys by Russian scientists identified at least 90 fresh-appearing submarine volcanic cones in the sea besides the many island volcanoes rising above the sea. There are likely hundreds of other submarine volcanoes along oceanic arcs, spreading ridges, and hot spots, including Loihi volcano east of Hawaii and vents such as the Surtsey volcanoes along the mid-Atlantic Ridge near Iceland.

Is it possible that an eruption of a submarine volcano may someday result in a major catastrophic event, even though no major historic tsunamis are known to have been produced by submarine volcanoes? The largest known wave from a submarine eruption capsized boats in 1781 off Sakurajima near the island of Kyushu, Japan. Unfortunately, at the present time there is no reliable way to predict the location or likelihood of such events, and no submarine volcano is continuously monitored by a volcano observatory.

## B. Tsunamis Produced by Eruptions through Lakes (1996 Eruption of Akademia Nauk Caldera, Kamchatka)

As originally defined, the Japanese term “tsunami” applied only to great waves produced in the ocean. However, eruptions can also produce high waves in lakes, and these are now also referred to as volcanic tsunamis. Volcanic eruptions often occur through large caldera lakes, and occasionally eruptions are initiated through preexisting nonvolcanic lakes. Such eruptions may be characterized by violent hydromagmatic explosions, especially where the lake is shallow but large in size. In some cases high tsunami waves have been produced. For instance, during a day-long sequence of hydromagmatic eruptions in January 1996 through the 60-m-deep and 8-km<sup>2</sup>-area Karymskoye Lake in the Akaemia Nauk caldera at the foot of Karymsky volcano in Kamchatka, waves with a maximum height of more than 30 m were generated. These waves stripped vegetation and sediment from beaches and cliffs around the shore of the lake, and also overtopped the lake outlet and flooded down the Kamchatka River for many kilometers. Smaller waves were produced on at least five separate occasions by phreatomagmatic eruptions and base surges during eruptions in 1965 through the Taal Caldera Lake in the Philippines.

An unusual tsunami was produced during the gas eruption at Lake Nyos in Cameroon in 1986. The sudden release of about 3 million m<sup>3</sup> of carbon dioxide from the lake waters produced a wave from 25 to 75 m high.

Occasionally eruptions occur through lakes that have not previously been volcanic vents. In the 1886 Tarawera eruption in New Zealand, a 17-km-long fissure eruption cut across older volcanic vents and adjacent nonvolcanic areas, producing phreatic explosions which enlarged and excavated what is now Lake Rotomahana. The eruption was immediately preceded by a small wave about 30 cm high on nearby Lake Tarawera. This seiche was apparently produced by earthquakes just prior to the main eruption, as Lake Tarawera was not in contact with either the faulting or the fissure eruption.

Although volcanic tsunamis in lake basins are much more restricted in their potential travel distance than those in the ocean, lake basins may be densely populated. Some caldera lakes are surrounded by agricultural developments, population centers, and recreation facilities. If tsunamis of similar size to those at Karymskoye Caldera Lake were produced by eruptions through the Taal Caldera Lake in the Philippines, the Towada and Toya Caldera lakes in Japan, the Taupo or Rotorua calderas in New Zealand, Yellowstone Lake in Yellowstone Cal-

dera, or many other caldera lakes around the world, significant damage and casualties would result.

### C. Landslides and Debris Avalanches (Unzen, Japan, in 1782; Mount St. Helens, Washington, in 1980; and Mount St. Augustine, Alaska, in 1883)

Volcanic debris avalanches generate impulse waves as they enter the sea by displacing huge volumes of water. The precise nature of the interactions and processes which generate waves during giant landslides is not well understood, as they have never been directly observed or measured. Physical models of these processes are also difficult to develop, as little information is available on the multiple factors which can influence the eventual size of waves. These include beach aspect, coastal morphology and water depth, the size and shape of the lake or bay where the avalanche occurs, and the thickness, density, mass, and velocity of the debris avalanche itself. The nature of the interaction between the front of the landslide debris and the propagating wave front in the ocean is also poorly understood. For instance, avalanches which are thicker than the water which they enter must act as a wall sweeping the water before them,

while avalanches which dive into deeper water must displace the water in a much different way. The travel distance of the avalanche mass as it moves into the water, and the magnitude of possible explosive interactions between hot rock debris in the debris avalanche, any associated blast or surge, and the seawater, may also influence the size of the resultant wave.

If the mass of the avalanche is very large relative to the size of the body of water, then masses of water can be totally displaced in a “splash” or surge of water, producing an exceptionally high, although volumetrically small, impulse wave. For instance, during the Mount St. Helens eruption in 1980, one arm of the debris avalanche completely crossed the Spirit Lake basin and produced a wave that reached 260 m up the hills surrounding the lake. The wave swept back downhill across the surface of the debris avalanche, crossed the lake basin, and sloshed up slope toward the volcano, and continued to oscillate for some time in the lake basin.

A similar but smaller well-documented debris avalanche and tsunami occurred in 1883 at Mount St. Augustine in Cook Inlet, southcentral Alaska. The debris avalanche travelled ~5 km into the waters of Cook Inlet on the north side of Augustine Island (Figure 2). Recent computer modeling suggests that the wave generated by the debris avalanche at Augustine volcano was as

**FIGURE 2** The 500-year-old West Island debris avalanche deposit, viewed from the summit of Augustine volcano, buried the former coastline of Augustine Island and traveled 5 km farther into the waters of Cook Inlet. Debris avalanches of this size typically generate tsunami waves that run up to 5–30 m above sea level at distances of 80–100 km.

much as 30 m high when generated at the leading edge of the debris avalanche and attenuated to heights of 7–9 m as the wave traveled toward the Kenai Peninsula and the mainland of Alaska. The computer models are in very good agreement with contemporary records of the tsunami waves. About an hour after the avalanche occurred, several tsunami waves 7–9 m high struck the small, native village of Port Graham at the southwest end of the Kenai Peninsula some 80 km southeast of Augustine Island. The waves inundated houses built along the beach and carried away fishing boats. Cook Inlet has the second largest tidal range of any inlet on Earth, with tidal cycles of 8 m. The debris avalanche and tsunami occurred at dead low tide, minimizing the impact on the small settlements which existed around Cook Inlet at that time. While only a few villages and scattered settlements were present around Cook Inlet in 1883, tens of thousands of people live around the shores of Cook Inlet today.

Geologic studies at Augustine volcano indicate the 1883 debris avalanche was just the latest of at least 12 debris avalanches which have occurred during the last 2000 years. This unusual pattern of activity in part reflects a very high and sustained eruption rate of 2–3 km<sup>3</sup> per thousand years. The pattern of frequent eruptions and high eruption rate has continued to the present, as the horseshoe-shaped crater left by the 1883 debris avalanche has been filled in and the volcano summit has regrown to the elevation it had as a result of five subsequent dome-building eruptions. If the volcano continues the same pattern of activity it has exhibited over the last 2000 years it is highly likely to collapse again into Cook Inlet and produce a tsunami wave. Indeed, a scientific prediction has been made that Augustine volcano will probably collapse and generate a tsunami again sometime during the 21st century, making this the only volcano on Earth where a volcanic tsunami is predicted to occur in the near future.

In some cases large rockfall avalanches can occur from volcanic edifices with little or no accompanying eruptive or seismic activity. Catastrophic events which happen without any warning are particularly dangerous to nearby human populations. A rockfall avalanche, possibly triggered by an earthquake, occurred without warning from Mount Maruyama dome on the Shimabara Peninsula in Japan in 1792, about a month after lava eruptions had ended on nearby Unzen volcano. The debris avalanche went through the historic town of Shimabara and traveled several kilometers into the Ariake Sea, generating a tsunami. The wave swept away numerous farmhouses and villages at elevations more than

30 m above the sea and produced an estimated 14,000 casualties.

#### D. Explosive Eruptions (Krakatoa, Indonesia, 1883)

The largest and most devastating volcanic tsunami of the last 250 years was produced by the August 26, 1883, eruption of Krakatoa volcano. This extremely energetic explosive eruption produced multiple tsunami waves as much as 37 m high, among the greatest tsunami waves seen in recent historic time. The waves raised large ships to 10 m above sea level and carried them as far as 3 km inland. These waves deluged more than 250 villages in western Java and eastern Sumatra, killing more than 36,000 people. Fatalities due to waves occurred as far as 800 km from the volcano (Figure 3). Small tsunami waves were recorded throughout the Pacific Ocean, and small sea level oscillations were measured at sites thousands of kilometers away in the Indian Ocean, France, and England.

The precise mechanisms associated with the generation of specific waves during the Krakatoa eruption remain controversial, as at least five different processes may have been involved. Firstly, the magmatic and phreatomagmatic explosions that destroyed the summit edifice were among the greatest volcanic explosions ever documented, being audible up to 4600 km away and recorded on barographs around the world. These energetic explosions may have directly generated waves. Secondly, coupling between the sound waves and the ocean surface may also have generated tsunamis and seiches. The small waves recorded at very remote sites such as England and France almost certainly were formed by coupling between the sea and atmospheric shock waves, while larger waves may have been produced closer to the eruption. Thirdly, after the explosion, several cubic kilometers of seawater from the Sundra Strait rushed into the caldera crater, filling it and perhaps producing a giant bore which propagated away from the crater as a tsunami. Fourthly, debris avalanches were generated during caldera collapse at Krakatoa, and may have produced tsunamis as they were emplaced into the sea around the caldera. And finally, recent field investigations, including submarine fieldwork done by scuba diving, have identified an extensive ignimbrite sheet preserved beneath the sea surrounding the caldera. Rapid emplacement of voluminous, hot pyroclastic flows into the ocean floor radially around the caldera evidently

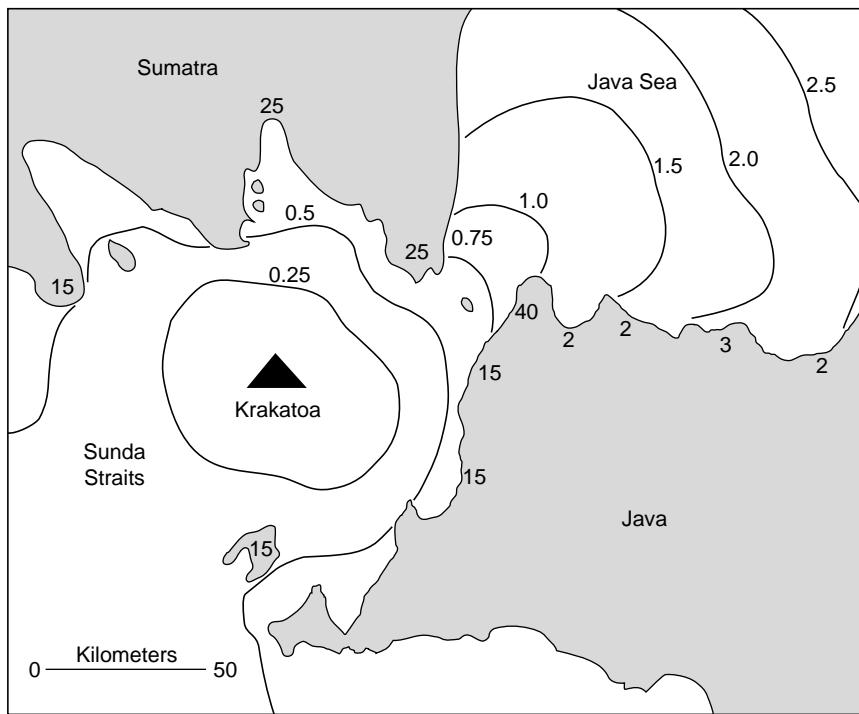

FIGURE 3 Travel times (hours) and wave heights (meters, bold) of the devastating Krakatoa tsunami as it propagated along the coastline away from the volcano. More than 36,000 people were killed by the tsunami wave as it inundated low-lying coastal areas. Note the significant differences in maximum wave height at similar distances from the volcano due to local variations in coastal aspect and morphology and their effect on wave run up.

displaced huge volumes of water and gave rise to tsunami waves.

### III. FUTURE RESEARCH IN VOLCANIC TSUNAMIS AND EVALUATION OF TSUNAMI HAZARDS

Volcanic tsunamis, like many volcanic hazards, occur rarely but can be highly dangerous and destructive. In order to evaluate future tsunami hazards realistically at active volcanoes, it is desirable to learn much more about the frequency and magnitude of past tsunamis. In addition, the behavior of potentially hazardous volcanoes around the world that generate tsunamis, and the processes of tsunami generation, travel, and wave run up, must be better understood.

Information on volcanic tsunamis comes mainly from historic events within the last 250 years, but it is desirable to examine the geologic record for the last several mil-

lennia or longer to learn more about the frequency and magnitude of volcanic tsunami events. Unfortunately, tsunamis typically leave thin and discontinuous geologic deposits which are extremely difficult to find and unambiguously characterize. It can be difficult to find deposits from tsunamis only weeks after their occurrence, and is likely to be much more difficult after centuries or millennia have passed. All evaluations of volcanic tsunami hazard must therefore integrate both investigations of ancient volcanic tsunami deposits and studies of the volcanic eruption history of island volcanoes and volcanoes lying near coastal areas to connect records of volcanic activity with the much more fragmentary geologic record of past tsunamis.

Much more also needs to be learned about the multiple processes that can trigger tsunamis. While it appears that some volcanic processes are more likely to trigger large tsunamis than others (Table II), the actual physics of the interactions between water and all types of volcanic phenomena is poorly understood. Similarly, the behavior of large waves is a complicated mathematical problem. In particular, the amount of run up which can

TABLE II Processes of Volcanic Tsunami Generation

Cause of tsunami	Percentage of total	Location	Tsunami magnitude
1. Volcanic earthquakes	20	I, C, L	S
2. Pyroclastic flows entering water	20	I, C, L	L
3. Submarine eruptions	20	—	S (L?) <sup>a</sup>
4. Debris avalanches (hot and cold)	15	I, C	L
5. Caldera collapse	10	I	L
6. Phreatomagmatic explosive eruptions	5	I, C, L	L
7. Air waves	5	I, C	S (L?) <sup>b</sup>
8. Lahars entering water	5	I, C, L	S
9. Lava flow entering water	<1	I, C, L	S

Notes. Table modified from Latter (1982) and Smith and Shepherd (1993). Location symbols are I, island volcanoes; C, coastal volcanoes; L, caldera lakes or volcanoes near lakes. Tsunami magnitude is S, small (waves > 10 m uncommon); L, large (waves 5–10 m common, may exceed 30 m in large events).

<sup>a</sup> Tsunami waves from historic undersea eruptions have been small, but it is possible that larger waves may be produced in some cases.

<sup>b</sup> Some distant seiches and tsunamis produced in 1883 at Krakatoa have been attributed to air wave coupling with the ocean surface, but it is uncertain if the largest proximal waves were formed in this way. No other large tsunamis can be definitely linked with air waves.

occur at specific locations along a coast is very difficult to estimate, as the height of tsunami waves usually increases as they near the shore in response to shoaling and refraction in bays and along curved coastlines. The wave height at the beach (run-up height) may be 3–10 times greater than wave amplitudes in the open sea.

The processes which trigger volcanic tsunamis are also poorly understood. Volcanic earthquakes are among the most prolific causes of volcanic tsunamis (Table II) but usually generate only relatively small seiches. Volcanoseismic events are predominantly caused by magma movement and its effects on conduits and surrounding rocks within volcanoes. Such processes are very unlikely to result in fault displacements in undersea areas that directly displace water and generate tsunamis. Also, although thousands of volcanic earthquakes typically accompany an eruption, the maximum known volcanoseismic events are circa Richter magnitude 7, and such large events are relatively rare. Earthquakes of this size generally produce tsunamis that have less than a 1-m run-up height, while seismic events of lesser magnitude are associated with even smaller tsunamis, so that seismic events large enough to trigger tsunamis are, fortunately, uncommon.

As discussed above, the potential hazards from submarine volcanoes are extremely poorly understood. During the last 250 years about 20% of all volcanic tsunamis have apparently been produced by eruptions of subma-

rine volcanoes (Table II). Much more work is needed to identify possibly hazardous submarine volcanoes, as well as to learn more about the processes which generate tsunamis during undersea eruptions. The debris avalanche from the Maruyama dome at Unzen in 1792 raises the possibility that some volcanoes can collapse, essentially without warning, and generate destructive tsunamis. The magnitude of such hazards is important to evaluate for several reasons, including: (1) most arc volcanoes around the world are located on islands or near mainland coasts, producing numerous potential debris avalanche sites; (2) active volcanoes tend to grow through time, producing increasingly higher and steeper edifices; (3) polygenetic cones typically consist of interstratified lava and pyroclastic rocks with variable hydraulic and geotechnical properties, and zones of weakness are probably present within most volcanic cones; (4) geothermal activity and high heat flow within volcanoes can alter rock to clay and further facilitate the development of zones of weakness within volcanic cones; and finally (5) most volcanic arcs are strongly affected by great subduction zone earthquakes, so the possibility that incipient debris avalanches can be triggered by giant seismic events without volcano eruptions must be evaluated. The 1792 debris avalanche and tsunami at Maruyama dome near Unzen volcano raises questions about the proclivity to failure and collapse of volcanic edifices and the likelihood of tsunami generation by debris avalanche, even when volcanoes are not in eruption.

Based on the pattern of volcano tsunami generation during recent times, it appears that large, destructive volcano tsunamis with more than 5-m waves are most likely to be generated by eruptions which produce voluminous pyroclastic flows or debris avalanches, or which are highly explosive and produce calderas at the sites of former volcanic islands (Table II). Explosive submarine eruptions or submarine avalanches may also have the potential to produce large tsunamis, although there are no well-documented historic examples of this type of event. Phreatomagmatic eruptions in lakes have also produced high tsunamis, although the potential for damage has been limited by the generally small size of lake basins. The other volcanic processes known to produce tsunamis have, in historic time, shown less ability to generate large, regionally destructive waves, and research is needed to confirm whether these types of volcanic events and eruptions actually present less tsunami hazard.

## GLOSSARY

**A-type earthquake** Events with clear P waves and S waves occurring under volcanoes at depths of 1–10 km [synonyms are volcanotectonic (VT) or high-frequency (HF) earthquake].

**B-type earthquake** Events with weak P waves and no S waves, a low-frequency content, and occurring under volcanoes at depths < 1 km (see also long-period and low-frequency earthquakes).

**explosion earthquake** Events with seismic waves in the ground (including P waves and S waves) and often air waves, which travel through the air and are transmitted back into the ground in the vicinity of the seismometer.

**long-period event** Discrete events with very regular, low-frequency (1–5 Hz) waveforms that resonate for many cycles.

**low-frequency event** General term for discrete events with either enriched low frequencies or deficient high frequencies compared with typical earthquakes (includes long-period and B-type earthquakes).

**magnitude** A measure of the size of an earthquake, determined by measuring the highest-amplitude waves and correcting for distance and type of instrument. The scale is logarithmic, so each increase of one unit corresponds to an amplitude increase of a factor of 10.

**P wave** Primary wave, an elastic wave with primarily compressional or longitudinal particle motion that travels faster than other waves and is thus the first to appear on seismograms.

**S wave** Secondary wave, a shear elastic wave with transverse particle motion, and usually the most prominent wave on a seismogram; travels more slowly than P waves and thus arrives later on seismograms; cannot pass through liquids.

**swarm** A group of many earthquakes of similar size occurring closely clustered in space and time with no dominant main shock.

**volcanic tremor** Continuous seismic signal with regular or irregular sine wave appearance and low frequencies (0.5–5 Hz). Harmonic tremor has a very uniform appearance, whereas spasmodic tremor is pulsating and consists of higher frequencies with a more irregular appearance.

**VOLCANO SEISMOLOGY** IS the study of earthquakes of volcanic origin as well as of velocity structure, attenuation, and other physical properties of earth materials that affect the passage of seismic waves at volcanoes. Volcanic earthquakes may be defined as

earthquakes which occur at or near volcanoes, generally within 10 km, or are related to volcanic processes. Volcanoes are places where heat and mobile fluids are concentrated, so the number of earthquakes per unit time is high compared with normal crust. Volcanic earthquakes take place at shallower depths (1–9 km) than tectonic earthquakes on typical faults (deeper than 15 km in the crust; as deep as 600 km in subduction zones). Volcanic events also differ in their patterns of occurrence: they often occur in swarms, groups of many small events with similar sizes and locations. This is in contrast with the typical mainshock–aftershock sequences on most faults for tectonic earthquakes. Volcanoes produce different types of earthquakes which represent different processes. Among these are high-frequency events, low-frequency events, explosions, and volcanic tremor. These occur in increasing numbers prior to or during eruptions. The seismicity also increases during intrusions—like eruptions, but where the magma fails to reach the surface—and thus the processes that cause various types of volcanic earthquakes are similar even though the eruptive outcomes differ. The source mechanisms of some volcanic earthquakes are not yet understood.

---

## I. INTRODUCTION

Volcanoes are the sources of a great variety of seismic signals which behave differently than events on earthquake faults. Nearly every recorded volcanic eruption has been preceded by an increase in earthquake activity beneath or near the volcano, and accompanied and followed by varying levels of seismicity. For this reason, seismology has become one of the most useful tools for eruption forecasting and monitoring. At the present time, approximately 200 of the world's volcanoes are seismically monitored, although the number and quality of stations at each varies considerably. This represents about one out of three of the 538 volcanoes that have erupted in historic times. Over the last several decades, 55 to 70 individual volcanoes have erupted each year. Because erupting volcanoes draw attention both publicly and scientifically, over half of these are seismically monitored.

This article reviews some of the developments in volcano seismology over the last 25 years that have led to an improved understanding of volcanoes and the volcanic processes that cause earthquakes and other seismicity. The article also describes a number of patterns and

relationships in volcano seismology that form the physical basis of contemporary monitoring and forecasting, although these topics are covered in greater detail elsewhere.

### A. Some Famous Early Eruptions

Throughout history the relation between earthquakes and volcanoes has been close, although there has been confusion about causal relations between the two. This is because of the parallel belts of volcanoes and earthquakes found at subduction zones, where 95% of the Earth's subaerial volcanoes are located. It is common in the historic record, and recently as well, to find an increase in reports of regional earthquakes around the times of eruptions. The reports of the eruption of Vesuvius in 79 A.D. tell of numerous local earthquakes preceding the eruptive activity. People living near Mount Nuovo, Italy, in 1538 and Mount Usu, Japan, in 1663 fled from the areas before the eruptions because of many felt earthquakes. Early observatories at Vesuvius starting in 1856, Usu in 1910, and Hawaii in 1912 recorded different types of earthquakes and began systematic study of eruption precursors. Three weeks of felt earthquakes heralded the formation of the new volcano Paricutin in Mexico in 1943. These and many other examples illustrate that volcanoes are active seismic features.

### B. Brief Review of Earthquake Seismology

In order to appreciate the unique features of earthquakes at volcanoes, it is first necessary to review some features of typical earthquakes. Most earthquakes, which volcanologists often refer to as "tectonic earthquakes" to distinguish them from the volcanic varieties, are caused by shear fracture. That is, rock masses on either side of a planar fracture slip past each other in a shearing motion, generating heat, deformation, and elastic waves. It may surprise most readers to learn that only about 1% of the energy of an earthquake is in the form of elastic waves, which is the part that is felt or recorded by instruments as ground shaking. Most of the energy is liberated as heat and deformation. While rock is fractured at all scales, in many places fractures are organized into large planar features known as faults. Faults can be the sites of large earthquakes, those that involve a large surface area of the fault, as well as many smaller ones that rupture only a small surface area. In general there are many more small earthquakes than large ones; in fact the

distribution of earthquake numbers versus magnitude follows a power law, known to seismologists as the frequency–magnitude distribution. The slope of the relation,

$$\log_{10} N = a - bM,$$

where  $N$  is cumulative number and  $M$  is magnitude, and  $a$  and  $b$  are constants, is known as the  $b$ -value, and usually takes on the value of 0.9 to 1.0 for tectonic earthquakes. This means that for every  $M = 3$  earthquake there are 10  $M = 2$  earthquakes, 100  $M = 1$  earthquakes, and so on.

There are several different measures of earthquake size. The most widely known is magnitude, which is the amplitude of the recorded elastic waves on a particular instrument (the Wood–Anderson torsion seismometer) corrected for distance. A more physical measure of earthquakes is seismic moment, which is the product of fault area, slip, and the rigidity or strength of the rock. The ranges of these parameters and how they relate to each other are called scaling relations, and they permit the calculations of Table I, which shows typical dimensions and other parameters for earthquakes of different magnitudes.

Once an earthquake occurs at the source (such as a fault), the elastic waves travel away along different paths and eventually reach the seismometers. Characteristics that contribute to a seismogram (the way the earthquake appears on a paper record or other media) may occur at the source, along the path, and at the recording site, thus a major task for seismologists is to determine, for each seismogram, the relative contributions of source, path, and site effects. Once these are known a basis exists to demonstrate that a particular earthquake is low-frequency, harmonic, etc., and physical models are then

TABLE I Typical Earthquake Parameters (Circular Fault, 30-Bar Stress Drop)

Magnitude	Radius	Slip	Moment <sup>a</sup> (dyne-cm)	Duration <sup>b</sup> (s)
-2	0.85 m	0.06 mm	$4 \times 10^{13}$	0.00053

<sup>b</sup> Assumed  $\beta = 3.18$  km/s.

constructed to evaluate the likely causes of peculiar (and normal) waveforms.

Seismology is also concerned with the distribution of velocities within the Earth. Seismic velocities are much higher than normal everyday velocities and are usually measured in kilometers per second, about the speed of satellites in outer space. For example, a car traveling on a highway at 60 mph is only going about 27 m per second, whereas air waves (sound waves) travel at 331 m per second and typical P waves at volcanoes travel at about 3 to 5 km per second or faster. Seismic waves travel more slowly in molten rock than they do in solid rock, so seismic tomography, similar to medical tomography, uses variations in the speed of elastic waves to recover information about where the magma is located.

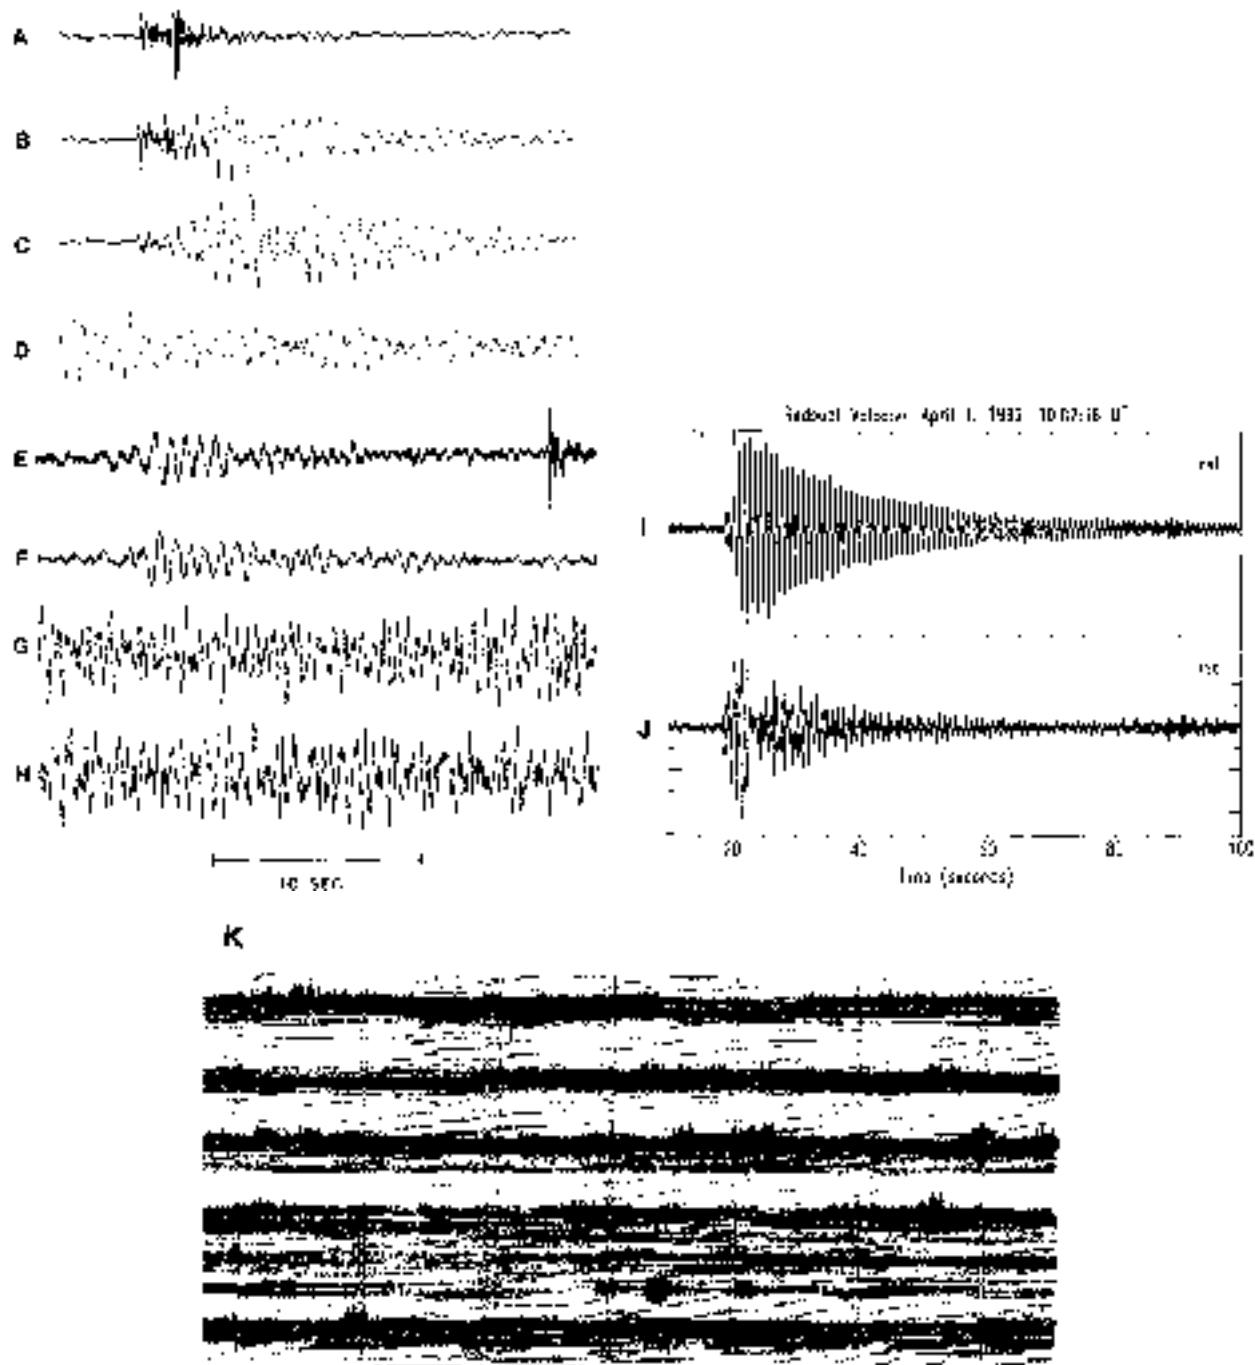

With this brief overview as a reference frame, we now turn our attention to some of the features of volcanic earthquakes.

## II. TYPES OF VOLCANIC EARTHQUAKES AND TERMINOLOGY

Active volcanoes are the sources of a great variety of seismic signals. Traditionally, volcanic earthquakes have been classified based on seismogram appearance into four different types: high-frequency (HF) or A-type, low-frequency (LF) or B-type, explosion quakes, and volcanic tremor. This classification scheme works very well at a large number of volcanoes, but see below for additional discussion on terminology. Other local signals, such as those caused by glaciers or landslides, are also recorded at volcanoes. Although the original classification included restricted depth ranges for various events, these have often been relaxed because of improvements in location accuracy and better understanding of source and propagation effects. Examples of volcanic events from several volcanoes are shown in Figure 1.

### A. High-Frequency Events

Most high-frequency events are thought to be caused by shear failure or slip on faults, and differ from their tectonic counterparts only in their patterns of occurrence. At volcanoes, earthquakes typically occur in swarms rather than mainshock–aftershock sequences. A swarm may be defined as a group of many earthquakes of about the same size and location with no dominant

**FIGURE 1** Typical waveforms of volcanic earthquakes: (A) High-frequency or volcanotectonic earthquake, 6.8 km depth, Redoubt volcano, Alaska, station RED, 8 km from the vent. (B) Hybrid or mixed-frequency event, -0.6 km depth (0.6 km above sea level), Redoubt volcano, station RED. (C) Low-frequency or long-period event, -0.4 km depth, Redoubt volcano, station RED. (D) Volcanic tremor, Redoubt volcano, station RED. (E) Explosion quake, Pavlof volcano, Alaska, station PVV, 8.5 km from the vent (note prominent air-wave arrival). (F) Low-frequency of B-type event, Pavlof volcano, station PVV. (G) Volcanic tremor before eruption, Mount Spurr, Alaska, station CRP, 4.8 km from the vent. (H) Volcanic tremor during eruption, Mount Spurr, station CRP. (I) Tornillo, long-coda event, or long-period event, Redoubt volcano, station REF, 3 km east of the vent. (J) Same event as (I) as recorded at station RSO, 3 km south of the vent. (K) Banded tremor from Manam volcano, Papua New Guinea, station TBL, 4 km from the vent (bands correspond to strong phases of subcontinuous Strombolian activity; tick marks are at 1-minute intervals; and recording speed is six lines (revolutions) per hour). Amplitudes for A–J are normalized. [After McNutt, 1996.]

shock. In practical terms, the difference in magnitude between the largest and second largest event of a swarm is 0.5 magnitude units or less, as opposed to 1.0 magnitude units or more for most mainshock–aftershock sequences. High-frequency events have clear P and S waves, and dominant frequencies are 5–15 Hz. Higher frequencies may be generated at the source, but are not recorded because of instrumental limitations or high local attenuation. A typical small high-frequency event is shown in Figure 1A.

### B. Low-Frequency Events

Most low-frequency events are thought to be caused by fluid pressurization processes such as bubble formation and collapse, and also by shear failure, tensile failure, or nonlinear flow processes which occur at very shallow depths for which attenuation and path effects play an important role. These events often have emergent P waves, lack S waves, and have dominant frequencies between 1 and 5 Hz, with 2–3 Hz most common. Examples of low-frequency events are shown in Figures 1C, 1F, 1I, and 1J.

Prior to eruption, magma must move from depth to the Earth's surface through conduits, dikes, sills, reservoirs, or various combinations of these. Thus, models of low-frequency volcanic earthquakes select a geometry, such as a rectangular crack or a cylindrical pipe, and then attempt to reproduce seismograms by appropriate choice of length, width, and velocity of the material within it, which can be either magma or water. (Seismicity similar to that at volcanoes is found at geysers and geothermal areas.) A source of mechanical energy is needed; this can be a small earthquake adjacent to a conduit, a flow transient or pressure fluctuation within a conduit, gas bubbles expanding or contracting, a shock wave from choked flow, or other causes. Some workers consider the source to be the mechanical energy alone, while others treat the source as the ensemble of the mechanical energy and the resonant response of the magma or water in conduits or dikes.

Some earthquakes share attributes of both high- and low-frequency events. These are called hybrid events. For example, the event shown in Figure 1B displays the high-frequency onset of a high-frequency event, but the later part of the signal (the coda) is similar to low-frequency events. It is thought that such events may represent a mixture of processes, such as an earthquake occurring adjacent to a fluid-filled cavity and setting it into oscillation. Others suggest that hybrids are shal-

lower than low-frequency events and thus preserve most of the high-frequency energy which is attenuated for deeper events.

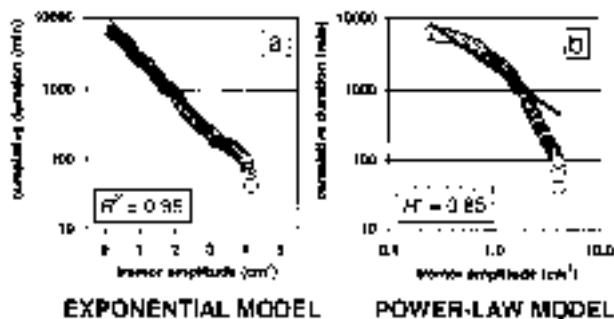

### C. Explosion Earthquakes

Explosion quakes accompany explosive eruptions, and many are characterized by the presence of an air-shock phase on the seismograms. There is a partitioning of energy at the source: part of the energy travels through the ground as seismic waves and part travels through the air as acoustic or air waves. The air wave then couples back into the ground and is detected by the seismometer. The air wave also shows up clearly on microphones or barographs. An example of an explosion earthquake is shown in Figure 1E.

### D. Volcanic Tremor

Volcanic tremor is a continuous signal with a duration of minutes to days or longer. The dominant frequencies of tremor are 1–5 Hz (2–3 Hz is most common), similar to low-frequency events, and many investigators have concluded that tremor is a series of low-frequency events occurring at intervals of a few seconds. Harmonic tremor and spasmodic tremor are two special cases of more general volcanic tremor. Harmonic tremor is a low-frequency, often single-frequency sine wave with smoothly varying amplitude, or sometimes it consists of a fundamental frequency with many overtones. Spasmodic tremor is a higher-frequency, pulsating, irregular signal. Examples of volcanic tremor are shown in Figures 1D, 1G, 1H, and 1K.

It has previously been stated that earthquakes obey a power law, known in seismology as the frequency–magnitude relation. There are more small earthquakes than large ones, and the relative numbers of events form a power law distribution. Volcanic tremor, however, obeys a different type of relation, which is an exponential law (Figure 2). For tremor, which is a continuous signal, we cannot count the number of events, so we compute the duration at different amplitudes. Synthetic experiments have shown that this is equivalent to counting events because large and small earthquakes have different durations (large ones shake longer). The exponential law has implications for the source of volcanic tremor. For earthquakes, both the fault area and the slip increase as magnitude increases, but for tremor, either the source size (such as conduit length) or the magnitude of pres-

**FIGURE 2** Volcanic tremor data from Mount Spurr, Alaska, comparing an (a) exponential and a (b) power law model. Note that the vertical axis is logarithmic in both cases, but the horizontal axis is linear for the exponential model and logarithmic for the power law model. The circles show the duration of tremor observed at various amplitudes; strong tremor occurs less often than weaker tremor. The lines are weighted least-squares mathematical fits of the data to the two models shown. The data fitted better using the exponential model, as shown by the higher value of the correlation coefficient  $R^2$ . [After Be-  
noit, 1998.]

sure fluctuations (analogous to slip) must remain constant to produce the observed exponential scaling. The available evidence suggests that the source (conduit) size remains constant.

#### E. Very-Long-Period Events

Over the past decade new types of seismometers known as a broadband seismometers have been deployed at volcanoes. These have the ability to detect a wider frequency band, particularly at the low end (down to  $f = 0.016$  Hz, or a period of 60 s). Not surprisingly, a new class of events called very-long-period (VLP) events have been observed at some volcanoes. Observations to date show events with periods of 3 to 20 s originating from shallow depths of 1.5 km or less under several active volcanoes including Kilauea, Stromboli, Aso, Sakurajima, and Satsuma-Iwojima. The VLP events at these volcanoes have been associated with either eruptions or vigorous fumarolic activity, and the observed events have fairly small amplitudes.

Normally it takes a large structure, such as a long fault, to produce waves with these long periods. However, many of the VLP events at volcanoes appear to come from small source zones despite the long wavelengths. Some current models suggest that these events may be produced as magma moves through a flapper valve (such as a restriction in a dike or sill) in distinct

pulses. Additionally, theoretical calculations show that it is possible for a crack or tube filled with fluid to produce long-wavelength (and long-period) waves if the acoustic velocity in the fluid is slow compared to the rigid walls. The interaction between the fluid and walls produces low phase velocities along the interface. Such waves are called crack waves or tube waves.

During its climactic eruption on June 15, 1991, Mount Pinatubo, Philippines, produced strong seismic waves with periods of 228 to 270 s. These are thought to be caused by a type of oscillation in the atmosphere in which thermal energy from the vent travels up and then reflects off the top of the ash column (in this case in the stratosphere). These waves also coupled into the ground and appeared on seismic stations thousands of kilometers away, lasting for over 2 hours.

Broadband sensors have been deployed at a number of volcanoes that produced no VLP signals, even though several of these were erupting. They include Mount Spurr, Montserrat, Arenal, Akutan, and Augustine volcanoes. Further, the scientific community has yet to record any precursors to truly large eruptions on broadband instruments. In spite of this, the VLP signals made visible by the new broadband instruments are an exciting part of volcano seismology, and it is anticipated that many new advances will be made in this area over the next few years.

#### F. Surficial Events

Seismometers located on volcanoes may record a variety of local signals caused by shallow processes. These include nonvolcanic processes such as glacial events, shore ice movement, and landslides, as well as volcanic processes such as outburst floods and lahars, pyroclastic flows, and rockfalls from crumbling lava domes. Some of the seismograms are similar, so they must be recognized and properly treated by analysts.

- *Glacial events.* Volcanoes at high latitudes and tall volcanoes are frequently covered by glaciers, which produce seismic events along the ice–rock boundary, and within the ice when cracks and crevasses form. Because the seismic wave velocity in ice is lower than that in rock, the seismic waves may become partially trapped in the ice and set up oscillations of the ice itself. Seismograms from such events resemble those for LF volcanic events. Glacial events are more common in the summer months when the glaciers are moving faster.

- *Shore ice.* Ice forms from seawater when the air temperature falls below 10°F. Large blocks of such ice gather

on the shores of Augustine Island, Cook Inlet, Alaska, and move around as the tides ebb and flood. When the blocks collide or break, they produce seismic events because the blocks are coupled to the ground. The events are shallow (surface) so the seismic waves are mostly low-frequency surface waves traveling in thin sediment layers. The individual ice events resemble LF volcanic events, and the events occur in swarms of a few hours duration because of the tides. Both of these features are similar to seismicity preceding eruptions, so good thermometers are needed to measure air temperature in such situations!

• *Landslides.* Avalanches and landslides of various sizes occur on volcanoes. Those associated with partial melting of ice and snow mainly occur in the spring and summer. The main avalanche or landslide generates a seismic signal of several minutes duration, depending on the size and runout. The amplitude varies with the amount of material, with larger avalanches generating stronger seismic signals. Some landslides on volcanoes (and elsewhere) are preceded by small discrete seismic events whose rate of occurrence increases up to the time of the main event. This is similar to a common pattern of earthquakes before some eruptions, so again, additional information is needed to distinguish between volcanic and nonvolcanic causes on the seismograms.

• *Rockfalls.* Rockfalls are a special type of landslide in which one or a few pieces of bedrock become detached and free fall. They are especially common at the edges of volcanic domes and at volcanoes with very steep slopes or cliffs. In the summer of 1995 workers at Mount Spurr, Alaska, observed rocks more than 1 m in diameter falling several hundred meters and impacting on the crater floor. The corresponding seismograms showed strong local signals lasting more than 1 minute.

• *Pyroclastic flows.* Pyroclastic flows are products of explosive eruptions and consist of particles of hot molten rock and gases which move rapidly over the ground surface. Large-scale collapses of volcanic domes can also produce pyroclastic flows. These latter events are characterized by complex seismograms which have been modeled as a sequence of forces. First, rock is removed from the dome (the dome moves up slightly in response); second, the falling rock collides with the slope below (an impact); and third, the rock breaks apart and the fragments continue to move down the slope as an irregular flow. These seismograms last several minutes, may contain high frequencies, and the larger flows are associated with larger amplitude signals.

Pyroclastic flows have also been associated with another seismic feature. At Pinatubo volcano, Philippines, pyroclastic flows traveled down a prominent valley be-

tween two seismic stations, one of which transmitted its signal to the other. As the ash clouds rose into the air the telemetry path was interrupted for several tens of minutes, after which the signal returned. Thus, the temporary absence of the telemetry could be used to infer that pyroclastic flows were occurring.

• *Outburst floods and lahars.* The surface melting of ice and snow, or heavy rains, may cause floods and lahars (volcanic mudflows). Similarly, a volcanic eruption under a glacier will melt the ice, and the flooding that subsequently occurs is called a jokulhlaup. All these floods or lahars cause long-duration seismic signals that resemble volcanic tremor, except that the signal is stronger near the flow channel, as opposed to tremor, which is stronger nearest the volcanic vent. The flood-water travels downstream, so the source is moving. Also, the recorded frequencies may be high if the seismometer is near the flow channel, even though this may be far from the vent.

Different groups of investigators and various observatories have used a number of different local terminologies. This is not a problem, however, because the goal of terminology at the local level is to communicate rapidly in an observatory setting. (This is similar to the local names of sandwiches, which can be "hoagie," "grinder," or "submarine sandwich" in different parts of the United States.) However, no consensus has yet emerged about an appropriate global terminology. The lack of a global terminology makes it difficult to evaluate critically the observations from different volcanoes, and creates confusion in the literature. Table II compares several of the more common local terminologies.

Different mechanisms acting at the seismic source are responsible for many of the features of the different events, and path and site effects, which are extreme at many volcanoes, may greatly modify the signals. Three principal seismic sources are shear failure, also called "double-couple" mechanisms; tensile failure, or "non-double-couple" mechanisms; and passive and active fluid involvement in producing low-frequency events and volcanic tremor. Nonlinear flow has also been modeled as a source for volcanic tremor. Some authors have investigated differences between volcanic and tectonic earthquakes by comparing factors such as magnitude using different waves, and seismic moment versus fault length. Such comparisons reveal that many volcanic earthquakes are enriched in low frequencies and occur on smaller structures (faults) than tectonic earthquakes of the same magnitude.

Intermittent or "banded" tremor occurs in regular, periodic bursts separated by periods of quiescence of

uniform duration. The resulting pattern looks like stripes or bands on seismograms recorded on rotating drum recorders (Figure 1K). Many other patterns are observed and various terms are used as adjectives to describe them, but this does not necessarily mean that different source processes are required.

### III. GENERAL FEATURES OF EARTHQUAKES AT VOLCANOES

The goals of volcano seismology include monitoring the present status of a volcano, forecasting eruptions, estimating size of eruptions in progress, locating magma chambers, and understanding the physical processes that are occurring. The following topics elucidate many of the features that are common to earthquakes at volcanoes.

#### A. Seismicity Rates and Background

Volcanoes nearly always have a high background level of seismicity caused by heat; movement of groundwater, volatiles, or magma; glaciers (if present), landslides, and rockfalls; and reactions to stresses from regional tectonics, tides, or other forcing functions. Thus, a baseline of measurements of at least a few years duration is necessary to characterize and understand the background seismicity. The background may consist of several different

types of events, which are related to different processes. Typical background rates of seismicity are a few to a few tens of events per day, depending on the locations and magnifications of the seismic stations. In contrast, the rates of seismicity before and during eruptions are typically several tens to several hundreds or more events per day, and include larger-magnitude events. Examples of rates and magnitudes of seismicity prior to selected eruptions are shown in Table III.

Many successful eruption forecasts have been made because of an increase in seismicity above previously recorded background levels. This is based on the idea that the level of seismicity reflects the level of volcanic activity, and suggests that there is a constant long-term probability of eruption, usually assumed to be a Poisson process. This means that eruptions behave as a random variable, and have no memory (mathematically) of previous eruptions. The average rate of eruptions is also assumed to be constant, and the probability increases when earthquake swarms occur. The main physical processes monitored, however, are those associated with magma intrusion. Thus, there will always be a false alarm rate because some intrusions remain at depth whereas others reach the surface and erupt.

#### B. Seismicity Associated with Large versus Small Eruptions

In general, large eruptions are relatively easier to detect than smaller ones. The amount of magma involved is large, and earthquakes tend to be numerous as well as

distributed over a large volume. Other precursors such as deformation and steaming are usually observed in conjunction with earthquake swarms. Recent examples include Mount St. Helens, Washington, 1980; Pinatubo, Philippines, 1991; and Spurr, Alaska, 1992. Small eruptions

tions and many phreatic (water driven) eruptions, in contrast, involve much smaller amounts of magma, and have subtle precursors or sometimes no precursors. They are, hence, generally harder to forecast. Recent examples include Galeras, Colombia, January–June

1993; Arenal, Costa Rica, August 1993; and White Island, New Zealand, February 1992.

Occasionally “unexpected” eruptions occur; often these take place during the later phases in a sequence of eruptions. Even though these may be large, they may have subtle or undetectable seismic precursors. This is a consequence of the vent remaining “open” or mechanically weak following an initial stage of activity, preventing buildup of stresses which would cause earthquakes. A recent example is the second eruption of Mount Spurr in August 1992, which occurred without immediate detectable precursors.

### C. Locations of Volcanic Earthquakes

Generally volcanic earthquakes occur beneath the point of eruption. This helps reduce the monitoring problem to that of estimating the time of eruption since the place is considered known. However, several cases have occurred in which the locations of earthquake swarms did not coincide with the eruptive vent, because different mechanisms were acting. During the Matsushiro, Japan, earthquake swarm of 1965–1967, which began beneath Mount Minakami, an extinct volcano, epicenters were aligned northeast-southwest, but a fissure oriented northwest-southeast appeared at the ground surface. Water flowed from this fissure but no magmatic eruption occurred. During the Miyake-jima, Japan, basaltic eruption of 1962, the epicenters were located northwest of the summit crater but the eruption occurred from a flank fissure on the northeast side. More recently, the initial earthquake swarms prior to the dacitic eruption of Pinatubo occurred about 5 km northwest of the volcano. Twelve days before the climactic eruption these earthquakes declined and vigorous shallower swarms began beneath the eventual eruption site. For volcanic systems with large dimensions, earthquakes may be widely separated: for Katmai, Alaska, 1912, there was a 10-km separation between the collapse structure (Mount Katmai) and the Novarupta vent; at Rabaul, Papua New Guinea, 1994, two vents, Tavurvur and Vulcan, erupted simultaneously 10 km apart. These cases demonstrate that earthquakes occur where stresses are concentrated, not necessarily where the magma is located.

It is expected that earthquake locations would migrate from depth toward the Earth’s surface as magma rises from depths prior to eruption. There are, however, surprisingly few well-documented cases of such a trend. This overall pattern was first shown for Kilauea volcano, Hawaii, in 1960; more recent examples include Au-

gustine, Alaska, 1986; Unzen, Japan, 1991; Pinatubo, 1991; and additional 1960–1983 eruptions of Kilauea. One spectacular case of lateral migration of hypocenters was observed at Krafla in September 1977; when the earthquakes passed a geothermal borehole, fresh pumice actually erupted from the hole!

### D. Large Regional Earthquakes Near Volcanoes

Large regional earthquakes occasionally trigger eruptions. Well-known examples include the eruption of Puyehue 48 hours after the  $M = 9.3$  Chile earthquake of 1960, and a small summit eruption of Kilauea shortly after the  $M = 7.1$  Kalapana earthquake of 1975. Exact mechanisms for this triggering are poorly understood, yet probably reflect local stress changes near the volcano induced by the nearby large earthquake (analogous to squeezing a tube of toothpaste). Recently, it has been demonstrated convincingly that the June 1992  $M = 7.3$  Landers, California, earthquake remotely triggered earthquake swarms at 17 volcanic areas in the western United States at distances of 165 to 1250 km. Although no eruptions occurred, these swarms demonstrated that small transient stress changes can trigger significant changes in seismicity in volcanic areas. One possible mechanism for this is known as rectified diffusion, in which oscillatory strains, such as those caused by passage of seismic waves, make existing bubbles expand and contract. Because the surface area is proportional to the radius squared, the bubble’s average size is larger than normal during the oscillations, and gases diffuse into the bubble, causing a pressure increase. Other mechanisms are currently under investigation.

### E. Caldera Earthquakes

Large earthquakes often occur at large structures, such as calderas. For example,  $M \geq 6$  earthquakes have occurred at or near calderas in Long Valley, California; Yellowstone, Wyoming and Idaho; and Aso, Japan.  $M = 5.1$  earthquakes have occurred at Rabaul caldera, Papua New Guinea, in 1982 and 1984. While small eruptions have occurred frequently at the central vent of Aso, no eruptions have occurred at Long Valley or Yellowstone. Rabaul finally erupted on September 19, 1994, following 13 years of caldera-wide seismicity and 37 hours of intense local seismicity. It is normal for large calderas to show frequent signs of unrest, the vast majority of which

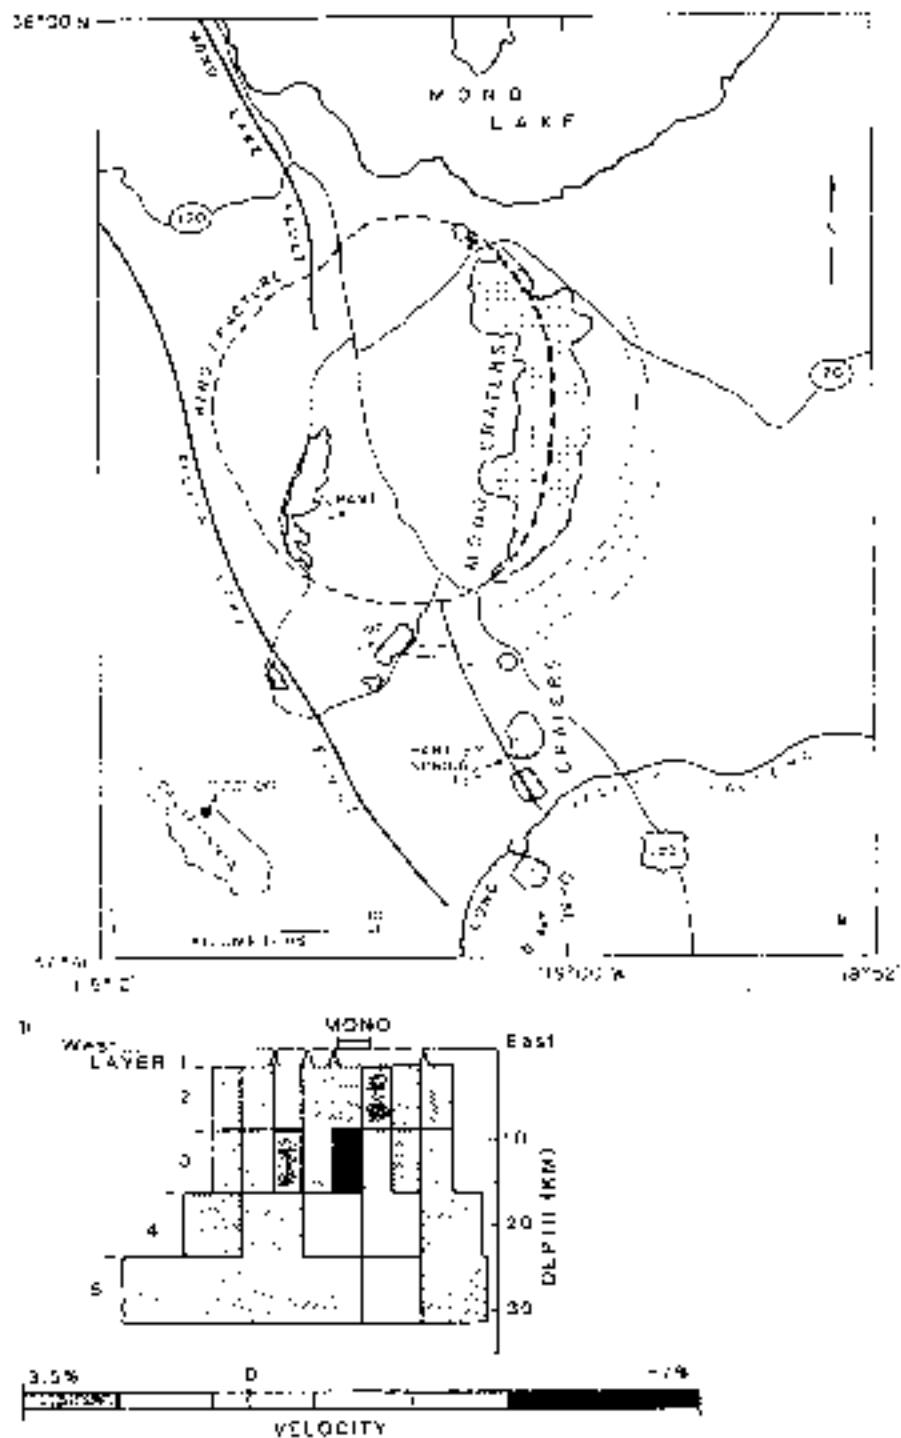

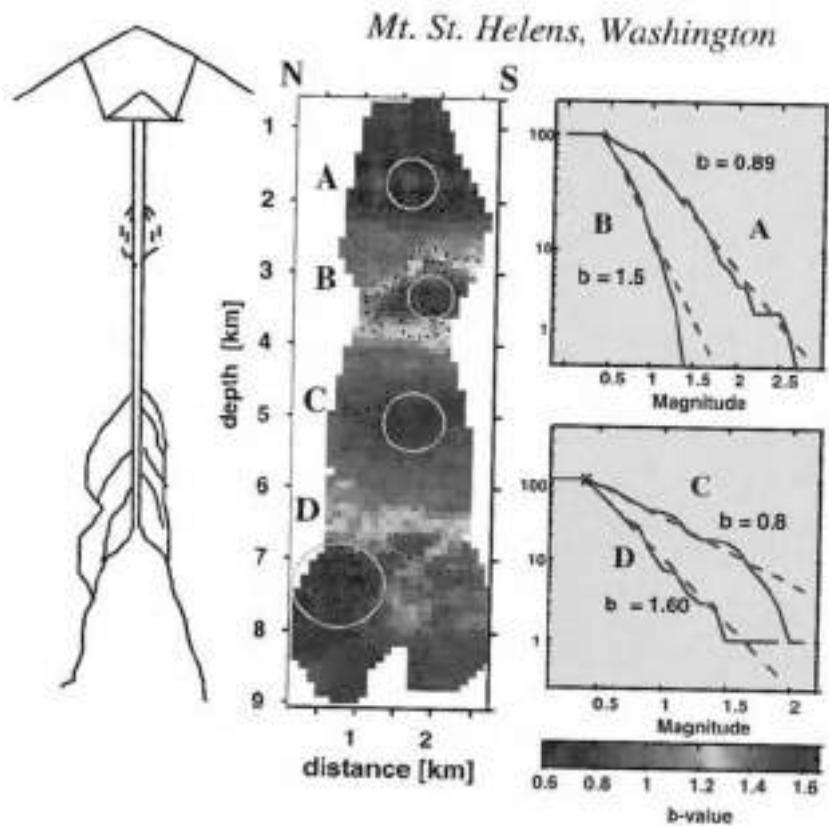

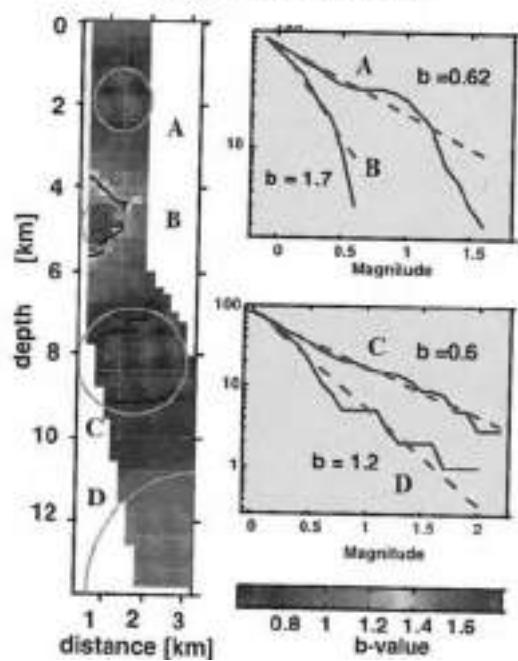

FIGURE 3 Tomography of Mono Craters, California, using P waves from distant earthquakes. (a) Map of tectonic and geographic features of the area of Mono Craters, just northeast of Long Valley caldera. Shaded areas are Holocene volcanic flows and domes. (b) An east-west cross section showing tomographic results. The velocities vary from 3.5% higher to 7% lower than the reference values. The strongest anomaly, a 7% lowering of the velocity (black rectangle), occurs 9 to 16 km beneath the Mono Craters. [After Iyer, 1992.]

*Mt. Spurr, Alaska*

are not precursors to eruptions. This adds to the uncertainty in dealing with earthquake swarms at calderas: false alarms are more likely, but large eruptions are also possible.

#### F. Seismicity at Volcanoes with Long Repose Times

Large eruptions often follow long repose periods, and the earthquake swarms may include relatively large events. Recent examples include Arenal volcano, Costa Rica, in 1968 (repose 440 years,  $M = 4.5$ ), Mount St. Helens, 1980 (repose 123 years  $M = 5.0$ ), and Pinatubo, 1991 (repose 600 years,  $M = 4.3$ ). This feature, however, is problematic at large structures such as calderas which routinely produce large earthquakes. While calderas are more likely to have large earthquakes not followed by eruptions, the possibility of a large eruption suggests caution when interpreting an earthquake sequence such as that at Long Valley caldera in May 1980 (four  $M = 6$  earthquakes; see case histories below). This and some of the later seismicity at Long Valley may have been related to intrusions of magma.

#### G. Synchronous Volcanic and Tectonic Activity

A 40-km-wide belt of volcanoes and frequent shallow crustal earthquakes is located above the subduction zone in Central America. While the general structural features are similar to most other subduction zones, the Central American tectonic seismicity is more abundant and appears to be more closely linked to volcanism. Both eruptions and damaging earthquakes have occurred in isolation, but occasionally the two have been coincident. For example, at Boqueron volcano, El Salvador, an  $M = 6.2$  earthquake alone occurred in May 1965, while in June 1917 and September 1659 eruptions and destructive ( $M \approx 6$ ) earthquakes occurred simultaneously. These may be cases of one phenomenon modifying or

triggering the other, or an external agent may be the cause of both.

#### H. Seismicity at Basaltic versus Dacitic Volcanoes

Differences between seismic activity at basaltic versus andesitic and dacitic volcanoes may be subtle. Extremely short-duration swarms of small events are more common at basaltic volcanoes. For example, the January 1991 eruption of Hekla volcano, Iceland, occurred after an earthquake swarm lasting only 0.5 hour, with the largest event about  $M = 3$ . Most of the handful of known eruptions that occurred essentially without detectable precursors took place at basaltic volcanoes (e.g., Hekla, 1981; Mount Etna, Italy, flank, March 1985). However, once initial eruption has occurred and the vent is open, subsequent eruptions may occur with virtually no additional seismicity at andesitic or dacitic volcanoes (e.g., Mount Spurr, August 18, 1992). Energetic earthquake swarms after eruptions are common at basaltic centers. Spatially, basaltic centers more often produce flank eruptions, whereas andesitic and dacitic volcanoes tend to erupt repeatedly from the same central vent.

#### I. Seismic Features of Magma Chambers

Magma is thought to be stored in some type of chamber or reservoir underground, and seismology is useful for determining the parameters of such chambers. Magma chambers at stratovolcanoes are generally equant in shape, and on the order of 1 to 20 km<sup>3</sup> in volume. Those at calderas are larger. Their depths are mapped at about 5 to 20 km or deeper based on tomography, S-wave screening, and posteruption seismicity. Seismic tomography, similar to medical tomography, requires seismic waves to travel through the target region. Thus, a good distribution of earthquakes and seismic stations is needed; both local and distant earthquakes have been used as sources for such studies. The technique exploits the fact that P waves speed up in competent rock and

---

**FIGURE 4** Images showing the distribution of  $b$ -values beneath Mount St. Helens and Mount Spurr. Each grid element shows the  $b$ -value for the nearest 100 earthquakes (original color version has low  $b$ -values as blue, normal values as green and yellow, and high values as red). Four samples labeled A–D are plotted to the right of each cross section. These show the actual data used to compute each  $b$ -value. Note the anomalies at 3–4 km for each volcano and 7–9 km for Mount St. Helens and 10–13 km for Mount Spurr. The deeper anomalies are near magma chambers and the shallower ones are at depths of vesiculation of gases. The black line drawing represents a schematic view of the Mount St. Helens plumbing system. [Original color version in Wiemer and McNutt, 1997.]

TABLE IV Parameters of Volcanic Activity: Seismic Case Histories

slow down in unconsolidated materials or magma. An example of a tomographic image of a magma chamber under Mono Craters, California, is shown as Figure 3. S-wave screening exploits the fact that S waves cannot pass through liquids. Thus, the target region will be illuminated by the presence of P waves but lack S waves for those waves that pass through magma. Posteruption seismicity is often concentrated at depths of 5 to 20 km.

Here, the removal of magma upward during eruption causes stress changes at depth that induce earthquakes. The idea is that the magma chamber walls collapse inward, and earthquakes are concentrated where these processes are most pronounced.

A new technique that requires well-distributed seismicity (as opposed to concentrated at one spot) looks for systematic spatial variation in the *b*-value, discussed

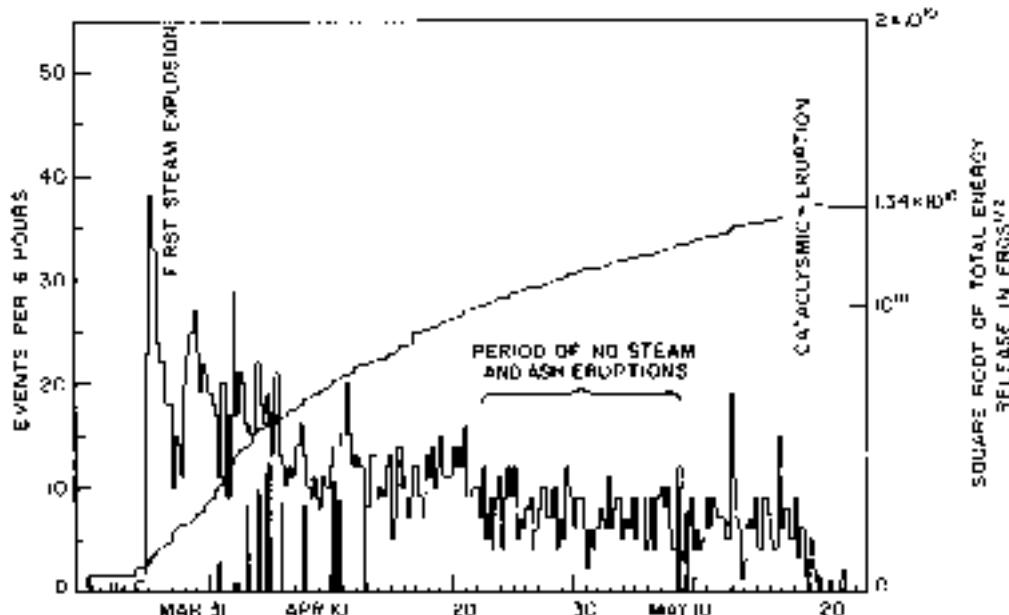

FIGURE 5 Counts of Mount St. Helens earthquakes larger than  $M = 2.5$  per 6 hours, volcanic tremor (vertical lines, length proportional to tremor duration), and square root of cumulative energy release (a way to convert from magnitude to energy) from March 20 to May 24, 1980. [After Endo et al., 1981, and Malone et al., 1981.]

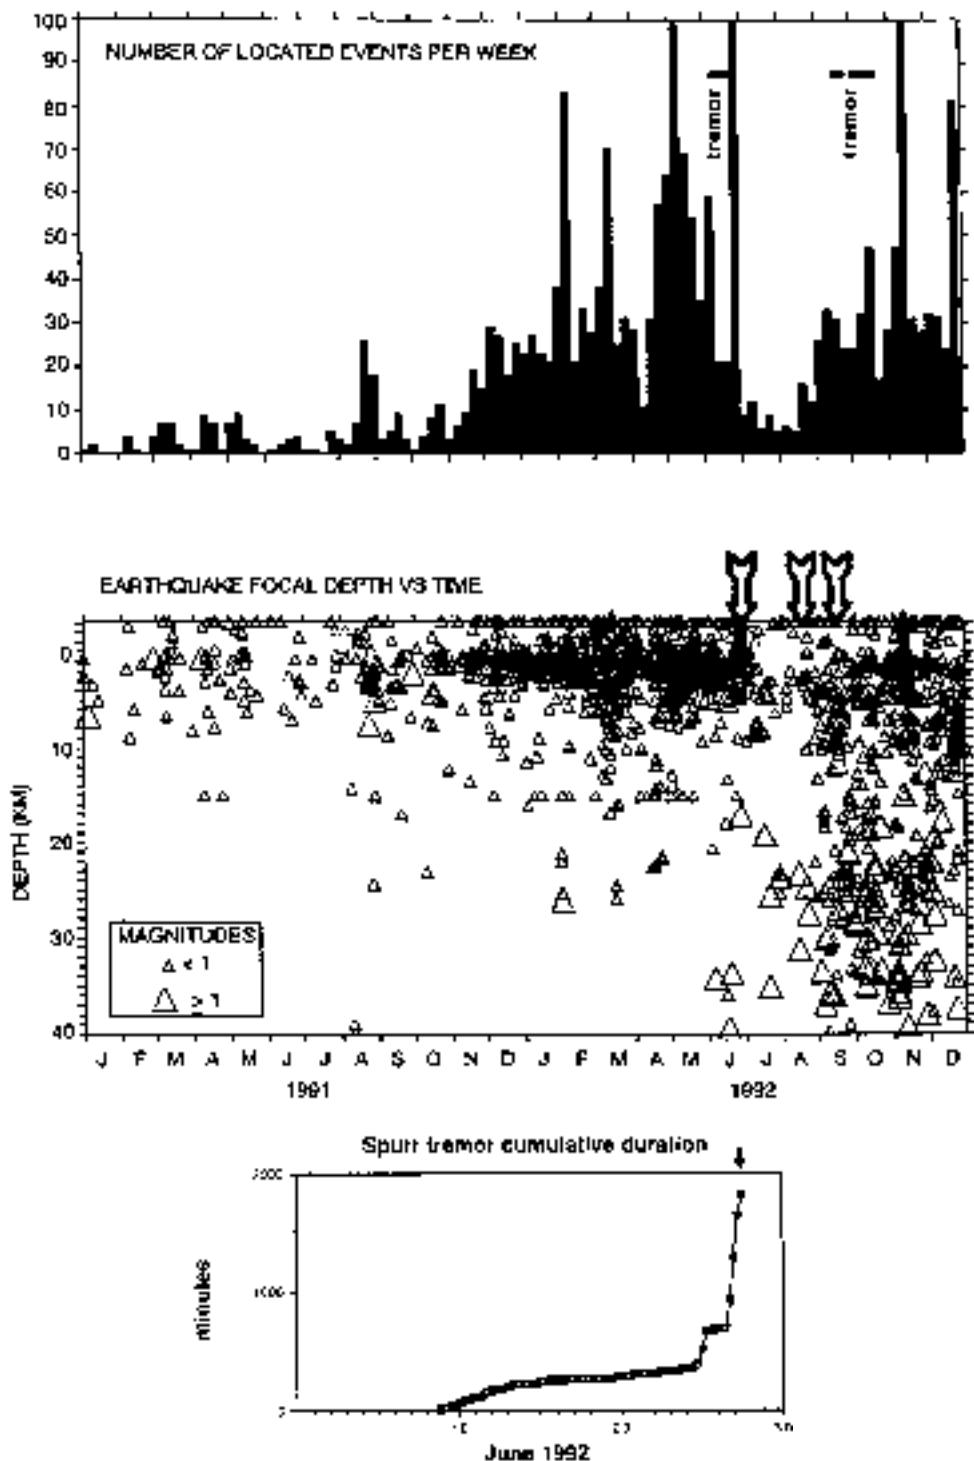

FIGURE 6 Seismicity in 1991 and 1992 associated with the eruptions of Mount Spurr. (Top) Number of events per week. Episodes of volcanic tremor are shown as horizontal bars. (Middle) Earthquake depth versus time. Each symbol represents one earthquake, and symbol size is related to earthquake magnitude, either  $M < 1$  (small symbol) or  $M \geq 1$  (large symbol). The three eruptions are shown as arrows. (Bottom) Mount Spurr volcanic tremor cumulative duration versus time. Data are computed for 6-hour intervals. The eruption occurred on June 27 (arrow). [After Alaska Volcano Observatory, 1993, and McNutt et al., 1995.]

earlier. It has been shown in the laboratory that heat, high pore pressure, low applied stresses, or heterogeneous materials all produce high *b*-values. These are also the conditions that would be expected in the vicinity of magma bodies. Although this technique cannot uniquely identify which process is dominant, strong anomalies have been found at depths of 3–4 km and 7–9 km beneath six volcanoes studied. Examples of *b*-value anomalies thought to represent magma chambers beneath Mount St. Helens and Mount Spurr are shown in Figure 4.

#### IV. CASE HISTORIES

We consider the earthquake activity at four volcanoes to illustrate the variety of seismic activity. The four include small and large eruptions, a noneruption, and systems dominated by basalt, andesite, and dacite magmas. The volcanoes chosen had high-quality seismic data. Parameters of the four cases are summarized in Table IV. The bibliography at the end of this article gives at least one recent reference for each of the case histories.

##### A. Mount St. Helens, May 1980: A Large Dacite Eruption

Mount St. Helens, Washington, USA, produced a large explosive dacite eruption including a lateral blast on May 18, 1980, following 59 days of increased seismicity. On March 20, 1980, a  $M = 4$  earthquake occurred, followed by many smaller events. Activity increased, reaching 8  $M \geq 4$  events in a single hour on March 25. Phreatic eruptions began on March 27. The earthquake sequence eventually included over 10,000 earthquakes, including high- and low-frequency events and volcanic tremor (Figure 5). Most events were located at depths of 3 to 7 km beneath the north flank of the volcano, the site of the eventual eruption. There were no immediate precursors in the hours before the climactic eruption. However, the shaking from a  $M = 5.1$  earthquake initiated the eruption by causing a sector collapse which uncapped the volcano. Strong volcanic tremor accompanied the main eruption (Table IV). Deep (5 to 20 km) earthquakes began shortly after the eruption and lasted for several days. Later smaller eruptions were generally preceded by swarms of small earthquakes lasting several

hours to several days, and were accompanied by volcanic tremor.

##### B. Mount Spurr, June–September 1992: A Typical Andesite Eruption

The Crater Peak vent of Mount Spurr, Alaska, erupted on June 27, 1992, following a 10-month swarm of high-frequency events. The largest event of this swarm was  $M = 1.8$ . Bursts of volcanic tremor began 3 weeks before the first eruption, and continuous tremor began 19 hours before (Figure 6). The final precursor to the first eruption was a 4-hour swarm of shallow HF events directly beneath the active vent. The vulcanian eruption lasted 4 hours and produced 44 million m<sup>3</sup> of andesite tephra. The second, larger eruption on August 18 occurred essentially without precursors. The third eruption, on September 17, occurred following several weeks of increased deeper (15 to 40 km) seismicity and 3 hours of small shallow events and weak tremor. This last eruption was followed by a vigorous swarm of earthquakes be-

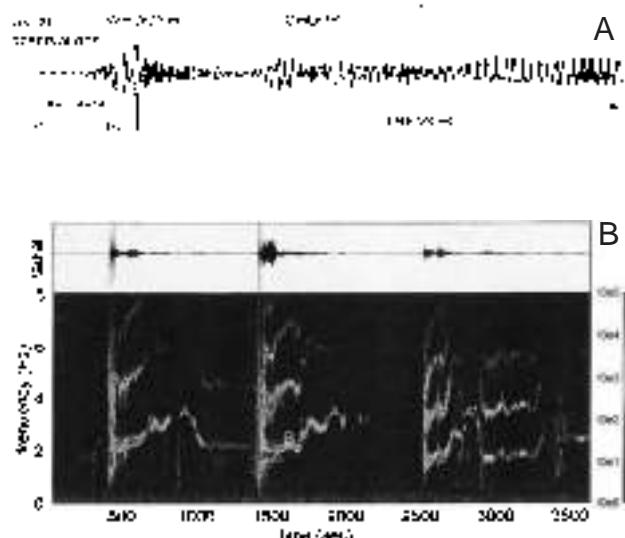

FIGURE 7 (A) An example seismogram of a small eruption (whoosh) at Arenal volcano, followed by rhythmic degassing (chugs), followed by harmonic tremor. The eruption ejected ash to 500 m above the crater and the chugs were audible at 2.8 km for 25 s. (B) Seismogram and spectrogram from April 1994 showing three small eruptions. The dark colors show lowest signal levels and the light the strongest. The spectra are dominated by narrow peaks spaced regularly in frequency, each of which changes frequency systematically with time. Spectrogram vertical scale is 0 to 8 Hz, and horizontal scale is 3600 s (1 hour). [After Benoit and McNutt, 1997; original version in color.]

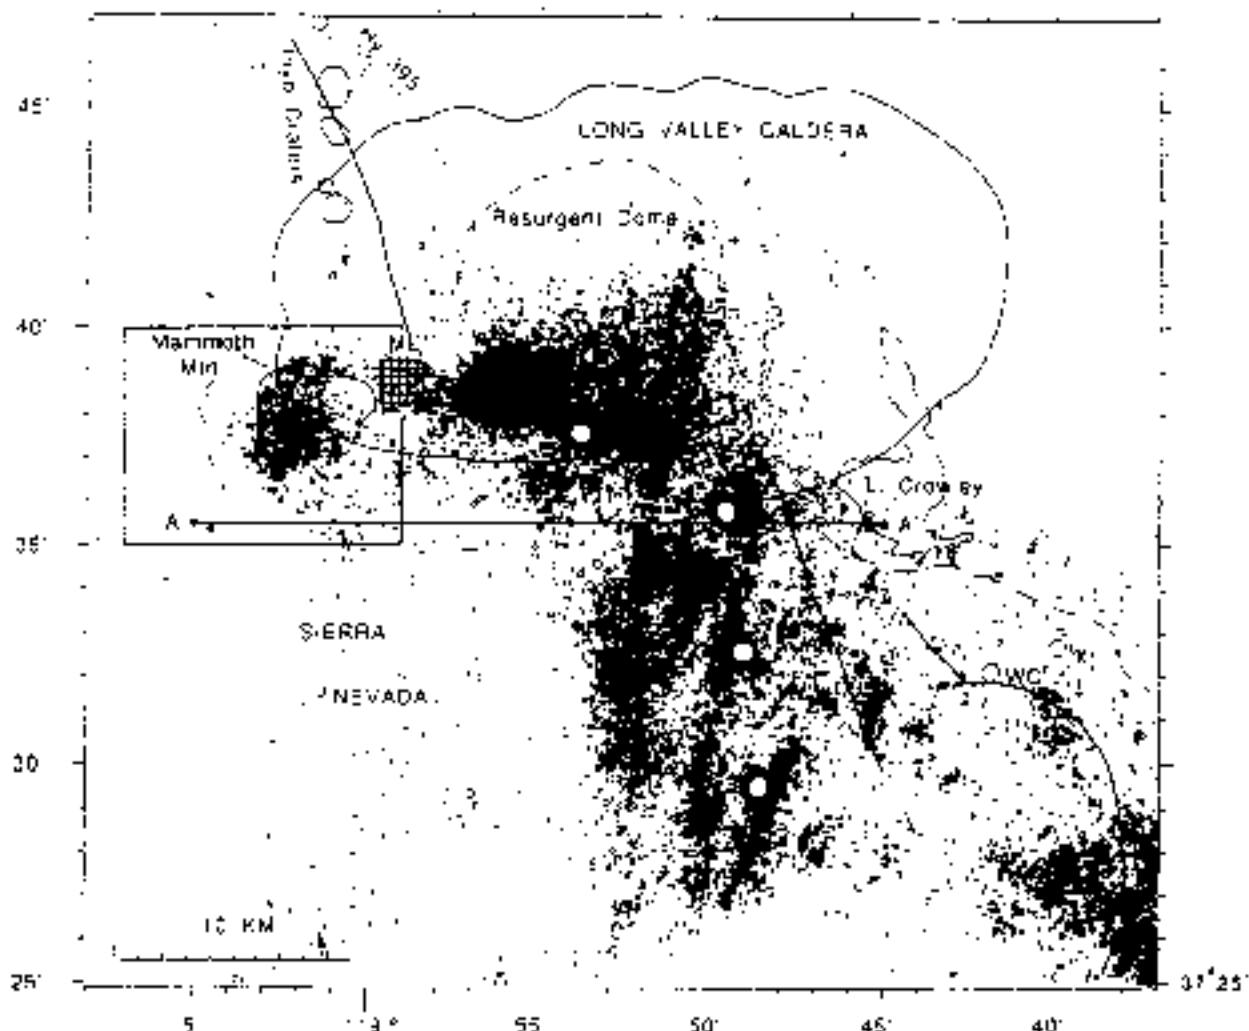

FIGURE 8 Map of Long Valley caldera and Sierra Nevada mountains to the south showing epicenters of  $M > 1.2$  earthquakes occurring from January 1978 to June 1995. Each symbol represents one earthquake, and symbol size is proportional to magnitude. The heavy circles are the four  $M \sim 6$  earthquakes that occurred in May 1980. ML is the town of Mammoth Lakes; WC is the epicenter of the  $M = 5.4$  Wheeler Crest earthquake of October 1978; Hy 395 is Highway 395; and L. Crowley is Lake Crowley. The caldera outline is shown as a solid line and the uplifted resurgent dome by a dashed line. [After Hill, 1996.]

tween 5 and 10 km in depth (Figure 6). A shallow swarm of several hundred events occurred on November 9 and 10 without eruption.

#### C. Arenal Volcano, July 1968 and Continuing: Strombolian Activity

Arenal volcano, Costa Rica, erupted explosively in July 1968 after several days of felt earthquakes (no local seismometers were operating at the time). Four new vents were formed along a fissure. At first activity was strong-

est at the lower craters, but shortly afterward activity shifted to a vent near the summit and an approximately steady-state eruption of andesite has occurred ever since. The eruption of a block andesite lava flow is punctuated several times per hour by small explosive eruptions of several types. A typical sequence is an explosion, followed by a whoosh (which sounds like a jet plane), followed by chugs (which sound like a steam locomotive). The seismic expression of these is an explosion quake, followed by irregular tremor, and then regular tremor (Fig. 7) with variable amplitude which gradually fades to background levels (similar data and frequencies are

found in acoustic data). The tremor consists of several integer harmonics or overtones, and these change frequency systematically over the course of several minutes (Figure 7). This suggests that the upper few hundred meters of the conduit is changing its bubble concentration, and hence its velocity and frequency. Every few years activity escalates and larger explosions occur, producing pyroclastic flows.

#### D. Long Valley, May 1980 and Continuing: A Restless Caldera

The Long Valley caldera region of eastern California has been a prolific producer of earthquakes from 1980 to 1998. The sequence began on May 25, 1980, when three  $M = 6$  earthquakes occurred, along with thousands of smaller events, followed two days later by a fourth  $M = 6$  event (Figure 8). Extensive ground deformation had also occurred, with uplift of 0.5 m near the center of the caldera. Later, it was found that measurable deformation actually preceded increases in earthquake activity by about 2 months, suggesting that earthquakes were a symptom of the deformation (or whatever caused it, such as underground movement of magma) rather than the cause. Repeated swarms of earthquakes occurred in the southern part of the caldera, and the strongest of these, in January 1983, included two  $M = 5.3$  events. Altogether 27 earthquakes with  $M > 5$  have occurred in and near the caldera over the last 18 years, a very high rate. No eruption has occurred; however, large quantities of CO<sub>2</sub> gas have been measured near Mammoth Mountain and have caused tree kills. It is also thought that several of the earthquake swarms accompanied intrusions of magma to shallow depths of about 5 km. Long Valley has become an archetype of a “restless caldera.”

---

#### V. CONCLUSIONS

This article has discussed many general features of earthquake activity at volcanoes, and it has been shown that the activity varies widely. This is true because the volcanoes and their eruptions vary, and also because the stresses differ, and volcanoes have different geometries as well as combinations of rock, magma, water, and gases within them. Although seismic data are plentiful, the complexities of the volcanic environment often make interpretations difficult. Different processes can gener-

ate similar seismograms, and similar processes can generate different seismograms, although detailed diagnostics can often distinguish between them. This keeps volcano seismology challenging, but also suggests that seismology alone can be a somewhat limited tool.

There is a close link between earthquakes and volcanoes. This is true at a large scale in the parallel belts of volcanoes and earthquakes at subduction zones. It is also true at the smaller scale of individual volcanoes, where rates of local seismicity often mimic eruptive activity. Although seismology is often viewed as a separate subject, we may also view seismology as a component of volcanology. Similarly, volcanology may be viewed simply as a component of the larger study of tectonics.

In spite of this, volcano seismology has helped to answer some fundamental questions: (1) Where is the magma? Tomography and *b*-value anomalies have identified large (kilometer scale) magmatic or near-magmatic structures, while low-frequency events and volcanic tremor are associated with small-scale movement of magma or water. (2) What is “normal” earthquake activity at volcanoes? The case studies and general features sections showed that activity varies widely, but with a number of systematic trends. Successful separation of source, site, and path effects of seismograms helps to elucidate the causes of specific activity. (3) What will happen next? Understanding of physical processes and study of case histories are the two main tools used to evaluate this question, which is treated more fully elsewhere. It is also possible, and indeed likely, that new high-quality data may lead to fresh insights about the new as well as older examples of earthquake activity at volcanoes.

- VI. Conclusion

## GLOSSARY

**acid rain** Pure water in equilibrium with atmospheric carbon dioxide has a pH of 5.6, but with pollution by strong acids the rain pH ranges from 2 to 4.

**asphyxia** Death from lack of oxygen.

**acute respiratory distress syndrome** A severe reaction of the lungs to injury, manifested by fluid filling the air spaces.

**crystalline silica** The three crystalline forms of silicon dioxide, namely quartz, cristobalite, and tridymite.

**gas gangrene** A soft-tissue infection caused by contamination of wounds by gas-producing organisms (*Clostridium welchii*) that thrive in the absence of oxygen.

**necrotizing fasciitis** A soft-tissue infection characterized by rapidly spreading inflammation and destruction of connective tissue (muscle fascia) and subcutaneous fat.

**silicosis** Chronic silicosis is a fibrous (scarring) reaction of the lungs caused by inhalation of crystalline silica.

**tetanus** A soft-tissue infection caused by contamination of wounds by the bacterium *Clostridium tetani*. The bacteria

produce a toxin that affects the nervous system, resulting in involuntary muscle spasms.

**traumatic asphyxia** Fixation of the chest by external pressure so the victim is unable to breathe.

**tmpanic membrane** The eardrum, or the thin membrane between the outer and middle ear, which is in contact with the air and transmits sound energy to the auditory apparatus.

**K**NOWLEDGE OF THE causes of death and injury in explosive eruptions has grown alongside the recent advances made by volcanologists in field studies of eruptive phenomena. A whole range of injury agents are involved in major eruptions and these are described for pyroclastic flows and surges, lahars, explosions, tephra falls, and gas emissions. The Earth's biological and geological activities have been linked throughout its long history. Burgeoning human populations have formed high-density settlements in volcanic areas, some of which were barely populated less than 100 years ago. Recent eruptions have revealed how explosive eruptions inflict death and injury, and provide insights into the mitigation measures needed for the management of volcanic crises. This chapter summarizes these observations, many of which have been made in and since the eruption of Mount St. Helens in 1980.

---

## I. INTRODUCTION

The solar system was formed 4.5 billion years ago, and life as microscopic single-celled organisms was born on Earth in an atmosphere of volcanic gases 1 billion years later. Plate tectonics and evolutionary theory have opened our eyes to the uniqueness of our planet and the interdependency of geological and biological processes in sustaining the living Earth. Many scientists now believe that mass extinction episodes in the Earth's remote history coincided with periods of intense volcanic activity, while in more recent times good evidence is found for major eruptions being able to affect global climate, which in today's world, with its large human population, could disrupt agriculture and lead to economic disruption and even famine.

*Homo sapiens* made its appearance in only the last 500,000 years, with much of the brain development of our species having occurred over a quarter of a million years, or the time scale for the building of the existing edifices of major composite volcanoes such as Vesuvius and Mount Etna. Early human populations settled in volcanic areas for many reasons, with the fertility of soils being an important factor, and they learned through religious rituals to coexist with their fiery mountains. Archaeologists have shown how major eruptions over the last few thousand years have had important destructive influences on early civilizations—Santorini in 1600 B.C. (east Mediterranean) and Popocatapetl in 800 B.C. to A.D. 822 (Mesoamerica). But the rapid growth of the world population over the last hundred years has increased the risks to life from volcanic activity as settlements continue to expand into areas at risk, especially those open to the direct impacts of explosive volcanoes. By ignoring the natural forces that have shaped our planet the human species is exposing itself, in its technological hubris, to the risk of more frequent and greater disasters.

---

## II. EARLY STUDIES ON HUMAN IMPACTS OF ERUPTIONS

Curiosity over the fate of victims in volcanic eruptions has always been at the heart of popular interest in the excavations at Pompeii and Herculaneum ever since they began in the 18th century. The younger Pliny's account of the A.D. 79 eruption of Vesuvius is the first recorded description of an eruption and it includes the first writ-

ten report describing the death of a victim, his uncle, Pliny the Elder, who was probably caught on the edge of a pyroclastic surge. In 1863, Italian archaeologists devised a method of preserving the positions of Pompeians in the moment of death; it involved forming a cast by pouring plaster of paris into the cavity that had once contained the victim's body. These eerie replicas led archaeologists to speculate on causes of death and it was widely believed that victims had died by being buried by mud or a heavy fall of ashes. In 1902, two eruptions occurred within 1 day of one another in the Caribbean and would alert scientists to a newly reported and highly destructive volcanic phenomenon. A May 8 eruptive blast from Mount Pelée on Martinique devastated the city of Saint Pierre, killing 28,000 people and leaving only two survivors in the city itself. In Saint Vincent over 1500 people died in another eruption of a "glowing cloud" from La Soufrière containing intensely hot ash and gases. But it was not until the eruption of Mount St. Helens in 1980 that volcanologists were able to extensively study firsthand the eruption of what by then were known as a pyroclastic flow and pyroclastic surge. About 60 people were killed, and for the first time it was possible to perform autopsies on surge victims to establish the mode of death. In the years that followed volcanologists investigated and reinterpreted the eruptive deposits around Vesuvius to show that Herculaneum and Pompeii had been overwhelmed by these phenomena, as well as from the fallout of pumice and ash.

Mount St. Helens also renewed scientific interest in lahars, but it was the lahar tragedy at Nevado del Ruiz in 1984 (see below) that demonstrated the scale of the threat posed by these phenomena and the importance of devising adequate emergency planning and warning measures. This disaster was a spur to the declaration of the 1990s as the UN International Decade for Disaster Reduction (IDNDR).

---

## III. INJURY AGENTS

We can categorize injury agents in general as various forms of energy, all of which may inflict harm in volcanic eruptions. These agents (and examples) are mechanical (lahars and rock/debris avalanches, ballistic ejecta, and tephra falls), thermal (pyroclastic flows and surges), chemical (gases and aerosols), electrical (lightning), and ionizing radiation (radon gas), or the result of too little energy as in the case of asphyxiation (carbon dioxide,

pyroclastic flows, lahars). The explosivity of an eruption is driven by the immense energy stored in the heat of the magma that becomes converted into kinetic energy in the event. But volcanoes can also present hazards in repose periods. People living on the flanks of volcanoes can be subjected to soil gas emissions that can flow into houses, or they may be in areas subject to fumigation by gases discharged in the plume from the crater or active fumaroles. Much more deadly are the hazards of lahars, for they can form without warning even in the absence of eruptive activity since many parts of volcanoes can be unstable because the rock has been weakened by hydrothermal activity and exposure to corrosive gases. The U.S. Geological Survey has extensively studied this hazard around Mount Rainier in Washington State, USA.

#### IV. DEATHS IN VOLCANIC ERUPTIONS

A recent study of records of eruptions since A.D. 1783 found that 220,000 deaths were reported. Most of the fatalities resulted from posteruption famine and epidemic disease (30%), pyroclastic flows and surges (27%), lahars (17%), and volcanogenic tsunamis (17%). These data should be regarded cautiously, as accurate mortality figures are not even obtainable today in natural disasters in developing countries. A span of just over 200 years is not representative of the whole range of eruption types and minimizes the real potential threat from a massive eruption, especially today when concentrations of populations around some volcanoes are much greater than even several decades ago. Estimates suggest that about 500 million people, or 10% of the world's population, are living in areas of active volcanism. In the Vesuvius area alone over 100,000 people could be killed in the first minutes of a major eruption in the absence of warning and evacuation measures. Thus a range of vulnerability factors and mitigation measures need to be considered when estimating mortality risks, and it is quite deceptive to use total deaths in the past as a reflection of the importance of volcanoes in the league of natural hazards. The dominance of winds, floods, and earthquakes in terms of numbers of deaths this century, with only a relatively small number attributable to volcanic eruptions, ignores the fact that volcanoes are capable of unleashing the most destructive forces on earth. It is indeed fortunate for our world that the recurrence rate of major eruptions in populated areas is substantially lower than that of other natural hazards.

Deaths in lava flows are rare. The flows of most effusive eruptions move slowly enough for people to avoid them, but vents may open unexpectedly at a low level on a volcano and rapidly threaten settlements. In the 1928 eruption of Mount Etna, the town of Mascali was destroyed in just over 1 day, the lava moving silently at about 2 m/minute over a 400-m front. Although eruptions of high effusion, low-viscosity flows of lava are rare, two have occurred on Hawaii and one in Zaire during historical times, with velocities of 40–100 km/hour. Possibly 600 people died in the Zaire event in 1977, when the lava lake at Mount Nyiragongo rapidly emptied. Onlookers may face the dangers of small explosions when flows come into contact with seawater and of the ignition of hydrocarbon gases formed by the pyrolysis of organic matter beneath the moving lava and escaping through porous old rock to and beyond the flow margin.

#### V. CAUSES OF DEATH AND INJURY

By studying eruptive phenomena and their impacts on people, we can learn to understand the types of injuries or health effects that can be caused by eruptions, as well as the special problems that may arise in the pre- and posteruptive phases that themselves can last for prolonged periods. Of course, such information is invaluable for health professionals, especially emergency workers, facing a volcanic crisis, who may be responsible for planning the management of casualties. But of much greater importance in terms of preventing loss of life is the application of this information to all aspects of volcanic emergency management, especially community preparedness and evacuation planning. Health sector involvement in volcanic risk management is therefore crucial to any risk assessment process, which with hazard assessment is a key step in setting priorities in emergency planning and long-term mitigation measures. The most common hazards to arise in explosive eruptions are now described, together with their consequences for human safety and health.

##### A. Pyroclastic Flows and Surges

The definitions of pyroclastic flows and surges are controversial, but here surges are regarded for convenience as similar to pyroclastic flows in being mixtures of gas and ash, but being much more dilute (and therefore

much less dense) and hence leaving behind fine ash deposits. The lateral eruption of Mount St. Helens on May 18, 1980, is regarded by most volcanologists as a surge, and certainly in its more distal parts conformed to this basic definition. Over a hundred people were enveloped by the surge cloud which sped out from the volcano at an average velocity of 160 m/s, slowing to about 28 m/s by the time it reached 25 km away. Fifty-two people who were at or near the edge of its run-out survived, mostly with minimal injuries, while 58 people who were closer to the crater died, many being buried by volcanic debris. The area impacted by the surge was wedge-shaped, extending 28 km from the crater, and was clearly demarcated by the flattening of the pine trees in the direction of the surge flow. The surge temperature was 200–300°C, except at its periphery, where it was hot enough only to singe hair and kill or singe the foliage of trees. Most victims caught in the main part of the surge, but who escaped burial, died from exposure to intense heat or, most commonly asphyxiation from breathing overwhelming amounts of ash into their lungs. One man was killed by a falling tree and another by a rock which flew through his car windshield. Two men who were employed logging trees at the time of the event subsequently died in the hospital from lung injury due to inhaling fine, hot ash (acute respiratory distress syndrome).

This remarkable eruption demonstrated the enormous destructive power of surges and highlighted the main human hazards they present. The flattening of the trees might suggest that an immense explosion was involved but, as in a snow avalanche or a strong wind, the destructive impact was due to the dynamic pressure of the surge, which is the product of its density and the

square of its velocity. The human body cannot survive being in temperatures over 200°C for more than a few moments, especially in the fast moving current of a surge. Trying to breathe in the dense cloud of hot ash in the absence of oxygen would lead to unconsciousness in a few breaths, as well as causing severe burns to the respiratory tract. In hotter surges than at Mount St. Helens, the clothes and hair would immediately ignite, but then go out in the absence of oxygen, only to rekindle again when the flow had passed and the body came into contact with fresh air. On the other hand, survival is possible in the more distal parts of a surge if there is adequate shelter to protect against the surge flow and its high temperature, as well as the missiles (rocks, building debris) entrained in the moving cloud of material. As the Mount St. Helens disaster showed, survival under such conditions is possible because the duration of the main impact is not more than a minute or two as the hot cloud convects and creates turbulence in its flow, thereby entraining air and cooling, as well as losing momentum.

More recent findings from victims caught in surge clouds at eruptions of Unzen, Japan (1991), Merapi, Indonesia (1994), and Soufrière Hills, Montserrat (1997), have added further weight to these conclusions from Mount St. Helens (Table I). The implications for future disaster planning apply mainly to human settlements around active volcanoes, such as Vesuvius. Failure for any reason to evacuate in time before a surge strikes would obviously result in many deaths, but there would also be areas in which large numbers of people could survive, especially if adequately protected by houses. Many would be injured, and fires could cause further deaths. The last time a city was struck by a surge was

TABLE I Casualties Due to Pyroclastic Flows in 20th Century Explosive Eruptions

Eruption	No. of deaths	Dead : injured ratio	Survivors after treatment
Pelée, 1902	28,000	230 : 1	163 treated, 123 survived
La Soufrière, 1902	1,565	11 : 1	194 treated, 120 survived
Taal, 1911	1,335	10 : 1	Not known
Lamington, 1958	2,942	44 : 1	70 treated, 67 survived
St. Helens, 1908	58	16 : 1	130 airlifted; 9 required treatment, 7 of whom survived
Unzen, 1991	43	5 : 1	17 treated, 4 with minor burns survived
Merapi, 1994	63	3 : 1	86 treated, 11 dead on arrival at hospital
Soufrière Hills, Montserrat, 1997	19	4 : 1	7 treated, all survived

in the destruction of Saint Pierre in 1902, but this was a lateral blast—a rarer and even more destructive type of event than the surge or flow that occurs in most explosive eruptions. The enormous forces involved were seen in a lateral blast that occurred on Montserrat on December 26, 1997. In the main area of impact all trees and structures were leveled to the ground with every piece of debris blown into the sea!

### B. Lahars

Just as the cataclysmic eruption of Mount St. Helens revealed much about the impact of pyroclastic flows, the eruption of Nevado del Ruiz, Colombia, in 1984 also confirmed the most destructive features of lahars. The eruption melted glacial ice on the summit and the mobilized water-entrained debris scoured out valley bottoms to produce a huge mudflow that ran under gravity toward the towns of Chinchina and Armero. As much as 85% of the town of Armero was left covered in 3–4 m of mud. Official figures put the death toll in the town at 21,015 out of a total population of 29,170. Altogether, there were 22,942 deaths and 4470 injured survivors in this event. In the rescue operation over the following 3 to 4 days, 1244 survivors, mainly from Armero, were admitted to hospitals (138 subsequently died). The main lahar struck Armero at around 11:30 P.M. and was preceded by a river of water that flowed along the streets and was fast and deep enough in places to overturn cars and sweep away people. The height of the lahar as it left the Langunillas River and headed toward Armero was 30 m above the riverbed. It traveled at an estimated velocity of 12 m/s and lasted for 10–20 minutes, during which time most of the town was devastated as buildings collapsed and broke up. Survivors clung to moving pieces of debris or were miraculously swept along on top of the mud. Overall, the inundation of mud lasted about 2 hours, with two slower moving major pulses and several smaller pulses over this period.

The head of the lahar would have been in turbulent motion and contain cobbles and boulders. Most people would have been killed immediately by the severe trauma caused by the collapse of buildings, flying debris, and burial by the slurry mass. As well as the risk of being engulfed, bodies would have been driven against stationary objects, or contorted and crushed by entrained debris such as trees and collapsed parts of buildings, resulting in mutilation and fractures of limbs and skull bones. Stones and other sharp objects would cut

into the skin, causing deep lacerations. Mud was inhaled as it forced its way into the eyes, mouth, ears, and open wounds. The pressure of the mud against the chest would have inhibited breathing in those buried to the neck and caused some deaths by traumatic asphyxia.

This type of flow arising after a volcanic eruption is described as being noncohesive, and in Armero became mostly granular or sandy in consistency, which would explain the presence of so many survivors trapped in the mud. Video film shows how the soft consistency made access to the injured so difficult, with many having to be airlifted from the mud by helicopter. The commonest lesions in the hospitalized patients were lacerations, penetrating wounds, and infections. Many of the wounds were infected on admission. Most of the deaths in hospitals were due to infections including gas gangrene, tetanus, and a form of necrotizing fasciitis, which occurred almost exclusively in victims rescued after being in the mud for 3 days. This dreaded complication was due to normally nonpathogenic soil organisms replicating in wounds in the absence of oxygen, and is resistant to medical treatment.

The eruption of Mount Pinatubo in 1991 left huge quantities of tephra on the flanks of the volcano, and repeated noncohesive flows are formed in the wet season every year when heavy rains readily mobilize the ash deposits. Six years later, the death toll had exceeded 500 and over 40,000 families remained evacuated from the at-risk lowland areas.

The Ruiz disaster has many implications for disaster planners. Emergency workers need to be aware of the special problems of trying to rescue people from lahars, including the danger to rescuers being themselves engulfed in further pulses of material which might come down 1 or 2 hours after the initial wave. Evacuation is the only safe precaution in the face of a continuing threat from an active volcano, but community preparedness should include last-resort advice to move quickly to higher ground if a lahar is on its way. A warning system located on a volcano might give an hour or more's warning of a moving debris flow. Such advice, however, is going to be of little value for the elderly, the sick, patients in hospitals, etc., who are obviously not going to be able to flee, or be moved, in time.

### C. Explosions

Ballistic ejecta and blast/sound waves come under this heading. Minor explosions on volcanoes can be steam

driven, or phreatic, with rocks being hurled without warning from fumaroles or craters. Very powerful blasts may occur in explosive eruptions. Small explosions may occur without warning at lava domes or plugged vents, which can be lethal to volcanologists taking gas samples, as happened at the crater of Galeras, Colombia, in 1994, when six scientists met their deaths.

Most explosive eruptions do not produce shock or blast waves since the release of energy is too slow. The sound of an eruption may not be heard at all close by and instead may undergo atmospheric reflection and concentration to be heard loud enough to rattle windows 100–300 km away, as occurred at Mount St. Helens in 1980. In some eruptions, initial shock velocities exceeding the speed of sound arise when ejecta are released at subsonic velocities and a shock wave can be produced. In some Vulcanian eruptions rocks may be hurled from vents with ejection velocities as high as the speed of sound, and in explosive eruptions at Ngauruhoe and Arenal, maximum ejecta velocities have been estimated as high as 660 m/s. The shock waves from these eruptions are unlikely to directly cause injuries unless an individual is close to the erupting center, when they are most likely to be killed in the eruption itself by being struck or obliterated by erupted material.

Loud sound waves can have enough energy to rattle and even break windows, as when a plane flying overhead breaks the sound barrier, but there should be no serious harm to hearing. Eruptions on Stromboli can rattle windows as far as 6 km away from the crater. The ear is the most sensitive organ to shock wave damage, but the blast required to rupture eardrums or cause more serious internal injuries to other organs will also cause major structural damage to buildings as well. Blast waves of this magnitude at some distance from the eruptive center are only rarely reported in eruptions. A possible example of this was at Mount Asama in 1958, which produced terrific detonations and airshocks which were heard at the foot of the volcano in an area 8–18 km away from the crater and caused damage to windows of houses as far out as 15 km. Seven persons were injured by flying glass. At Galeras, historic eruptions were reported to have generated shock waves that knocked down people as far as 13 km from the crater. In summary, injuries to the tympanic membrane of the ear (eardrum), or the hearing apparatus, from loud noise or blast waves in eruptions are rare, as are deaths and injuries caused by the effect of blast waves on major organs. Blast waves with overpressures of 7 kPa may break windows, and the threshold for rupture of the normal eardrum is 35 kPa.

In contrast, ballistic ejecta thrown out in explosions

present a more common hazard. To be truly ballistic the diameter of clasts of typical density has to be at least 15–20 cm for them to have the momentum to be driven against air resistance in an explosion. Rocks (clasts) of this size, unless they are made of light pumice, are easily capable of causing lethal skull injuries, lacerations, and internal chest and abdominal injuries on impact at their terminal falling velocities. Nevertheless, reports of people being killed from such fallout are rare. Mount Sakurajima, Japan, has been erupting every few days for years, and schoolchildren on Sakurajima Island wear hard hats to walk to school; concrete shelters have also been built in fields and public places. A potentially more serious risk to life is the danger of fire from ballistics since large clasts can readily penetrate galvanized steel or wooden board roofs and shatter in small, hot pieces inside. The maximum recorded range for ballistic hazards is about 5 km from the crater.

#### D. Tephra Fall

Although it has been recognized that the weight of ash from the fallout in volcanic eruptions can bring down roofs and cause serious damage as well as injury, it was not until the eruption of Mount Pinatubo in 1991 that the potential scale of this hazard became fully appreciated. Most of the 300 deaths in this eruption occurred outside the 30- to 40-km radius of evacuation as a result of roofs collapsing under the weight of ash. The ash on the roofs had been made even denser by the addition of rain from Typhoon Yunya on the afternoon of June 15, when the climactic eruption occurred. At the city of Olongapo, about 35 km from the summit, widespread damage to roofs occurred as a result of a deposited depth of ash of 15 cm, which when wet gave a loading of some  $2.0 \text{ kN/m}^2$  (approximately  $200 \text{ kg/m}^2$ ). Typical designed loads for pitched roofs would rarely approach this level. Longer-span roofing fared worse than domestic roofs. Although the causes of death were not studied at Pinatubo, the collapse of roof members may cause direct impact injury to the skull and the body, and the inflowing ash may partially bury and suffocate those inside unless they are able to rapidly extricate themselves. Future eruptions with ashfalls into cities will present a similar hazard, especially as heavy rainfall is known to be triggered by Plinian eruptions. Unfortunately, the best way to mitigate the risk is not clear at present, as shoveling ash off tall house roofs, for example, is not an easy option for householders during a heavy ashfall.

Much concern is usually voiced over the respiratory effects of ash. Ashfalls from explosive eruptions, either falling directly from eruption columns (e.g., Mount St. Helens, 1980) or from coignimbrite clouds generated by pyroclastic flows (e.g., Montserrat, 1996–1998), can contain a large component of particles less than 10  $\mu\text{m}$  in diameter, the size of most concern in health studies of air pollution ( $\text{PM}_{10}$ ). Inhalng ash 5–10  $\mu\text{m}$  in diameter in sufficient amounts will irritate the lungs and provoke symptoms in asthma sufferers. In the weeks after the Mount St. Helens eruption in 1980, increased numbers of asthma sufferers attended hospital for treatment, and patients with chronic respiratory conditions in general were significantly affected, but no deaths were recorded as a result. Rainfall has a dramatic effect in clearing the air and reducing levels of suspended fine ash in the air.  $\text{PM}_{10}$  is routinely monitored in cities in developed countries because of pollution from vehicle emissions. The UK air quality standard for  $\text{PM}_{10}$  is 50  $\mu\text{g}/\text{m}^3$  over a 24-hour averaging period, but concentrations of  $\text{PM}_{10}$  during and after a heavy ashfall can be in the  $\text{mg}/\text{m}^3$  range until it rains!

An important new respiratory hazard was encountered in the eruptions of Soufriere Hills volcano on Montserrat in 1995–1998. The fine, respirable ash that fell in populated areas as a result of the pyroclastic flow activity contained elevated amounts of cristobalite, a form of crystalline silica that can cause silicosis, a disabling and potentially fatal lung disease typically found in miners and quarry workers exposed to high concentrations of siliceous dust. It was shown that the cristobalite formed in the hot lava dome and was invariably present in the ash clouds generated whenever portions of the dome collapsed.

High levels of respirable ash in the ambient air are not in themselves a reason for medically advising the evacuation of a population from an area of heavy ashfall unless the conditions are persistently arid and dry. People should stay indoors or wear lightweight industrial masks during very dusty periods, but children and even adults with bad asthma and other lung disorders could need to be advised to leave temporarily as a precaution. Repeated or persistent exposure to ash in the air containing harmful levels of cristobalite, or quartz, would be an indication for evacuation from, or not returning to, an area, if exposure was likely to continue over years (as with repeated eruptions), rather than months. In all instances a full risk assessment, based on monitoring airborne ash levels in the populated areas, must be undertaken before the appropriate advice can be given.

## E. Gases

The principal volcanic gases are water vapor, carbon dioxide, sulfur dioxide, hydrogen chloride, hydrogen fluoride, and hydrogen sulfide, with minor amounts of radon, helium, hydrogen, and carbon monoxide. Exposure to these gases in active craters or discharging fumaroles can present a hazard to volcanologists monitoring volcanoes unless adequate respiratory equipment is worn. Sudden loss of consciousness and death is a hazard from hydrogen sulfide if its concentration in the air goes above 1000 ppm, especially as its presence is not readily detectable by smell at dangerous concentrations. Fortunately, the usually more abundant and highly irritant acid gases ward off scientists from receiving too much exposure to this lethal gas, and no cases of asphyxiation are known to have been reported among them.

People living close to degassing volcanoes can suffer from air pollution if local topography and weather result in the grounding of plume emissions. Sulfur dioxide is the main gas of interest as it can provoke asthma attacks in asthma patients at the low concentrations that can be found at long distances from the source of emission. The classic example is Masaya in Nicaragua, where an extensive area as far as 30 km from the crater is denuded of normal vegetation as a result of the prevailing winds blowing the plume into a populated area during years of repeated degassing. About 50,000 people live in an area where WHO air quality standards for sulfur dioxide countries have been regularly exceeded in years of strong degassing. Acid rain also has an important impact on soils and vegetation at Masaya. Around volcanoes the principal agent in the formation of acid rain is hydrogen chloride, which is very soluble and immediately taken up by rainwater falling through the plume (this is in contrast to acid rain formation in industrialized countries where it is mainly due to sulfur dioxide which is slowly oxidized to eventually form the more soluble sulfuric acid; nitrogen oxides and nitric acid may also contribute). In Hawaii the abundant white clouds which are formed when the outpouring lava from Kilauea runs into the sea comprises water vapor, hydrogen chloride gas, and hydrochloric acid, which can be blown downwind toward residential areas where acid rain can fall. The visible lava-induced haze in the air is known locally as LAZE. Sulfur dioxide emissions from the eruptive site of Pu'u O'o have also been of concern at times during the period of activity that began in 1983, the haze of gas, sulfuric acid, and ammonium sulfate aerosols being labeled as VOG (volcanic smog).

Poas volcano in Costa Rica went through a period of

increased emissions starting around 1986 and lasting until 1995. The crater lake began to dry out in the dry season and refill with rainwater at other times of the year. The already acidic lake became even more so when its level fell and gas emissions through the lake carried with them highly concentrated acid aerosols that damaged vegetation and provoked respiratory complaints in the local villages exposed to the prevailing winds. The crater lakes of active volcanoes can therefore make the air pollution hazard worse. As well as its impact on humans, volcanic air pollution can impair the health of farm animals since they may spend most of their lives outdoors, and may cause marked deterioration in the outer fabric of buildings.

Gas bursts of carbon dioxide from the ground or from lakes have been agents of disaster in volcanic areas. In 1979 at the Dieng Plateau in Java, 139 people died fleeing from a phreatic eruption when a gas cloud flowed out from a crater above their route of escape. The release had probably been triggered from the ground hydrothermal system by earthquake activity associated with the eruption. In 1986, an estimated quarter of a million tons of carbon dioxide were suddenly released from Lake Nyos, Cameroon, in West Africa, on a still night in August as local villagers were going to bed. About 1700 people and countless numbers of birds and animals died as the denser than air gas flowed down the adjacent valleys. A similar overturning of the lake waters had occurred at Lake Monoun, only 100 km south of Lake Nyos, in 1984 when 35 people died. The source of gas at Lake Nyos is believed to be a soda water spring at the bottom of the 200-m-deep lake. This recharges the lower, well-stratified water layers where the gas is held under high pressure until some unknown trigger provokes an overturning of the lake, releasing the gas rather like opening a champagne bottle.

Soil gas emissions are another way in which carbon dioxide from the underlying magma can present a ever-present hazard in volcanic areas. Studies at Vulcano (Italy), Furnas (Azores, Portugal), and Mammoth Mountain (California, USA) have shown that enough gas may be released into structures to present an asphyxia hazard to occupants by accumulating in confined spaces or parts of buildings below ground level. Carbon dioxide will induce distressed breathing and eventual loss of consciousness at levels of 5–10% in the air, but it is odorless, and at concentrations above 10–15% can cause immediate loss of consciousness after a few breaths and before the individual becomes aware of any danger. Carbon dioxide is a carrier of radon gas from the magma, and at Furnas levels of radon daughters can also accumulate in the indoor air in sufficient concentrations to be

hazardous to health. Radon acts as a cause of lung cancer in conjunction with tobacco smoke. The ground emissions of carbon dioxide may increase without warning during periods of magma unrest or unfelt seismic activity, and so the hazard should be regularly monitored. In pre- and posteruptive phases of Vesuvius there are reports of people having been overcome by carbon dioxide in cellars or caves on the volcano's flanks.

Undoubtedly, more attention needs to be given to the hazard of carbon dioxide in areas of volcanic and hydrothermal activity. Where volcanic gas emissions are considered to be a health and safety hazard the concentrations should be carefully monitored as part of a risk assessment. The hazard of gases in eruptions has tended to be ignored by volcanologists since gas bursts such as that at Dieng have so far proved to be rare events. However, gas releases may have occurred in past eruptions and in some unexplained incidents but gone unrecognized.

---

## VI. CONCLUSION

Understanding the human impacts of eruptions requires interdisciplinary studies of the behavior of volcanoes in periods of repose as well as during and after eruptive events. The lessons learned are essential for devising mitigation measures to reduce losses of life in future explosive eruptions. For such events of great destructiveness but low probability, mitigation measures need to be interdisciplinary-based and placed in the context of sustainable development, rather than seen among a host of what are usually the more immediate and pressing health priorities for decision makers. Computer numerical simulation models may become important tools for predicting injury impacts in the future. With the continuing rise of global urbanization it will be the management of volcanic crises in cities and other densely populated areas that will present the major challenges for scientists and disaster workers in the next millennium.

## GLOSSARY

**CDT** The reference standard for expressing sulfur isotope values in delta ( $\delta^{34}\text{S}$ ) notation. This standard is troilite from the Canon Diablo Meteorite and has been assigned a value of 0 by definition. In the delta notation (see PDB below), the relative isotopic differences are expressed in permil (o/oo) or parts per thousand.

**isotope** An element may have several isotopes which differ in mass but have the same number of protons in the nucleus as the element itself. For example, carbon ( $^{12}\text{C}$ ) has six protons and six neutrons in the nucleus, giving it an atomic mass of 12. The other stable isotope of

carbon ( $^{13}\text{C}$ ) has six protons and seven neutrons for an atomic mass of 13. The difference in mass between the two isotopes of carbon leads to slightly different behavior during chemical reactions, thereby leading to changes in the ratio of one isotope to another. Usually, the relative abundance of isotopes of the same element differs greatly. For example,  $^{13}\text{C}$  is about 1.1% and  $^{12}\text{C}$  is 98.9% of the total carbon on Earth.

**juvenile gas** A volatile phase that was formed or present during the initial accretion of the Earth and degassed to the Earth's surface through time.

**MORB** Midocean ridge basalt.

**pCO<sub>2</sub>** The partial pressure of carbon dioxide gas in the atmosphere (taken in this paper as 365 ppmv).

**PDB** The reference standard for expressing carbon isotope values in delta ( $\delta^{13}\text{C}$ ) notation. This standard is Peedee Belemnite and is assigned a value of 0 permil by definition:  $\delta^{13}\text{C} = [({^{13}\text{C}}/{^{12}\text{C}}_{\text{samp}})/({^{13}\text{C}}/{^{12}\text{C}}_{\text{PDB}}) - 1] \times 10^3$ .

**T**HE PROCESSES THAT lead to outgassing of the Earth include: (1) midocean ridge volcanism; (2) hot spot or intraplate (plume) volcanism; (3) island arc or convergent plate margin volcanism; (4) subduction and collision zone metamorphism; and (5) volatile loss during burial diagenesis of sediments. Outgassing

processes 1–4 are strongly influenced by mass transport in the plate tectonic cycle, coupled to the upwelling of partially molten mantle material beneath midocean ridges, plate subduction, and associated arc volcanism over subduction zones. In fact, many geochemical cycle models have assumed that the total rate of outgassing of carbon dioxide scales linearly with seafloor spreading rate and/or subduction rate. This article is concerned primarily with presenting estimates of the present fluxes of volatile carbon (mainly carbon dioxide) and sulfur (mainly sulfur dioxide) from subaerial and submarine volcanism, and an assessment of their fluxes and impacts on the carbon and sulfur geochemical cycles now and in the past.

mantle. For example, the total inventory of carbon in the crust-ocean-atmosphere at present is about  $8 \times 10^9$  Tmol ( $1\text{mol} = 10^{12}$  mol). If we stipulate that this carbon accumulated as the result of some average rate of juvenile CO<sub>2</sub> degassing over the past  $4 \times 10^9$  years, we would obtain an estimate of 2 Tmol year<sup>-1</sup>. If today's juvenile CO<sub>2</sub> outgassing rate is only between 10 and 20% of this average flux, as might be suggested by the rare gas data mentioned above, the present rate of juvenile CO<sub>2</sub> outgassing could be 0.2–0.4 Tmol year<sup>-1</sup>. As will be shown below, this is only a very small proportion of the total carbon flux required to balance the preindustrial global carbon cycle and less than about 20% of the estimated contribution of CO<sub>2</sub> by subaerial volcanism today.

---

## I. INTRODUCTION

The flux of primary (juvenile) volatile gases to the surface (outgassing) from the Earth's interior has, over time, supplied much of the inventory of carbon, sulfur, water, and other elements in the crust, ocean, and atmosphere. It has been suggested that this outgassing accompanied volcanism and that the volatiles were added gradually over geologic time to Earth-surface reservoirs. Subsequently, it has been argued that rapid outgassing may have occurred in the early stages of Earth accretion, when intense bombardment during bolide impacts may have maintained a hot interior, vigorous mantle convection, and a "steam" atmosphere. Some workers have suggested that a substantial proportion of the Earth's volatiles could have been derived from the impactors themselves. Nonetheless, following the early accretionary phase of the Earth, the flux of heat from the Earth's interior decreased progressively, resulting in surface cooling, condensation, and rain-out of the early steam atmosphere and formation of an early ocean. Most models for degassing history assume that the outgassing rate has been proportional to the heat flux from the Earth's interior. The Earth does continue to outgas primary volatiles, as evident from measurable fluxes of <sup>3</sup>He, a primordial volatile element, occurring today. For example, on the basis of primordial rare gas (<sup>20</sup>Ne and <sup>26</sup>Ar) distributions in the atmosphere at present it is estimated that these rare gases are presently outgassed at about 10–15% of their average rate through geologic time.

It is thought that the contribution of juvenile carbon to the outgassing of carbon dioxide at present is minor, and that continued recycling and degassing of carbon dioxide is necessary as a part of the plate tectonic crust/

---

## II. MAKING GLOBAL ESTIMATES OF VOLCANIC VOLATILE C AND S FLUXES

Estimates of volcanic emissions are based on measurements for relatively few volcanoes. For carbon dioxide emission rates this is particularly critical because the measurements must usually be made directly from the volcanic eruption plume by using instruments aboard light aircraft.

At issue in extrapolation to global degassing rates are the emissions accompanying eruptive activity of subaerial volcanoes as compared to longer-term "passive" degassing and the number of volcanoes or events that must be sampled in order to extrapolate the results to a global average emission rate. A further consideration is what area of a given volcano is included in measurements of degassing rates—for example, summit crater versus flank degassing. Another possible normalization factor useful in making these estimates is the volcanic explosivity index (VEI). Clearly, it is not a simple procedure to quantify emissions, particularly for carbon species, which cannot be measured in any straightforward way. Volcanic sulfur emissions are somewhat easier to quantify because of the variety of remote sensing techniques that may be applied. These methods include instruments such as COSPEC (correlation spectrometer) which can be deployed at the active crater or flown in a plane, or even driven under a gas plume in a car. The atmospheric loading of sulfur dioxide can be measured by satellite-based methods (e.g., a total ozone mapping spectrometer, or TOMS). In some cases, direct measurements of sulfur outgassing are made, and carbon dioxide emis-

sions are estimated by measuring or assuming an average sulfur/carbon mass ratio in the volcanic gases.

The problems confronting those who extrapolate emissions from one or more volcanoes to global emission rates are best illustrated for the case of carbon degassing estimates for Mount Etna (Italy). This volcano, which is not associated with a subduction zone, is by far the major CO<sub>2</sub>-emitting volcano on Earth at present. Degassing occurs both during episodic eruptive events mainly from summit craters and as diffuse emissions from the flank of the 25-km diameter volcano. The carbon isotope composition ( $\delta^{13}\text{C}$ ) of CO<sub>2</sub> from the volcano's flank is similar to that of summit CO<sub>2</sub> and indicates a magmatic source. The total Mount Etna carbon dioxide flux has been estimated at 1 Tmol C year<sup>-1</sup>, with about 0.6 Tmol year<sup>-1</sup> from summit crater degassing and the remainder from diffuse flank emissions. The CO<sub>2</sub> degassing rate from this one volcano represents between 30 and 60% of global volcanic CO<sub>2</sub> emissions (see below). How do we treat this single volcano which is clearly unusual today?

Such problems have received considerable attention in the literature. For example, some workers have shown that there is merit in treating volcanic volatile emissions as power-law distributions rather than Gaussian distributions. Rates of many geologic processes appear to obey power laws. A power-law distribution indicates what measurements are necessary to satisfactorily predict global degassing rates; in other words, the community does not have to measure every volcano to assure that a given flux is known adequately. The adequacy of emission estimates depends on the power-law exponent. Raw CO<sub>2</sub> emission data suggest that the power-law exponent is much less than 1 and that large volcanoes dominate degassing; analysis of emissions from the 20 largest volcanoes would, therefore, provide a good estimate of degassing rates associated with volcanism. If

this reasoning holds up, we may be able to effectively estimate global degassing rates for many gaseous species with the proper distribution of measures. Such considerations have also been applied to volcanic SO<sub>2</sub> emissions.

### III. PRESENT VOLCANIC CARBON FLUXES

A number of recent estimates for volcanic emissions of CO<sub>2</sub> for subaerial and marine volcanism are given in Table I. These estimates must be used with caution because they are based on relatively few direct measurements of emission rates and depend on a variety of techniques and assumptions outlined briefly in the preceding section. The range of CO<sub>2</sub> emission estimates for subaerial volcanism (mainly subduction-zone-related volcanoes but including continental rift and subaerial extensions of midocean ridge and/or hot spot volcanoes) is narrower than that for submarine volcanism at midocean ridges. Subaerial volcanoes are estimated to emit a minimum of 1.47 Tmol year<sup>-1</sup> to a maximum of 3 Tmol year<sup>-1</sup> at present.

However, the CO<sub>2</sub> outgassing accompanying submarine volcanism at midocean ridges is not well quantified (range of estimates is 0.23–16.4 Tmol year<sup>-1</sup>). It seems likely that present CO<sub>2</sub> emissions from this source lie between 2 and 8 Tmol year<sup>-1</sup>. Many estimates of degassing rates use fluxes of noble gases to estimate degassing rates of other gases. Models for melt-vapor partitioning of noble gases can account for most observed noble gas ratios in midocean ridge basalt (MORB), hot spot volcanoes, the atmosphere, and various elements of the mantle. However, the noble gas technique for degassing estimates may lead to inaccurate estimates because of

TABLE I Estimates of Annual Subaerial Volcanic Carbon Dioxide Emissions at Present

Volcanic CO <sub>2</sub> flux (Tmol year <sup>-1</sup> )	Method	Source
0.33	Arc volcanic flux	Le Cloarec and Marty (1991)
1.8	Extrapolation (to 60 volcanoes) of measured flux (7 volcanoes)	Gerlach (1991)
1.47	Passive and active crater degassing, extrapolation from measurements using S/C ratios in gases	Williams <i>et al.</i> (1992)
1.5	C/ <sup>3</sup> He in arc volcanoes with extrapolation	Varekamp <i>et al.</i> (1992)
1.8	Plume volcanism (magmatic CO <sub>2</sub> content and eruption rate)	Varekamp <i>et al.</i> (1992)
2.0–3.0	Power-law distribution of nine volcano flux measurements	Brantley and Koepenick (1995)

the wide variety of gas solubilities, which would lead to different degassing histories for each gas considered. Nonetheless, the  $C/^{3}\text{He}$  ratio of gases emitted from the midocean ridge may provide a reasonable indication of the  $C/^{3}\text{He}$  ratio in degassed mantle because the experimentally determined solubilities for  $\text{CO}_2$  and  $^{3}\text{He}$  are similar. If we adopt a reasonable  $C/^{3}\text{He}$  outgassing ratio at the midocean ridge (MOR) of  $2 \pm 0.5 \times 10^9$  (range 1–8) and a  $^{3}\text{He}$  outgassing flux of  $1140 \pm 150 \text{ mol year}^{-1}$  we obtain an estimated  $\text{CO}_2$  degassing flux for MORs of  $2.3 \pm 0.6 \text{ Tmol year}^{-1}$ . A similar  $\text{CO}_2$  degassing flux of  $2.5 \text{ Tmol year}^{-1}$  has been obtained based on a simple estimate using a  $20 \text{ km}^3 \text{ year}^{-1}$  MORB emplacement rate with a  $\text{CO}_2$  concentration of 1900 ppm. However, in more recent carbon cycle models the MOR  $\text{CO}_2$  flux is estimated at only  $1.5 \text{ Tmol year}^{-1}$ . The estimates in Tables I and II suggest that the emissions from arc volcanoes, plume volcanoes, and the midocean ridges are roughly equivalent at about  $1.5 \text{ Tmol year}^{-1}$  each.

---

#### IV. PRESENT VOLCANIC SULFUR FLUXES

Some recent estimates of volcanic sulfur emissions, primarily as  $\text{SO}_2$ , are given in Table III. These estimates are primarily for subaerial volcanic sources. The sulfur emission rates to the atmosphere for subaerial volcanism range from 0.2 to  $0.8 \text{ Tmol S year}^{-1}$ . Most of the estimates are on the lower side of this range. The most recent estimate for subaerial volcanic S outgassing is

based on the most comprehensive data set of volcanoes (72) and measurements and suggests a time-integrated annual sulfur flux of  $0.33 \text{ Tmol year}^{-1}$ .

The estimated S flux associated with submarine volcanism is more uncertain by far than that for subaerial volcanoes. The midocean ridge hydrothermal circulation is primarily a sink for sulfur, at least initially, with seawater sulfate precipitating mainly as anhydrite in the oceanic crust. At  $380^\circ\text{C}$ , sulfate is more or less completely removed from seawater and a flux from seawater to oceanic crust has been estimated as high as  $3.8 \text{ Tmol S year}^{-1}$ . This is certainly an upper limit (see below). There is a flux of sulfur to seawater from oceanic crust, in the form of  $\text{H}_2\text{S}$ , at hydrothermal vents. The sulfur isotopic composition of this reduced sulfur is consistent with the hypothesis that it is *magmatic* sulfur leached from basalt by the high-temperature hydrothermal fluids. This flux is probably less than about  $0.1 \text{ Tmol year}^{-1}$  (Table III), consistent with the estimated loss of S during low-temperature alteration of the upper oceanic crust ( $0.08 \text{ Tmol S year}^{-1}$ ). We will nominally refer to this as the volatile sulfur flux from the mantle to seawater. No direct degassing during actual submarine basalt eruptions has been observed or measured, although this flux could be important, as it is in subaerial basalt eruptions. The rather large flux of sulfur from seawater to oceanic crust in the form of anhydrite requires an equally large sulfur flux from some other source, as yet poorly understood or quantified (see discussion of sulfur cycle below).

---

#### V. IMPACT OF VOLCANISM ON THE GEOCHEMICAL CYCLES OF CARBON AND SULFUR

##### A. The Preindustrial Carbon Geochemical Cycle

The estimated present rate of outgassing of carbon dioxide from all sources—volcanism, metamorphism, and geothermal activity—is generally thought of as the amount required to balance the carbon fluxes required in weathering and carbonate precipitation (Figure 1). This value is at least  $6 \text{ Tmol year}^{-1}$  and has been estimated to be as high as  $6.6 \text{ Tmol year}^{-1}$ . If we take the reasonable “median” estimates of present-day  $\text{CO}_2$  degassing associated with subaerial (ca.  $1.5 \text{ Tmol year}^{-1}$ ) and submarine (ca.  $2.5 \text{ Tmol year}^{-1}$ ) volcanism, we find that the flux is about two-thirds of that needed to balance

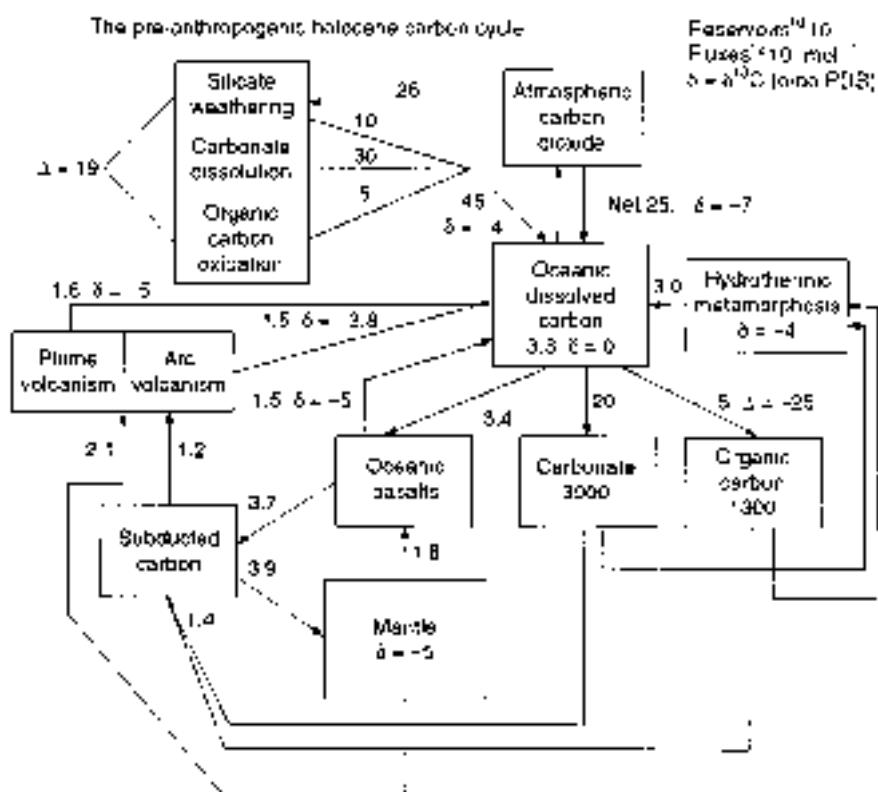

FIGURE 1 Reservoirs ( $10^{18}$  mol C), fluxes (Tmol  $\text{year}^{-1}$ ), and carbon isotopic values ( $\delta^{13}\text{C}$  in permil, PDB) in a balanced carbon cycle as estimated for the preindustrial Holocene. Most reservoirs and fluxes after Kump and Arthur (1997) and Berner (1994); volcanic  $\text{CO}_2$  fluxes adopted from Tables I and II (see text).

the carbon cycle. However, it has also been suggested that alteration of oceanic crust represents an additional carbon sink of 2–3.7 Tmol year<sup>-1</sup>. If the upper estimate is valid, the basalt alteration source would demand all of the estimated midocean ridge carbon flux and more, and would increase the total CO<sub>2</sub> outgassing flux required to balance the carbon cycle to about 10 Tmol year<sup>-1</sup>. In other words, the metamorphic-hydrothermal flux would have to be 6 Tmol year<sup>-1</sup>, assuming a total volcanic flux of 4 Tmol year<sup>-1</sup> given above.

Metamorphism and hydrothermal activity associated with collisional orogenies could supply substantial fluxes of CO<sub>2</sub> to the atmosphere. These sources presently are being more explicitly considered in carbon mass balance models. For example, it has been estimated that hydrothermal activity associated with Eocene metamorphism of the North American cordillera alone could have resulted in degassing of a substantial 3 Tmol C year<sup>-1</sup>. Today, it appears that the present major areas of metamorphic-hydrothermal degassing are focused in extensional regions, and the estimated global flux of CO<sub>2</sub> by this mechanism is roughly equivalent to estimates of that derived from volcanic degassing. Therefore, it seems reasonable that the estimated total volcanic CO<sub>2</sub> flux is about 50% of that required to balance the preindustrial global carbon cycle as presently understood. Thus, variations in past rates of volcanic outgassing are probably important to the carbon cycle and to considerations of global climate variation.

## B. The Preindustrial Sulfur Geochemical Cycle

The volcanic volatile sulfur flux, mainly as SO<sub>2</sub> evolving from silicic magmas (and not including venting of hydrothermal sulfide at the MOR), is generally not explicitly included in global sulfur cycle models. However, the volcanic sulfur flux is important. The sulfur isotopic composition of this source is somewhat depleted (ca. +1–3 permil, CDT) relative to average weathering-related sulfate (+6–7 permil, CDT) transported by rivers. Also, the estimated volcanic sulfur flux amounts to between 20 and 40% of the preanthropogenic riverine sulfur (Figure 2), excluding the contribution of recycled sea salt sulfate and other forms of rapidly recycled sulfur such as DMS (dimethyl sulfide). In other words, subaerial volcanism may continually add new sulfur to the exogenic system, and/or that sulfur may balance the loss through subduction (see below). The present-day sulfur cycle is imbalanced because of the very large pollutant sulfur source to rivers and atmosphere and, ultimately,

to the oceans. However, the preindustrial long-term sulfur cycle can be balanced as shown in Figure 3. This version of the sulfur cycle uses the estimates of pyrite and evaporite sulfur contributions to the river dissolved sulfate flux and the subaerial volcanic sulfur flux adopted for this contribution (Table III). Mass and isotopic steady state then requires a pyrite to oxidized sulfur burial ratio of 9:1, with a relative sulfur isotopic difference between these burial outputs of 33.3 permil (so-called Δ<sup>34</sup>S<sub>pyr-evap</sub>). This assumed value of Δ<sup>34</sup>S<sub>pyr-evap</sub> lies within the range of published estimates.

A major uncertainty in the sulfur cycle lies in how seawater–basalt interactions are treated. As discussed briefly above, the cycling of seawater through oceanic crust probably results in wholesale extraction of seawater sulfate from seawater into the crust as anhydrite at temperatures of 150–200°C. This contention is supported by laboratory experiments and theory, the absence of sulfate in high-temperature hydrothermal vent fluids, and anhydrite veins observed in the upper oceanic crust recovered in Deep Sea Drilling Project drillholes. This apparently limits the amount of sulfate that penetrates into the higher temperature regions of the hydrothermal system, and there is apparently little direct reduction of seawater sulfate to sulfide at higher temperatures. Thus, the sulfide that does emanate from high-temperature vents is hypothesized to be primarily of magmatic origin. Further support for this concept of seawater sulfate cycling is that the anhydrite in veins has sulfur isotopic values very similar to those of seawater sulfate. Unfortunately, the sulfur isotopic composition of sulfide emanating from high-temperature vents is consistent with either a magmatic source, possibly contaminated by seawater sulfate drawn in and reduced during seafloor venting, or with reduction of seawater sulfate within the hydrothermal system at 300° C.

Nonetheless, the mass flux of sulfate (0.8 Tmol S year<sup>-1</sup>) estimated to enter the near-ridge crest hydrothermal system (estimated using axial, high-temperature venting of  $2.9 \times 10^{13}$  kg seawater year<sup>-1</sup> at a sulfate concentration of  $28 \times 10^{-3}$  mol kg<sup>-1</sup>) is much larger than the flux of sulfide out of oceanic crust estimated for axial vents (about 0.1 Tmol S year<sup>-1</sup>). Thus, we must appeal to redissolution, with increasing age, of much of the anhydrite precipitated from seawater in oceanic crust (Figure 2). Then, this sulfate must diffuse or be advected into seawater with little or no difference in sulfur isotopic composition in order to maintain mass and isotopic balance in the sulfur cycle. On the basis of this consideration, it is not clear whether the presumed magmatic contribution, ultimately from the mantle, is a net contribution to the global sulfur cycle or must be considered as part of the compensation for longer-term seawater

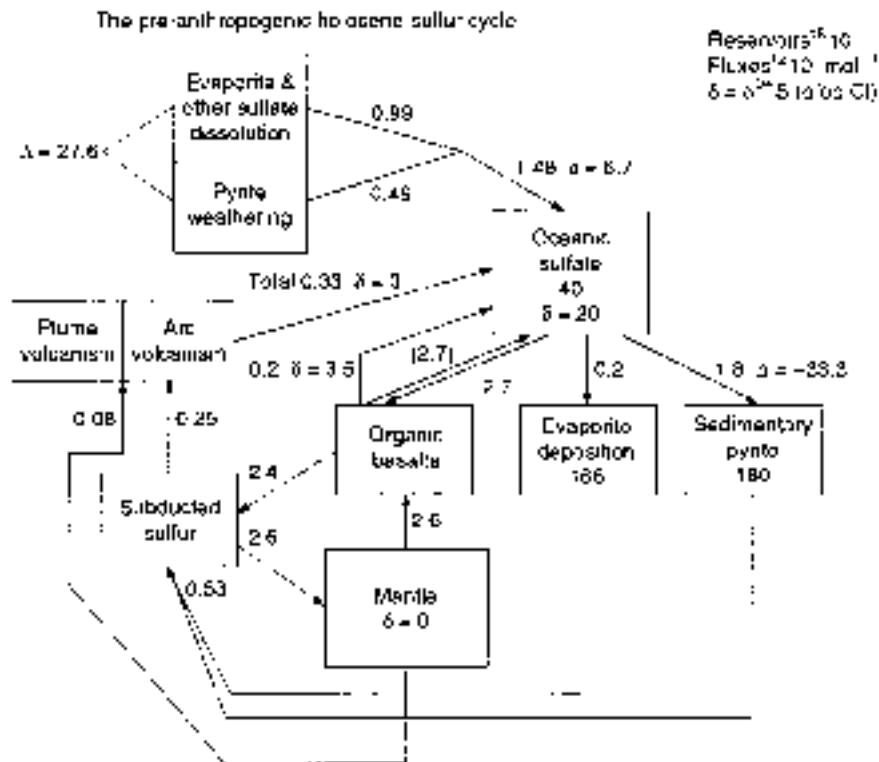

FIGURE 2 A balanced (mass and isotopic) preindustrial Holocene sulfur cycle, with reservoirs ( $10^{18}$  mol S) and fluxes ( $T\text{mol year}^{-1}$ ). Note that the fluxes of sulfur that represent short-term cycling mainly from ocean-land-ocean, such as DMS production and atmospherically cycled sea salt, are not included. The flux of sulfur representing weathering accepts the value estimated for “natural” (less, DMS, volcanic, and recycled sea salt contributions) sources to rivers (Berner and Berner, 1996). The sulfur isotopic composition ( $\delta^{34}\text{S}$ ) of riverine sulfate is taken as 6.68 ‰ (CDT), assuming that one-third derives from pyrite oxidation and two-thirds from evaporites and other sources of sulfate (e.g., Berner and Berner, 1996). The mass and isotopic compositions of oceanic sulfate, sedimentary evaporite, and pyrite reservoirs are from Holser et al. (1989). Sizes of other reservoirs and fluxes are summarized in this article.

sulfate storage in the oceanic crust. Of course, if most of the hydrothermal sulfide is precipitated in chimneys and other metal-sulfide-bearing sediments near the ridge axis and not later oxidized, the hydrothermal sulfur flux would not be a consideration in the longer-term sulfur cycle; it would continue to be associated with oceanic crust. Thus, most models treat the midocean ridge-related system as having no net influence on the global sulfur cycle. A net flux of  $0.1 \text{ Tmol S year}^{-1}$  from the “mantle” to seawater at the MOR is adopted for this article.

If the estimates of exogenic sulfur sources and sinks tabulated in Figure 2 are valid then volcanic sulfur sources might be considered part of the mass flux required to balance extraction of seawater sulfate at midocean ridges. This could be the case if either a significant remainder of the anhydrite stored in subducted upper oceanic crust or subducted sedimentary sulfide minerals contribute to volatile sulfur fluxes from volcanic arcs.

If, however, we assume that the submarine sulfur cycle is in balance in the long term, we must accept that the average annual preindustrial fluxes of sulfur to pyrite and evaporite reservoirs are as shown in Figure 2. If not, the preindustrial sulfur cycle is not balanced, in terms of either mass or isotopic composition.

## VI. POSSIBLE VARIATIONS IN VOLCANIC EMISSIONS AND THEIR EFFECTS IN THE PAST

At the suggested present-day rate, the entire crust-atmosphere-ocean C inventory could have accumulated in about  $3 \times 10^9$  years. Some workers favor continuous slow degassing of  $\text{CO}_2$  throughout Earth’s history without recycling back to the mantle. However, it is likely

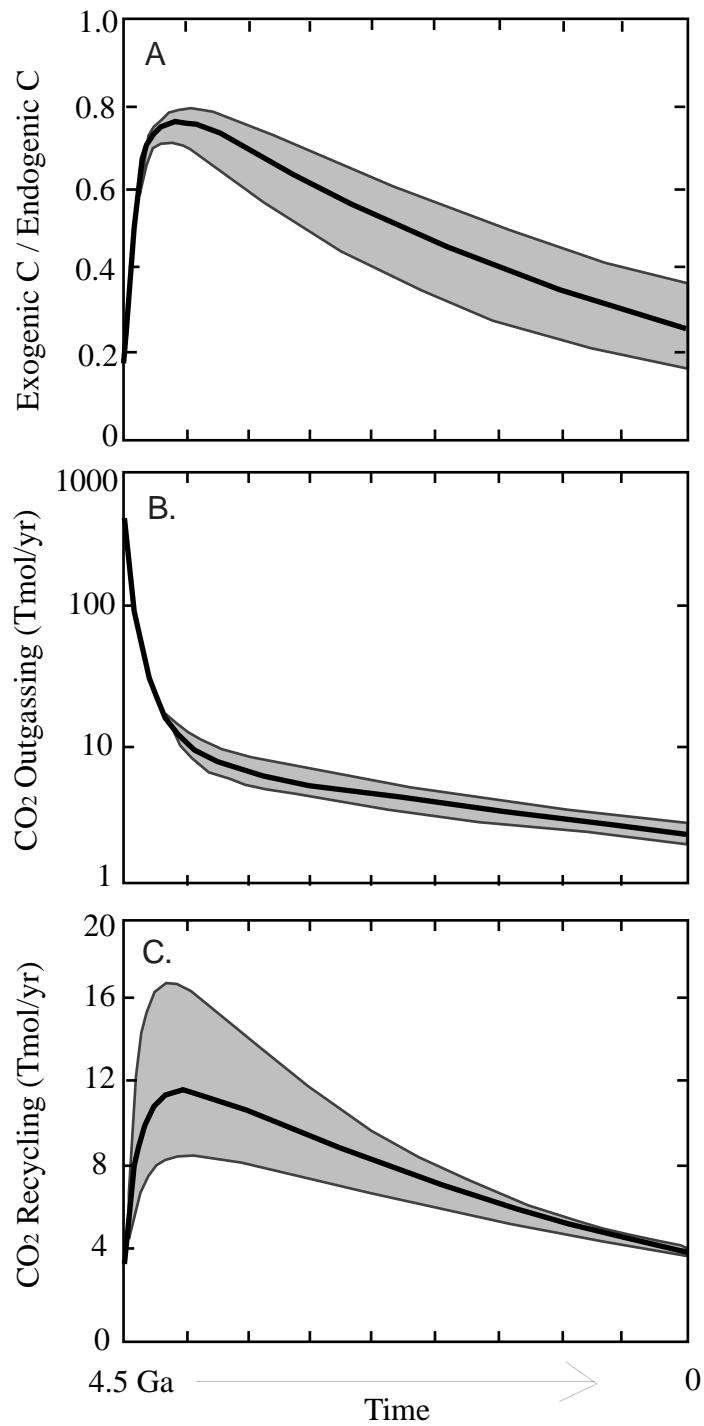

FIGURE 3 Results of simulations of the carbon degassing history of the Earth modified after Zhang and Zindler (1993). (A) Ratio of carbon in exogenic reservoirs (crust-ocean-atmosphere) to that in degassed (upper) mantle. (B) rate of CO<sub>2</sub> degassing from the upper mantle for the past 4 Ga. (C) The CO<sub>2</sub> recycling rate representing carbon subducted back to the mantle. Shaded area represents model uncertainties.

that recycling by subduction has occurred because the mantle contains significant CO<sub>2</sub> that could be degassed (estimated at ca.  $1.8 \times 10^{10}$  Tmol), representing about 72% of the total carbon in the crust-ocean-atmosphere plus upper (degassed) mantle. This is in sharp contrast to the suggested severe depletion of noble gases in the degassed mantle.

The recycling of CO<sub>2</sub> back to the mantle during subduction is reasonable in light of the amount of carbonate in veins in altered oceanic crust, which is estimated as perhaps 3.7 Tmol year<sup>-1</sup> entering subduction zones today. This subducted carbon flux may have been higher in the past because of much higher subduction rates, assuming that carbonation during MORB alteration occurred at all times in the past. The advent of pelagic carbonate sedimentation about 200 m.y. ago could have increased the total carbon being subducted, and thereby compensate, or even overcompensate, for the diminishing rates of subduction toward the present.

Figure 3 provides the results of one of several numerical model simulations which portray CO<sub>2</sub> outgassing and recycling rates for the Earth through time. The curves presented are for a model simulation driven by assumed rates of outgassing for noble gases, which depend on an assumed model for the thermal evolution of the Earth. The numerical simulation assumes a constant average carbon content in subducted crust and sediment, but requires that the recycling rate constant be sufficient to produce a degassed mantle at present with 72% of its original carbon content as required by available carbon inventory estimates discussed above. The final rate of carbon outgassing equals that estimated for outgassing at the midocean ridge today. Note that this simulation produces an initial crust-ocean-atmosphere carbon inventory for the Archean that is considerably higher (by a factor of about 2.5) than today's inventory. Required recycling rates of C into the mantle by subduction are higher than the degassing rate over the past  $3.5 \times 10^9$  years. The results of this particular simulation suggest that the amount of carbon in the crust-ocean-atmosphere reservoir has progressively decreased since the early Archean and is still decreasing today!

The results of this numerical simulation may also generally account for the evolution of  $p\text{CO}_2$  over the past 4 Ga envisioned by other workers. The suggested very high CO<sub>2</sub> outgassing rates would have produced a high Archean  $p\text{CO}_2$  (perhaps 1–10 bars) that would have offset the much lower solar flux to the Earth at that time and produced rather warm surface temperatures. Evidence for glaciations at about 2.5–2.3 Ga and again at about 0.8–0.6 Ga probably required substantially low-

ered  $p\text{CO}_2$  consistent with much reduced CO<sub>2</sub> outgassing and high rates of carbon recycling to the mantle in the model (Figure 3) for that interval of time.

This model has appeal as a general model for the Earth because it has reasonable implications for cycling of other elements as well. Nonetheless, if, as portrayed in the simulation, the carbon recycling rate has exceeded the outgassing rate for several billion years by a factor of 2 or so, we are left with a dilemma. There must be other sources of CO<sub>2</sub> that provide for the flux required by weathering. In this consideration we assume for the moment that there is no net CO<sub>2</sub> source or sink associated with the organic carbon subcycle, that is, that in the long term ( $10^7$ – $10^8$  years) organic carbon burial is offset by organic carbon oxidation.

In various versions of models for the carbonate-silicate geochemical cycle, total CO<sub>2</sub> flux to the atmosphere from magmatic-metamorphic sources is scaled to the seafloor-spreading rate inferred from long-term variations in sea level. Doing so results in CO<sub>2</sub> outgassing rates about 1.65 times higher 100 million years ago than at present. This is essentially the result obtained when using estimates of the seafloor creation rate for the Cretaceous, which suggest oceanic crustal production at rates as high as 1.8 times the present rate. These models treated CO<sub>2</sub> degassing as a long-term rate increase, and the impact on global mass balances included other CO<sub>2</sub> sources such as metamorphic and geothermal processes.

Using a simple carbon cycle box model (Figure 1), we can illustrate the possible effects of a sudden and prolonged (0.5 m.y.) 1.5× increase in volcanic CO<sub>2</sub> outgassing on  $p\text{CO}_2$  and  $\delta^{13}\text{C}$  of oceanic total dissolved inorganic carbonate and consequent changes in  $\delta^{13}\text{C}$  of marine organic carbon. If such variations occur, they have the potential to leave an imprint on the geologic record, but calculations show that the effects are subtle and complex (Figure 4) and likely to be masked by changes in burial outputs or other factors. Figure 4 indicates that the greatest change in carbon cycle indicators might be expected in the carbon isotopic composition of organic matter produced by marine phytoplankton because the fractionation of carbon isotopes by such organisms is sensitive to  $p\text{CO}_2$  changes. The increase in  $p\text{CO}_2$  (Figure 4A) that results from the simulated volcanic CO<sub>2</sub> outgassing produces greater relative carbon isotope fractionation by the phytoplankton—an approximately 2 permil decrease in  $\delta^{13}\text{C}_{\text{org}}$  (Figure 4B). Because the burial of this  $^{13}\text{C}$ -depleted organic matter drives changes in  $\delta^{13}\text{C}_{\text{carb}}$ , the increase in relative carbon isotope fractionation damps the response of the oceanic dissolved carbon reservoir to the addition of  $^{13}\text{C}$ -depleted volcanic CO<sub>2</sub> (which has a  $\delta^{13}\text{C}$  similar to riverine dis-

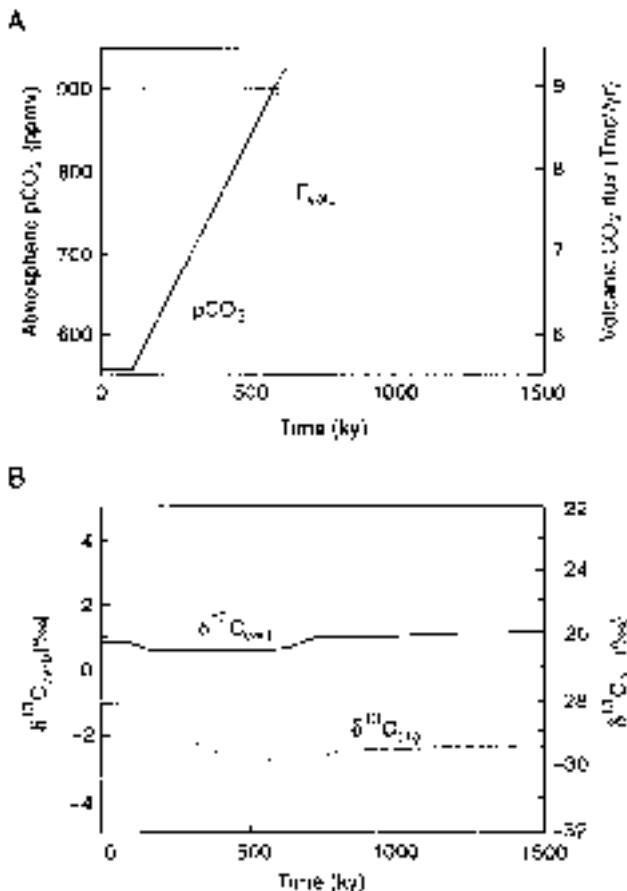

FIGURE 4 Carbon box model results using values for fluxes and reservoirs shown in Figure 1. The plots illustrate the effects of a  $1.5 \times$  increase in volcanic  $\text{CO}_2$  outgassing for 0.5 m.y. (modified after Kump and Arthur, 1999). (A)  $F_{\text{volc}}$  is history of volcanic  $\text{CO}_2$  flux stipulated in the model and  $p\text{CO}_2$  is the computed atmospheric  $\text{CO}_2$  concentration. (B)  $\delta^{13}\text{C}_{\text{carb}}$  represents oceanic dissolved inorganic carbon reservoir and  $\delta^{13}\text{C}_{\text{org}}$  is the carbon isotopic composition of marine phytoplankton organic carbon.

solved carbon; Figure 1). Thus, we might detect the effects of such relatively short-term volcanic events in the geologic record by the differential response of  $\delta^{13}\text{C}_{\text{org}}$  and  $\delta^{13}\text{C}_{\text{carb}}$ .

However, the question is whether such significant changes in rate of outgassing really do occur. For example, LIPs (large igneous provinces) represent significant increases in eruptive activity, largely through extrusion of flood basalts, either subaerially or as a submarine process. One such event, the latest Cretaceous, earliest Tertiary Deccan Traps of India, has been examined in several studies for potential effects of resulting enhanced rates of  $\text{CO}_2$  and  $\text{SO}_2$  emissions. Using the volume of

basalt erupted of  $3 \times 10^5 \text{ km}^3$  and assuming that 80% of this was erupted in just  $1 \times 10^6$  years, one can calculate a cumulative  $\text{CO}_2$  yield of 0.68 to  $4.6 \times 10^4 \text{ Tmol C}$ . This corresponds to an average rate of 0.007 to 0.05 Tmol C year $^{-1}$ , corresponding to an average basalt eruption rate of  $0.3 \text{ km}^3 \text{ year}^{-1}$ . For this calculation a  $\text{CO}_2/\text{SO}_2$  ratio (0.5–2.6) was assumed for volatile degassing measured or estimated for basaltic eruptions of Laki and Surtsey and the  $\text{SO}_2$  emission rate per  $\text{km}^3$  of basalt erupted (about 0.04 Tmol S/km $^3$ ) in the 1738 eruption of Laki. Using these data, even at eruption rates of  $3 \times$  the average estimated for the Deccan Traps, the annual carbon and sulfur fluxes to the atmosphere would only represent an increase of about 3–6% over present subaerial volcanic carbon emissions, and 5–20% over present subaerial volcanic sulfur emissions. Other workers have used a degassing rate of 0.06 Tmol km $^{-3}$  extruded for the Deccan Trap basalts and arrived at a total outgassing of  $\text{CO}_2$  of  $0.6\text{--}2.0 \times 10^5 \text{ Tmol}$ , using larger basalt volume estimates. Nonetheless, a carbon cycle model predicted a very small (<40 ppmv) increase in  $p\text{CO}_2$  during the Deccan eruption event, assuming that the eruptions ensued over at least 0.5 m.y.

The impact of changes in rates of volcanism or individual volcanic events, such as LIP episodes, on total rates of  $\text{CO}_2$  outgassing appears to be relatively minor. Inasmuch as sulfur emission rates are, on average, a factor of about 0.4 to 0.7 times that of  $\text{CO}_2$  emissions in subaerial volcanoes, and as little as a factor of 0.15 of  $\text{CO}_2$  emanated from MORB settings (on the basis of vesicle gas compositions), the general effects of LIP episodes on sulfur cycling should be relatively minor. Figure 5 illustrates the effects of doubling volcanic sulfur degassing rates for  $1 \times 10^6$  years. This simulation uses

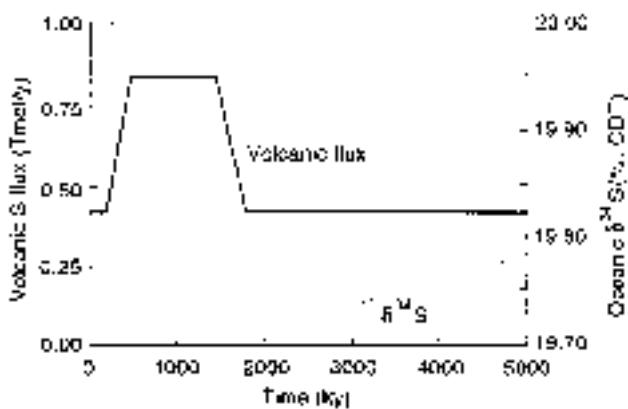

FIGURE 5 The response of oceanic sulfate sulfur isotopic composition to a doubling of volcanic S flux of 1 m.y. (shown as a curve), using values of fluxes and reservoirs in Figure 2.

the flux and reservoir sizes for the sulfur cycle shown in Figure 2 and assumes that, with the exception of the volcanic S flux, there is no other change. Because the oceanic residence time of sulfur is long ( $10^7$  years) relative to the interval of the perturbation, the doubling of volcanic sulfur degassing causes only minor changes in the sulfur isotopic composition (Figure 5) and concentration (not shown) of oceanic sulfate. Thus, with these assumptions, only the effects of more sustained and massive changes in volcanic sulfur input would be observable in the ocean geochemical record.

## VII. CONCLUSIONS AND FUTURE RESEARCH

Mass and stable isotopic fluxes of volatiles from volcanic activity must be taken into account when attempting to balance the modern carbon and sulfur geochemical cycles. At present, volcanic-associated outgassing must be about 50% of the total flux of carbon dioxide to the atmosphere. However, the proportion of the carbon dioxide volatile flux assigned to each of the arc-volcanic, midocean ridge, and metamorphic sources remains uncertain. Past variations in long-term outgassing rates assume some scaling between volatile production and crustal production rate at midocean ridges and/or subduction rates. Such longer-term variations could have produced an increased  $p\text{CO}_2$ . Although it has been proposed that increases in the rate of carbon dioxide outgassing may have been associated with rapid formation of LIPs, which in turn could have caused short-term (e.g.,  $<10^6$  years) perturbations of  $p\text{CO}_2$  and climate, the impact of these events remains questionable.

The volcanic volatile sulfur flux, mainly as  $\text{SO}_2$  evolving from silicic magmas (and not including venting of hydrothermal sulfide at midocean ridges), amounts to between 20 and 30% of the preanthropogenic riverine sulfur flux, excluding the contribution of recycled sea salt sulfate and other forms of rapidly recycled sulfur. The impact of volcanic sulfur outgassing at midocean ridges and associated with submarine volcanism in general is difficult to assess because of uncertainties in the values assigned to hydrothermal sources and sinks. The subaerial volcanic sulfur flux is generally not explicitly included in global sulfur cycle models, but is important in that the sulfur isotopic composition of this source is depleted (ca. +2 permil, CDT) relative to average weathering-related sulfate (+7 permil, CDT) transported by rivers. Short-term (e.g.,  $< 10^6$  years) variations

in volcanic sulfur flux have little impact on the global sulfur cycle. However, long-term changes in volcanic sulfur emanations potentially could have produced some of the observed changes in the sulfur isotopic composition of the oceans through time.

## GLOSSARY

- aerial plankton** The usually small plants, plant parts (e.g., seeds, spores), and animals with little or no powers of locomotion that drift passively in the air.
- arthropod** Segmented animal with an exoskeleton and jointed legs.
- biota** The full complement of species of living things (fauna, flora, and, strictly, micro-organisms) of a region.
- carnivore, carnivorous** Feeding on animals.
- collembolans** Small wingless insects known as springtails which have a forked springing organ on the abdomen; most live on or near the soil surface and feed on decomposing organic material.

**community** A well-defined assemblage of interacting species, almost always including both animals and plants.

**crepuscular** Active at or around dawn or dusk.

**cyanobacteria** Photosynthetic bacteria formerly known as blue-green algae.

**debris avalanche** Debris flow resulting from the partial collapse of the volcano's edifice.

**ecosystem** The system formed by the interacting living organisms of an area and the nonliving environment with which they in turn interact.

**effusive eruption** An eruption in which lava is poured out of a vent or fissure.

**extirpation** Destruction, wiping out.

**frugivore, frugivorous** A feeder on fruit, feeding on fruit.

**guild** A group of species having similar feeding habits and thus similar roles in the community; for example, taking animal prey in midair or feeding exclusively on grasses.

**heliophilous** Adapted to grow in full sunlight.

**herbivore** A plant eater.

**invertebrate** An animal without a backbone; the term includes arthropods (q.v.), worms, and mollusks, among others.

**kipuka** A Hawaiian term, now in general use, for a habitat "island" of land not covered by ash or lava, in an ash- or lava-covered landscape.

**legume** Plant of the pea family, Leguminosae.

**macrobiota** The biota of an area, excluding micro-organisms.

- magma** Molten rock produced by the partial melting of material in the layer of the Earth below the outer crust. Becomes lava when extruded.
- microsite** The space occupied by a single plant.
- monitor** A large lizard-like reptile of the family Varanidae. In this article, the five-banded monitor, *Varanus salvator*, often over a meter in length.
- neuropterans** Insects of the order Neuroptera, including lacewings and ant lions.
- nitrogen-fixing** The incorporation of atmospheric nitrogen into living tissues and its chemical conversion into a form that can be used by the organism.
- omnivore, omnivorous** A mixed feeder whose diet includes plant and animal food.
- photosynthesis** The process whereby green plants use light energy trapped by the green pigment chlorophyll to build up carbohydrate from carbon dioxide and water, releasing oxygen.
- primary colonist** A species that becomes established in an environment devoid of life; the first species in a primary succession (q.v.).
- primary producer** A species that synthesizes organic matter from inorganic materials; green plants are primary producers.
- primary succession** Succession (q.v.) on an area previously devoid of life.
- pumice** Highly vesiculated, low-density, glassy rock formed when large volumes of gas expand within magma (q.v.).
- pyroclastic flow** Very hot, glowing mass of solid fragments ejected by a volcano, cushioned on escaping gases and moving at high speed.
- scavenger** An animal that feeds on the dead remains or waste material of animals and plants.
- scoria** Loose rubble of pieces of pumice.
- strombolian/vulcanian** Eruption style or phase in which intermittent eruptions send plumes of steam, gas, and ash several kilometers high and cause a rain of fine ash downwind.
- succession (biological)** The sequence of natural stages (in structure and species representation) of a developing ecosystem such that one community gradually replaces another.
- successional mosaic** The pattern resulting when an area has a number of smaller patches at different stages of succession (q.v.).
- symbiotic** Pertaining to a close, usually obligatory, association of two species living together.
- tephra** Solid fragmented matter ejected by a volcano, often extremely rapidly; includes ash, lapilli ("little stones"), and larger bombs, and blocks.
- tertiary consumers** Consumers (usually animals) of species

that eat species that consume primary producers (q.v.).

**vascular plants** Plants with well-defined tracts of fluid-filled supporting cells within their tissues; seed plants and ferns are the largest groups.

**zoochorous** Dispersed by animals, either internally, in their guts, or by adhering externally.

**O**VIOUSLY VOLCANIC ACTIVITY can damage and may even destroy natural living communities, and yet from even a cursory examination of volcanoes it is equally clear that sooner or later life returns to devastated areas. From studying oceanic volcanic islands we know that, given time, rich and complex land communities may develop on substrates that must have been devoid of life, certainly of land life, when they first broke the sea's surface. Here I review some of the destructive and constructive processes involved in the interaction between volcanoes and living communities.

---

## I. THE EFFECTS OF VOLCANIC ACTIVITY ON LIVING COMMUNITIES

The damage caused to living organisms by volcanic activity clearly depends on the type of eruption. Damage may result from the effects of volcanic gases, explosive blast, debris avalanche, pyroclastic flows, mudflows (lahars), lava flows, or tephra (including ash) fall. The extent of the damage varies with the physical and chemical properties of the eruptive products, time of year, amount of snow and ice cover, behavior of the organism, type of vegetation, and even time of day of the eruption. Because so many factors are involved, generalizations about eruptive effects are unwise, and extrapolations from one environment or one eruption to others are likely to be unreliable.

### A. Types of Volcanic Damage

Perhaps the most well-known case of the effect of toxic gases on a biota is the 7-month-long effusive eruption of Lakagigar in Iceland in 1783. Emissions of SO<sub>2</sub>, SO<sub>3</sub>, CO<sub>2</sub>, and HF destroyed birch woods 200 km away from the vent and were mainly responsible for so stunting

the grass crop that about 70% of the livestock and 20% of Iceland's human population perished.

The effects of blast and of debris avalanche were clearly seen at Mount St. Helens (northwestern USA). Trees were felled and the vegetation razed to the ground by the blast, which reached supersonic speeds as it expanded, creating a substrate on which only primary colonists could become established. An area of almost complete devastation—the “blast zone”—could be clearly identified, and its bare mineral surfaces were the slowest to recover; 5 years after the eruption this zone appeared much as it did in the immediate aftermath. The 45-m-deep, 2-km-wide debris avalanche moved at about 75 m/s and extended for 25 km, breaking off and transporting plants and covering mature forest in a new raw substrate composed of particles the size of sand grains. The few survivors were the result of regrowth from roots and suckers of plants transported by the avalanche.

Pyroclastic flows (previously known as *nueées ardentes* or “glowing clouds”) are infamously dangerous. Such a flow is a turbulent, ground-hugging, expanding cloud of gas-charged incandescent particles that are fluidized (i.e., moving freely among themselves, flowing like a liquid). It moves silently and rapidly (up to 100 km/hour) on a cushion of its own continuously exsolved gases. These flows are lethal to animals and death comes rapidly; they are the most dangerous to humans of all volcanic effects. Pyroclastic flows are a feature of Peléan eruptive phases, named after the 1902 eruption of Mount Pelée, on the island of Martinique in the West Indies, where a pyroclastic flow rolled silently and rapidly down the volcano’s slopes to engulf and incinerate the town of St. Pierre and its 30,000 inhabitants. In the same year, 144 km to the south, pyroclastic flows from the eruption of La Soufrière devastated about a third of the island of St. Vincent’s surface, and killed about 1350 people of the (fortunately) sparse population. The depth of ash and pumice varied from a few centimeters on steep slopes to 27 m in some valleys. In 1911 on Taal volcano on Luzon in the Philippines, such flows totally destroyed the vegetation over most of Volcano, an island in Taal’s crater lake, although the ash deposits were neither very deep (up to 2 m) nor very hot. The zone devastated by 1968 pyroclastic flows on Mayon volcano, also on Luzon, Philippines, was surrounded by a “seared zone” from a few meters to over 2 km wide, within which all animals were killed outright, presumably from burns or by inhaling the fluidized incandescent cloud. On the inner parts of the zone all vegetation was charred and many trees stripped of foliage on the side facing the crater; at the zone’s outer edges plant leaves were shriveled and browned.

Mudflows (lahars) can also be devastating. They are sometimes formed when dust clouds rising from pyroclastic flows trigger torrential rainstorms within minutes of the passage of the flow, as on Mayon in 1968. Burial in mud halts photosynthesis and exchange of gases in plants, and surviving animal herbivores are deprived of access to food.

Clearly, lava flowing over an area will obliterate and kill all organisms on the surface that are unable to move out of its path, but the damage, although extreme, may be sharply circumscribed. Anak Krakatau is an active volcano that emerged from Krakatau’s submarine caldera in Sunda Strait, Indonesia, in 1930 and was self-sterilized in 1952. Trees only a meter from the edge of its 1993 lava flow, which obliterated trees in its path, survived without evident ill effects.

From his review of large Icelandic eruptions, Thorarinsson concluded that the extent of damage from ashfall depends on the fall’s thickness, timing, and chemical and physical properties. A depth of 10 cm of freshly fallen tephra (ash) caused farms to be abandoned for a year, ash 15–20 cm deep led to abandonment for from 1 to 5 years, and where the thickness was 20–50 cm, settlements were abandoned for decades. In the 1902 eruption of Santa María in Guatemala, coffee plants that received less than a meter of tephra recovered within a year, although grazing areas were seriously damaged where it was over 15 cm thick. In contrast, during the 1912 Katmai eruption in Alaska most trees in an area covered by 50 cm or more of tephra were killed, and a 30-cm-thick layer at Kodiak, 160 km from the volcano, caused extreme crop damage.

Ash can be removed quickly by erosion, of course, and rain erosion can be quite rapid on volcanic slopes. For example, after the 1964 Irazu eruption in Costa Rica, at least a third of newly fallen tephra was lost from the upper slopes within a year, and more than half the tephra deposited around La Soufrière in 1902 had been eroded to the ocean within 6 months.

Susceptibility to damage by tephra and gases also varies widely between species. On Mount St. Helens, in grassland communities that had received ash deposits more than 1 cm thick, plant damage through overloading and necrosis (tissue and cell death) was greatest among species with a prostrate habit or with broad, sheathing leaves; annual and perennial grasses, for example, were unaffected. Living communities in subalpine meadows that were covered by less than 20 cm of tephra in spring appeared to have returned to normal by the end of summer. Regrowth penetrated the ash layer, and insects, birds, and terrestrial vertebrates recolonized as the plant cover was re-established. In Alaska, small mam-

mals such as squirrels, mice, and marmots were killed by tephra falls less than 10 cm deep. Massive ash deposits, several meters thick, can maintain temperatures of from 600 to 800°C for weeks and months, and the survival chances of macrobiota under such conditions are practically zero.

Ash fallout can have a significant and special effect on insects. The Mount St. Helens tephra, for example, consisted of a fine powder of volcanic glass fragments which acted as a natural insecticide. They abraded the insects' thin, outer layer (epicuticle) of external skeleton, which is waxy and waterproof, thus causing fatal dehydration. Insects exposed to the tephra in the laboratory lost water and died within 30 hours. In the field, Colorado potato beetles died within 24 hours of exposure unless they happened to have been washed clean by overhead irrigation systems, and an economically significant outbreak of grasshoppers was controlled by tephra fallout, obviating the need for insecticide treatment. In contrast to these effects, however, on Sertung, an island some 2–3 km away from the vent of Anak Krakatau, daily fallout of basaltic ash in 1996 had no obvious effect on grasshoppers, carpenter bees, or dragonflies. Physical texture of the particles is of prime importance for ash to have insecticidal effects.

The chemical nature of tephra fallout also may be an important determinant of its lethality. Sometimes chemical poisoning occurs. Fluorine, for example, becomes concentrated on the surface of ash grains, and fluorine poisoning of livestock is a fairly common hazard in Iceland.

Size of the tephra particles also affects the extent of damage, and is important in relation to fluorine poisoning. Whereas coarse-grained wind-blown tephra, such as that of the 1875 Askja eruption in Iceland, can destroy plants by tearing, finer-grained ash, deposited further afield, may carry fluorine concentrations 20 times higher (at 20,000 ppm) than those of the coarser ash falling close to the source. In contrast, at Mount St. Helens, fodder containing up to 10% by weight of ash was not toxic to livestock, milk production and growth rate of cattle were unaffected, and day-old chicks given tephra as 30% by weight of food suffered no additional mortality. Over most of the fallout area plants and animals seem to have resumed normal activities fairly quickly.

The timing of the ashfall may be crucially important. A thin, fine-grained layer deposited during the plant growing season may have a greater effect than a thicker layer falling at other times. As illustrated at Mount St. Helens, tephra falling onto a winter covering of snow or ice under which the living community is often dormant will have far less damaging effects than would the

same fallout in the summer, when the community is active and lacks this protection.

### B. Local Survival

The distinction between total eradication and the local survival of a few individuals, although seemingly trivial, is important to the biologist considering the process of revival of a natural community. Spread from survival foci, what Edwards termed "survival and revival," is very different from colonization of a "clean slate" by immigrants from outside the devastated area, and the species assembly process as well as the nature of the resultant community may be quite different in the two cases. In the recovery of vegetation, survival of pre-existing plants is generally more important than the establishment of new immigrants.

On a number of volcanoes rapid erosion of ash by heavy rainfall has facilitated recovery. There are many reports of herbaceous plants (i. e., having a nonwoody green stem) surviving burial to depths of over 30 cm, and the large grass *Saccharum spontaneum* survived burial to 1.5 m in New Guinea. After the Katmai eruption most plant species withstood burial for a year or more. Herbaceous plants may take up to 4 years to penetrate the deposit, and a growth from of "runners" or adventitious roots is related to survival ability. The growth of woody plants may sometimes actually increase after burial in tephra, in spite of the low concentration of available nutrients. On Hawaii, Paricutin (Mexico), Katmai, and Taal, trees have recovered from a 2-m-thick tephra fall.

As on Mount St. Helens, but much more slowly, on the Galapagos Islands' Fernandina volcano erosion of an 8-m-thick layer of tephra facilitated the reestablishment of plant communities, and these survivors were important as pioneers. On Mount St. Helens a grylloblattid insect (grylloblattids are a small group of cricket-like wingless terrestrial insects confined to cold damp situations) and 15 species of nonballooning spiders (in which juveniles are not dispersed aerially, suspended on trailing silken threads) were recorded as surviving by sheltering in rock debris in an area where tephra fallout was 10 cm deep, and whereas only a single ant species was collected at depths of about 50 cm, 9 species were found at depths averaging a third of this. Those buried trees that had their roots exposed by rapid rain erosion resprouted, stabilizing the ash slopes. But on this volcano the question of survival was complicated in some cases by the possibility of local reinvasion from

contiguous unaffected areas. For example, lupins, which appeared early on the cooled pyroclastic flows, may have grown either from viable seed that survived the eruption in sheltered sites or from wind-borne seed dispersed into the area after the eruption (perhaps less likely, for their seeds are rather large and heavy). A carabid (ground beetle) with reduced eyes and wings that lives underground was captured at a pyroclastic site in 1983 and may have been a survivor, but even in this case immigration by wind was thought to be a more likely explanation.

After the eruption of Krakatau in 1883 there was no question of immigration from contiguous unaffected reservoirs; the recovery was either from survivors or from colonists arriving from over the sea. Nevertheless the question was the topic of considerable international debate for some years. The speed and nature of recovery of communities on Krakatau's remnant and its two closely neighboring islands strongly indicated that the macrobiota had been eradicated and recovery was from new colonists. The two Dutch biologists who studied the reassembly of Krakatau's biota, Docters van Leeuwen and Dammerman, both argued that the first organisms to appear were not those likely to have survived by persisting underground, for example, but those with good dispersal powers. The question of bacterial survival under deep hot ash deposits is unresolved and must be regarded as a possibility, and some species of soil nematodes are also capable of surviving very high temperatures. In contrast to the Krakataus, the first plants to appear on Sebesi, an island about 15 km from Krakatau which received a much shallower deposit of ash in 1883, were largely species with underground storage organs or vegetative structures; they were survivors, not new colonists. Dammerman pointed out that on Krakatau any animal survivors would not have found sufficient food in the devastated landscape and would soon have perished. This point is illustrated by observations of ants on Komagatake volcano, Japan. Two species of *Formica* were active a days after ash fell in the 1929 eruption but lasted for only another 11 days.

A plant or animal may be spared the effects of lava flows or lahars by being in the lee of natural obstacles, by being on high ground when the flow will move around it, leaving a *kipuka* (Figure 1), or of course, in the case of animals, by moving out of the way. Crannies and overhangs may also provide shelter from tephra fallout and obstacles may protect organisms in their lee even from the effects of pyroclastic flows. In 1883, Ketimbang village in Sumatra was devastated by pyroclastic flows traveling 40 km across the sea surface from Krakatau, whereas just a kilometer or so away, in the lee of the intervening island of Sebesi, there was no such damage.

FIGURE 1 Kipukas, "islands" of vegetation not covered by lava, in Marchena Island's crater, Galapagos Islands, 1967.

Seed "banks" can survive in the soil under ash deposits, and plants have been grown from seeds covered for more than 60 years by 106 to 175 cm of Anak Krakatau ash. Had such seeds been exposed by erosion, germination would have been possible *in situ*. Whether seeds could remain viable under the very much deeper (30 m or more) and therefore more persistently hot layers resulting from cataclysmic eruptions such as those of Thera (Cyclades, Mediterranean), Krakatau, or Long Island (off New Guinea) is doubtful.

On Mount St. Helens at the end of the first growing season no vascular plants were found in regions that had been subjected to pyroclastic flows. In the blast zone, however, ferns, grasses, horsetails, rosette biennials, and other plants with underground stem tips survived extensively, but the only woody species surviving were those resprouting from basal buried portions of stems. Almost all survivors in upland habitats after the first year were perennials which had sprouted from underground plant parts present in the pre-eruption soil and penetrated the ash cover, or which were protected from the effects of the blast and associated ash deposits by packed snow. Snow also protects small organisms from desiccation and heat, and moistens and compacts tephra, making it less likely to abrade arthropod cuticle. A few plants of about 20 species survived the debris avalanche by regrowth from roots and suckers transported by the landslide, and lupins were shown to be capable of regrowth from root fragments 10 cm long.

Animals' lifestyles may also protect them. The Mount St. Helens eruption had no long-term impact on birds; they quickly returned to devastated areas except where trees had been killed. Many of the small mammals that survived the event are burrowing species, and in May

1980 they had the additional protection of snow cover. Even within a single guild, lifestyle may be of vital importance. Leaf-feeding caterpillars inevitably ingest ash lying on the surfaces of their food leaves, and those feeding on hairy leaves that retain ash suffered significantly greater mortality than those feeding on vegetation, such as grasses, from which ash tends to be shed. Time of day was also a factor on Mount St. Helens. Had the volcano erupted 6 hours earlier than 08:30, many animals would have been out of their burrows, exposed on the surface.

Aquatic insect larvae withstand the effects of accumulated ash on their exoskeleton well, the ash deposits quickly dissipating in water. Within 5 years of the Mount St. Helens eruption several fish and amphibian species that had become locally extinct had returned, and invertebrate faunas of even drastically disturbed streams had returned to 80% of their original diversity within 10 years. Amphibians proved to be surprisingly resilient, returning even to the pyroclastic zone, with some populations recovering quickly.

Recovery clearly varies between damage zones on the same volcano. On Mount St. Helens, 7 years after the eruption, 6 of the presumed 32 resident small mammal species had returned to the zones of pyroclastic and debris flow, 15 had reoccupied the areas of tree blow-down, and 22 were found in the area of tephra fall.

San Benedicto is an island of the Revillagigedos group, about 700 km from the Pacific coast of Mexico. Bayard Brattstrom reported that in 1952 it carried an oceanic biota; mammals, reptiles, amphibians, and freshwater fish were completely lacking and there was only one species of land bird (a rock wren). There were several species of seabirds and the island was almost completely covered in 11 species of grasses and low herbs. The only invertebrate that happened to have been recorded on the island was a land crab.

In August 1952, a highly explosive eruption on the island created Barcena volcano. Within a day the cone was 335 m high and activity continued until February 1953, when the whole island was covered in ash and pumice almost a meter deep, and no plants were visible. Some 20,000 seabirds perished. Six plant species survived by resprouting from surviving root stocks or germinating from buried seeds that were exposed by subsequent erosion. Three of these species became extinct but three others colonized the island. The rock wren survived only until December 1952, but after a slow start the seabirds recovered well, and there are now seven species. The land crab also survived.

Recovery need not be uniform over the whole volcano of course. On Anak Krakatau a successional mosaic was

FIGURE 2 Anak Krakatau, 1985, from the north. The North Foreland, in the foreground, was largely grassland at this time, when the Northeast Foreshore and East Foreland (foreground of Figure 5) were *Casuarina* woodland. Rakata, Krakatau's remnant, is to the south of Anak Krakatau, and the southern tip of Panjang is seen to the east.

apparent by 1992. The developing communities on the three coastal ash forelands were not at the same stage of biological succession. The North Foreland, which from 1979 to 1989 was largely grassland (Figure 2), was rapidly changing to *Casuarina* woodland and lagged by about 17 years behind the East Foreland, where *Casuarina* woodland was already beginning the transition to mixed forest (Figures 3 to 5). The Northeast Foreshore was intermediate between the two. This mosaic appears to have resulted from differentially damaging eruptions in 1972 and 1973 and involved not only plants but also

FIGURE 3 East Foreland of Anak Krakatau, with Panjang Island in the distance, in 1971. Cover of grass *Imperata cylindrica* and patches of the taller grass *Saccharum spontaneum*, with some *Casuarina equisetifolia* trees. (Photograph by Kyoji Yoda.)

birds, spiders, butterflies, tropical fruit flies, and invertebrate communities feeding on microepiphytes (algae, fungi, and lichens living on the bark and leaves) of the *Casuarina* trees.

On Anak Krakatau the species of resident land birds, mammals, reptiles, and butterflies that persisted after a 3-year episode of almost continuous strombolian/vulcanian activity in the 1990s were predominantly those that had been early colonists three times on the Krakataus after destructive eruptions. The fact that early colonizers tend also to be those that persist after disturbance may mean that they tolerate volcanic disturbance better than later colonists, or simply that they recolonize more rapidly after local extinction.

## II. PRIMARY COLONIZERS OF NEW VOLCANIC HABITATS

One of the central questions of ecology is the origin of communities. This comprises a number of subsidiary questions, one of which is how the primary plant and animal colonists become established on abiotic (nonliving) substrates. After an extirpating eruption, biologists have a rare opportunity to monitor the natural reassembly of a biota from the beginning. Systematic observations on the new, sterile habitats formed by lava flows and tephra deposits provide the framework for an attempt to answer the first of these questions: how pioneers become established in such forbidding environments.

### A. Starter Nitrogen

Volcanic substrates are unweathered, without organic content to begin with, and often with poor availability of water and phosphorus. Nitrogen must come from a source other than the substrate itself. This may be (as at Paricutin) the ammonium chloride of fumaroles, but is more usually the atmosphere, via a number of possible intermediaries: rain water (if plant cover reduces wasteful runoff); photosynthetic bacteria known as cyanobacteria (and formerly as blue-green algae) that “fix” or incorporate atmospheric nitrogen into their living substance, converting it chemically into a form that they can use; plants (mostly legumes) that have symbiotic nitrogen-fixing bacteria in their root nodules; or water- or wind-borne organic material.

The first colonization of the barren surfaces by macroscopic organisms is often by animals arriving by air. Terrestrial arthropods, particularly ballooning spiders and small weakly flying or wingless insects, can be lifted into the air under certain atmospheric conditions and carried for considerable distances. Fallout of this arthropod component of the “aerial plankton” can be considerable and diverse: for example, in the Canaries, on deposits on the snowfields of Teneriffe’s 3718-m-high volcano Pico Tiede, the Ashmoles found individuals of 37 families, 17 of them Diptera (flies), at densities reaching 18 individuals/m<sup>2</sup>.

Such fallout is not restricted to volcanoes of course; it probably occurs on all mountains, but is most noticeable on those (including extinct volcanoes) which have barren upland areas, above the plant zone or covered with snow, ice, lava, or ash. On new volcanoes, however,

the fallout often takes on a special significance, providing an input of organic resources, including nitrogen, from outside the barren area, which can serve as a basis for an important pioneer food chain. On the ash-covered lava flows of Anak Krakatau, in 10 days water traps set for arthropod fallout collected more than 70 species of arthropods representing 10 orders. Diptera and Hymenoptera (which comprises the ants, bees, and wasps) made up more than half the catch, and beetles were represented by 10 families. Aerial fallout onto the island was shown to be considerable; 20 individual arthropods were collected per square meter of trap surface per day and it was estimated that over the 10 days at least half a million arrived on the 2.34 km<sup>2</sup> of the island's surface. Many of these may have originated on the adjacent islands some 2 km away, but many others probably had traveled at least 44 km from the mainlands of Java and Sumatra.

On Mount St. Helens, aggregations of arthropod, spore, and seed fallout were thought to contribute to the fertility of the pyroclastic flow and tephra substrates and to facilitate the early development of micro-organisms and plants by providing nitrogen (and nutrients). John Edwards estimated conservatively that from 2 to 10 mg dry weight of fallout/m<sup>2</sup>/day represented nonresident arthropod bodies, and in the summer the total organic (arthropod and plant) fallout was 5–15 mg dry weight/m<sup>2</sup>/day. The nitrogen content of this deposit decreased by 25% within the first 17 days, then stayed fairly constant for the following 2 years. This longer-lasting nitrogen was presumably locked in the chitin and sclerotized protein of the arthropod cuticle, which remained more or less intact over the period. In contrast, phosphorus declined by 73% in the first 17 days, and by a total of 83% over the whole period. It was estimated that for the years 1983–1985 the mean net seasonal (150 days) input of nitrogen was 81.8 mg/m<sup>2</sup>, and for phosphorus 5.5 mg/m<sup>2</sup>.

Sprent noted that although, at its maximum, nitrogen fixation by bacteria could supply all the nitrogen necessary for the growth of some angiosperms, plants that have root nodules containing nitrogen-fixing bacteria are rare in early stages of primary succession. He thought that this was probably not because of difficulty in acquiring their symbiotic bacteria, but rather that their seeds, necessarily rich in starter nitrogen, are too heavy for rapid or long-distance dispersal. And in fact cyanobacteria, including forms that fix nitrogen, were the first colonists of Rakata (the remnant of Krakatau's explosive 1883 eruption), Surtsey (North Atlantic), La Soufrière, Paricutin, and Vesuvius since its 1944 eruption. In most cases these were probably wind dispersed,

although on Surtsey they were found particularly in the splash zone. On La Soufrière (1456 m), where persistent cloud maintains hydration, they provided a substrate for nitrogen-fixing lichens, and their gelatinous substrate facilitated the colonization of ferns on Rakata, of mosses on Surtsey, and of lichens, mosses, and ferns on Paricutin. Both mosses and lichens obtain nitrogen from the activities of nitrogen-fixing cyanobacteria. Lichens appeared on 1944 Vesuvius lava after 10 years, but seed plants not until 14 years after the eruption, and most surfaces were still at the lichen stage in 1989. Even on Mount St. Helens, where legumes (lupins) were pioneers, their role was localized; their seed dispersal was poor and they did not spread. Here, nonsymbiotic mechanisms—rain and organic fallout—were the initial means of nitrogen supply and this atmospheric deposition rate was estimated as more than twice the rate for nitrogen fixation.

On Rakata wind-dispersed seed plants followed the fern phase. One of the important pioneers of ash on the Krakataus, the sea- and then wind-dispersed tree *Casuarina equisetifolia*, has root nodules that harbor nitrogen-fixing bacteria. Like the *Casuarina*, most of the 34 or so legumes (30 of them known to possess root nodules) which make up almost half the pioneer sea-dispersed group of plants in the Krakatau flora are strand or near coastal species. Although several (again like *Casuarina*) have spread inland, none occurs above about 100 m altitude. Schlesinger's research group estimated that the accumulation of organic nitrogen in the soil profiles of Rakata implies a minimum nitrogen input from twice to three times the atmospheric deposition rate reported in a forest of central Java. This of course suggests that much of the nitrogen in the Rakata soils must derive from biological fixation.

## B. Pioneers Tapping Extrinsic Energy Sources

Energy usually enters a system as sunlight, passing through the photosynthetic pathways of green plants to animal herbivores and then carnivores, parasites, and scavengers. The general textbook sequence of colonization is plants, herbivores, and carnivores. In this context spiders have been regarded as exceptional carnivores; they arrive early because most have good dispersal as ballooning juveniles, and can survive on food carried to the area, like themselves, in the air. But they may not be so exceptional.

There is now a considerable body of evidence to show

that in many instances the first organisms to colonize areas devastated by volcanic activity may not be primary producers. In the case of several volcanic areas the first colonists are carnivore-scavengers that are members of guilds which exploit organic input arriving either by sea as flotsam or as wind-borne organic fallout onto the new volcanic substrates. These guilds of secondary consumers may themselves form the base of a volcanic food web. The tapping of energy flowing through ecosystems outside the area, through the conduits of these guilds and (on volcanic islands) through land-based feeders on fish, sea snakes, crabs, and turtle eggs, short circuits the usual plant-herbivore-carnivore energy pathway and enables the establishment of some animals without the need for the prior establishment of plants.

### **1. Exploiters of Organic Flotsam**

On volcanic islands, both vertebrates and invertebrates may exploit organic matter that arrives by floating on the water surface. A pair of ravens, *Corvus corax*, has been seen on Surtsey regularly from the second year after its emergence. These carrion-feeding omnivores exploit resources such as washed-up carcasses, in many cases those of marine organisms, that derive from outside the island. A pair of this species also nested at one of the Ashmoles' coastal sampling sites on Lanzarote in the Canaries, and Brattstrom noted that the same species was an occasional visitor to San Benedicto Island after the 1952–1953 eruption of Barcena (see above). A pair of large-billed crows (*Corvus macrorhynchos*) were early pioneer animals on Anak Krakatau.

Seabirds, the only vertebrates on Surtsey other than the raven, and the first to reside there, also derive their sustenance from the surrounding ocean, bringing their catch onto land to feed, and sometimes feeding on carcasses washed ashore.

Very few of the arthropod species that arrived early on Surtsey by air (see below) became established, but within 6 months of the island's emergence in 1963 a strand community dependent on washed-up flotsam such as bird carcasses, algae, or logs had become established. Flies were one such group, but without carrion they became extinct. By 1975 only three terrestrial invertebrates were thought to have become established, a fly, a midge, and a collembolan, all of them inhabiting washed-up carcasses.

In contrast, within 6 months of Anak Krakatau's emergence from the sea in 1930 a pioneer community consisting of representatives of three families of beetles, large numbers of collembolans (springtails), and chloropid flies was exploiting sea-borne organic debris.

Shore birds and kingfishers, which feed on crabs, fish eagles, which feed on sea snakes as well as fish, and the large monitor, *Varanus salvator*, whose food includes organic flotsam, carcasses, crabs, and eggs of the green turtle, have together also acted as food web links through which marine resources entered the land system.

On Motmot, an emergent volcanic island in the large freshwater caldera lake of Long Island, off New Guinea, a primary succession began in the 1960s with a strand fauna again depending directly or indirectly on the input of organic material from outside the island. Ants and bugs among vegetation around Motmot's pond and rove beetles and springtails beneath a hardened algal crust at the pond margins had all arrived within about 4 years.

### **2. Exploiters of Organic Airborne Fallout**

Not all volcanic substrates are surrounded by water of course. Another conduit of extrinsic energy (i. e., energy deriving from outside the island system) was discovered when the barren ash/lava areas of a number of volcanoes were carefully investigated. The organic airborne fallout which was noted above as being a source of nitrogen provides a resource base for a guild of consumers (carnivores and scavengers), enabling them to become established on the otherwise barren ash and lava fields, free from the competition that would occur in more complex habitats.

Traps set on Anak Krakatau's barren ash, but not those set near vegetated areas, captured representatives of a guild of scavenger-predators including wolf spiders, earwigs, ants, a mantis, and numbers of a crepuscular flightless cricket. Feeding in turn on these on the ground was a guild of tertiary consumers which included two migrant birds, the common sandpiper and grey wagtail. Aerial predators—two or three species of dragonfly, two swiftlet species, a swift, and a swallow—took some of the fallout before it settled. They, in turn, were preyed upon by the oriental hobby and perhaps also by the peregrine falcon when this replaced the hobby.

This aeolian-based community is the ecological analogue of communities found on other volcanic areas such as Mount Etna, the Canary Islands, and Mount St. Helens, and, in particular, on lava fields on the island of Hawaii. In the alpine zone near the 4205-m summit of Mauna Kea on Hawaii, Frank Howarth had found an unusual, long-legged, flightless lygaeid bug, *Nysius wekiuicola*, and on the heights of Haleakala (3055 m) on the island of Maui a strange flightless moth, *Thyrocopa apatela*. On both islands lycosids (wolf spiders) were also present. Hawaiian species of *Nysius* are seed-feeders, but the Mauna Kea species is unusual in being a scavenger.

ger and predator, presumably having evolved the scavenging/carnivorous habit as an adaptation to the barren habitat. The larvae of the Haleakala moth make silken web traps under stones and feed on wind-borne debris, mostly fragments of the dead leaves of *Dubautia menziesii*, an endemic alpine shrub. On bare lava fields of the Kilauea volcano on Hawaii (but, as on Anak Krakatau, not in adjacent vegetated areas) the fallout-exploiting community comprised a wolf spider, an earwig, a mantis, and, dominating this guild, a nocturnal flightless cricket of the same subfamily as that occurring on Anak Krakatau. The parallel between this community and that later found on Anak Krakatau is remarkable.

On the Canaries, an earwig, two species of Thysanura ("silverfish" relatives), and a cricket are important scavenging/predaceous pioneers both on the surface and in subsurface cavities. Some members of this guild exploit fallout on the surface by night and take refuge during the day in deep cracks and subterranean spaces. In the course of succession this lavicolous (i. e., inhabiting lava) community is replaced by more specialized communities above and below ground. A guild of tertiary consumers, feeding on the fallout exploiters, includes pipits and lizards.

On Anak Krakatau, Hawaii, and the Canaries, the scavenging/predaceous guild is present on new lava flows or areas of recent ashfall, where there is little or no primary productivity. It is absent or poorly represented in areas where productivity is provided by macroscopic terrestrial plants.

Organic fallout derived from outside the area was also shown to be an important source of nutrients in the recolonization of Mount St. Helens (see above), and here the resident pioneer predator and scavenger guilds included ground beetles, darkling beetles, spiders, and neuropterans. The first successful colonists of the blast zone were three ground beetle species of a genus that is generally restricted to disturbed, barren habitats, and whose species are specialist, necessarily transient, pioneer colonists. Within the first two summers 43 species of spiders had ballooned in from lowland areas. However, only 19 species of arthropods showed evidence of breeding within the first 3 years, including 11 predaceous ground beetles and representatives of three families of scavenging beetles. In the first 5 years more than 30 ground beetle and 125 spider species (mostly lycosids) had arrived in the blast zone, making up about a quarter of the fallout fauna and contributing about 100 individuals per square meter per year. On the surface of pyroclastic flow deposits, populations of 6 spider species were established by 1986. Other colonizing insects included neuropterans, and in later years hemipteran bugs [lygae-

ids and saldids ("shore bugs")], orthopterans (gryllacridids, a cricket-like family), and members of the Grylloblattodea (an order of small, soft-bodied, apterous, cryptozoic insects evidently confined to cold, damp situations) made their appearance. For all of these the fallout was shown to be an important source of nutrients; for example, ground beetles were frequently seen with aphids or nematoceran flies in their mouthparts, particularly at night. Crows (*Corvus* species) were also significant consumers of fallout during the day.

Such aeolian (wind-dependent) communities appear to be characteristic of, and may have evolved in, areas with a long history of sustained volcanic activity. Howarth suggested that the entire aeolian community is a special subset of a more extensive guild of arthropods living below the surface of lava flows and dependent on input of organic material to the network of caves and interstices. For example, most species of the Hawaiian endemic cricket genus *Caconemobius* are rock dwellers on cliffs, lava flows, and lava caves, and Howarth believed *Caconemobius fori*, the exploiter of organic airborne fallout, to be closely related to a cave-dwelling species.

On Surtsey, an island of about the same height and size as Anak Krakatau but more isolated and in a much harsher environment, colonization by airborne pioneer animals has been slow. Spiders of the family Linyphiidae, which includes the "tent spiders," were seen alighting on the lava, and flies were the most diverse group of the island's early fauna. However, 7 years after the island's emergence there were still only three species of beetles.

On Motmot, wolf spiders were seen in inland high dry areas in 1969, "when, in spite of a careful search, no other life was found there," and Ball and Glucksman believed that a major part of the spiders' diet may have been fallout of aerial plankton sucked in following updraughts caused by differential heating of the island's surface and the surrounding lake. Damsel flies, dragonflies, and Pacific swallows may have exploited the aerial plankton before it reached the ground; all were present at the first survey, in 1969, and the swallow nested on Motmot in 1971.

### C. Colonists of Primary Volcanic Substrates

Erosion of the purely mineral, infertile substrates that are the first provided by volcanic activity is rapid and unimpeded, and water retention very poor. Primary colonists of such dry, unsheltered, unconsolidated substrates must not only have good dispersal powers but

also the ability to survive and grow in this forbidding habitat, among the most inhospitable of Earth's environments.

Although bacteria, algae, lichens, mosses, and ferns are often the first pioneers, in many cases it is seed plants that are the primary colonizers. They are often long-lived, perennials, or slowly growing woody shrubs or trees with light seeds that are wind dispersed. For example, on Vesuvius after the 1944 eruption, the first colonizers in the primary succession on coarse scoria were woody species; annuals were unimportant. Also on Anak Krakatau, Mount St. Helens, Motmot, Hawaii, Galapagos, and Usu and Sakurajima in Japan, seed plants were among the pioneer colonists. The success of all primary colonists depends on their growth form and growth rate being appropriate to the substrate's supply of water and minerals. In contrast, secondary pioneers, which in many volcanic situations follow the primary colonists, generally have high growth rate.

### **1. Colonists of Lava Flows**

As noted above, on many newly formed barren volcanic areas biological aerial fallout is the most important resource for animals. New lava flows are of course completely devoid of even the rudiments of soil, and their surfaces are fully exposed to the elements and subjected to temperature extremes. Yet where there is enough moisture, micro-organisms, mosses, and lichens colonize them. Temperature, humidity, nature of the substrate, and nature and size of the reservoir of potential colonists all determine the primary succession, which thus varies according to different primary situations.

On Lanzarote in the Canaries, lava flows were colonized primarily by lichens and mosses provided they were not far from kipukas and not within 2 km of the sea. In contrast to Surtsey, for example, on the dry Lanzarote lava significant populations of heterotrophic bacteria (that take in nutrients from external sources rather than photosynthesizing them) were recorded and the Ashmoles' group believed that input of marine bacteria is important in order to maintain the lava ecosystem close to the sea.

New lava flows on the Icelandic mainland, particularly those at high altitude, are colonized first by lichens, as those on the Canaries, yet although Surtsey was searched carefully for lichens each summer since its 1963 emergence, the first lichen was found on its lava only in 1970. Three years later there were 12 species, 4 of which were thought to have been dispersed by wind, and 1 by seabirds. On Rakata (where the volcanic substrate was ash) lichens were also unimportant but the buildup of

bryophyte species was much slower than on Surtsey's lava and ash, which after 9 years supported 68 moss and 4 liverwort species. Although 2 moss species were present on Rakata in 1886, 3 years after the eruption, no more had been found by 1906. By 1922 there were 18, but the bryophyte flora did not achieve the diversity of Surtsey's remarkable 9-year-old flora until some time between 1933 and 1979 (50–96 years after the eruption); 32 moss and 37 liverwort species were recorded in 1983.

On the Galapagos, as well as lichens, primary pioneers are cereoid cactuses of the genus *Brachycereus* (Figure 6; see also color insert), and on the Hawaiian Islands lichens predominate where it is relatively dry, but ferns and flowering plants can get in first in very wet areas. Indeed, the tree *Metrosideros* is capable of becoming established on new Hawaiian lava flows and forming a forest.

### **2. Colonists of Tephra Deposits**

Mazzoleni and Ricciardi noted that after the 1944 eruption of Vesuvius, colonization of scoria was much faster than that of lava. This observation was supported by Galapagos work; Hendrix and Smith found that Fernandina lava flows mostly remained barren for more than 100 years, whereas tephra on Fernandina's rim was re-vegetated after less than 10 years. In general, tephra deposits are colonized much more quickly than lava flows.

Del Moral and Bliss stressed that the nature and localization of microsites (a microsite is the place at which an individual plant grows) may affect colonization success in the harsh environments immediately after catastrophic eruptions. On Fernandina, for example, major sites of colonization were water runoff channels and

FIGURE 6 A colony of *Brachycereus nesioticus* on a lava flow on Santiago Island, Galapagos. (See also color insert.)

collapsed land iguana burrows. The effect of microsite patterns, however, is complex. On Mount St. Helens the presence of a colonizing plant species in the early stage of primary succession depends in a complex way on interaction between the seed-trapping ability of the microsite, the density and composition of the seed rain, and the ability of the species to become established under the conditions obtaining there. Plant establishment and growth were monitored in two seasons both in seeds planted at different naturally occurring microsites and in seeds naturally dispersed into different artificially constructed microsites. The microsites at which most seeds arrived naturally were not those at which there was peak establishment and seedling growth. Moreover, microsites with the highest establishment rate of seedlings when artificially seeded did not have the seedlings with greatest growth. Further, microsite colonization patterns changed from year to year, as climatic differences presumably affected the amelioration of microsites and the amount of seed "rain" coming to them.

On Anak Krakatau's tephra deposits, grasses, including *Ischaemum muticum*, *Imperata cylindrica*, and *Saccharum spontaneum* (a wild relative of sugarcane) (Figure 7; see also color insert), are also found inland of the beach, and on new substrates the tree *Casuarina equisetifolia* is a pioneer species. The sea-dispersed primary colonizers of the Krakataus' black sand beaches, the creepers *Ipomoea pes-caprae* and *Canavalia rosea* (a legume), were both found covering bare ash some distance from the sea on Anak Krakatau. They were also primary colonists of Volcano Island in the crater of Taal volcano, where they were found some distance from the shore. Brattstrom noted that colonization of San Benedicto Island would be slow because of lack of rainfall and slow soil formation, but the *Ipomoea* species was the first immigrant to become re-established on Barcena volcano there.

### III. BIOTIC REASSEMBLY

Most cases of the recovery of biotas following natural extirpation occurred too long ago for the predevastation biota and stages of recovery to be known. One of the many problems besetting studies of these cases is that destruction may have been incomplete, as on Taal and Barcena, and its extent often only imprecisely known, as on Thera, so that the base from which recovery proceeded can only be guessed. Sometimes insight can be gained by assuming that the pre-eruption biota was simi-

FIGURE 7 A clump of so-called wild sugarcane (*Saccharum spontaneum*) growing on the ash slopes of Anak Krakatau, 1992. [Photograph by David Walsh.] (See also color inserts.)

lar to the existing biota of similar but unaffected islands in the same area, if such "control" islands exist. A comparison between these biotas and the reassembled biota of the affected island may provide a fairly rough and ready estimate of the extent of recovery. One such case is Long Island, 50 km north of New Guinea.

#### A. Long Island

Some time around the middle of the 17th century an explosive eruption occurred on Long which was later estimated to have been several times larger than that of Mount St. Helens and about the size of that of Krakatau. The layer of hot ash deposited on its forested surface was 30 m or more thick, resulting in completely carbonized trees and destroying most or all life.

Long's present rainforest flora has not been studied in the context of recolonization but Jared Diamond described the lowland vegetation 3 decades ago as an arrested subclimax which probably has not yet returned to its former composition, and the description is still appropriate. Diamond noted that the trees are either sea-dispersed (e.g., *Terminalia catappa* and *Barringtonia asiatica*, both also present on the Krakataus) or bird- or bat-dispersed (e.g., species of *Ficus*, *Canarium*, and *Eugenia*). Around the rim of the 13-km-diameter caldera the forest is fairly open, and although a few very large old banyan figs and other trees might date from immediately after the eruption, most trees are clearly much younger. Recovery may have been constrained by the porous substrate and lack of streams, as Diamond suggested, as well as intermittent ashfall (not all subsequent eruptions may have been recorded). In the clouds above 700 m on the two higher mountains the forest evidently recovered more quickly and is already structurally mature. The island now has c. 50 species of land birds, from 9 to 12 reptiles [a crocodile, monitor, snake (the Pacific tree boa), two geckos, and several skinks], six bats (one insectivorous bat, two fruit bats, and three long-tongued nectar bats), and the Pacific rat. The cuscus (a loris-like arboreal marsupial) is common and probably introduced by humans.

In 1888 another event occurred on the island of Ritter, about 100 km east of Long. About 2 km<sup>3</sup> of the island disappeared in a massive collapse which left only about 5% of the island's bulk and a submerged caldera 2.5 km in diameter. Large tsunamis triggered by this event wiped out coastal villages within a radius of 112 km, causing many casualties and eradicating the fauna of several coral islets in the vicinity. It is very likely that all life on Ritter was destroyed. The island remnant's eastern slopes are now covered in scrub and grass.

Diamond studied the Long and Ritter cases, comparing their bird faunas and those of coral islets from which birds had been exterminated with those of islands whose bird faunas had been unaffected by the eruptions or tsunamis. On the devastated coral islets bird species numbers quickly returned to equilibrium. By the 1970s the avifaunas on Ritter and the lowlands of Long had also reached equilibria but species numbers were less than those of unaffected islands of their size, in spite of the fact that the latter are low and so may be expected to carry a smaller fauna. After almost 3 centuries Long had recovered three-quarters of its expected number of species but it gained few if any between 1933 and 1972. Diamond attributed the relative poverty of the new avifaunas on Long and Ritter to the fact that their lowland forest habitats were still at an immature developmental

stage. However, although Long's montane forest had recovered more quickly, bird species numbers were low there also, and Diamond concluded that montane bird species generally had poorer dispersal powers than lowland species. Ball has suggested to me an alternative explanation: Long's forests may have returned to a climax and the biotic poverty may reflect the fact that, apart from the two isolated peaks, the island is relatively dry.

## B. The 1883 Krakatau Islands

From ships' reports we know that before the 1883 eruption the Krakatau Islands were clothed in forest, although only about half a dozen plant species are identifiable from various reports and sketches. Two-thirds of the island of Krakatau disappeared in the explosive eruption, and its remnant, Rakata, and the two adjacent islands, Sertung and Panjang, were covered in hot ash to depths of more than 30 m (Figure 8).

The first living thing to be found on the islands, 9 months after the eruption, was a spider. Sea-dispersed plants were among the first to colonize, forming an association of creeping beach plants and a coastal forest of small trees and shrubs just inland of the shore. Pioneers of the inland areas were wind-borne plants able to survive in full sun (heliophilous) and with little water. The plant colonists of the first 3 years comprised only such water- and wind-borne pioneers, most of which were hermaphrodites (with male and female organs in the same flower) (Table III).

On the inland slopes of Rakata (Krakatau's remnant),

**FIGURE 8** The west coast of Sertung, Krakatau Islands. The cliffs are composed of tuff from the 1883 eruption of Krakatau, which enlarged Sertung considerably. (Photograph by David Walsh.)

the microclimatic and soil conditions were modified by the heliophilous fern cover which followed the cyanobacteria. The fern cover was succeeded by wind-dispersed flowering plants such as grasses and orchids, capable of growing in open sun. In contrast, in the later development of forest, dispersal by birds and bats was a major factor; only one important forest tree on the islands is wind-dispersed.

The early coastal pioneers included some fruit-bearing, small-seeded small trees and shrubs, which are diplochorous, that is, have two means of dispersal—the sea surface and fruit-eating bats and birds—and could have made their first landfall by sea. Flying frugivores may have been first attracted to the islands by the presence of these pioneer fruiting trees, and it is not surprising that facultative frugivores (generalist fruit-eating birds that are capable of surviving on seeds and/or insects, without fruit) predominated on the fairly open, unforested islands in the early years after the eruption. It was these early facultative frugivores that were responsible for extending the range of the pioneer fruit-bearing trees inland.

Some of the early-arriving facultative fruit eaters, like the black-naped oriole, were certainly capable of bringing seeds of fruit-bearing trees, such as several heliophilous pioneer fig tree species, from the rich sources of the Javan or Sumatran mainlands some 44 km distant. Four such fig species were established and fruiting within 14 years of 1883. Once figs were established in numbers, their fairly constant supply of fruit would permit obligate frugivores (which feed only on fruit) to colonize, including larger fruit bats and some of the doves and pigeons that are extremely effective seed dispersers. These wide-ranging animals were largely responsible for bringing important forest canopy trees (almost all the Krakataus' canopy trees are bird- or bat-dispersed) from the rich sources on Java and Sumatra, and thus instigating an important ecological change on the islands (forest formation and canopy closure) which affected all future colonization. Small dog-faced fruit bats probably assisted the spread of fruit-bearing trees throughout the archipelago and Louise Shilton has recently shown that they could have brought some of the fig species to the islands.

In the calmer, cooler, shaded, more humid, mesic environment of the forest, many of the heliophilous pioneer species persisted, but with the changed role of gap fillers. Now a second wave of wind-dispersed plants, shade-loving forest dwellers, mainly ferns and orchids, were able to become established. Also, with the change to forest conditions several animal species, such as grass-feeding skipper butterflies, sphecid wasps, and ground-

living beetles that prefer dry to moist surface conditions, and open-country birds and reptiles, became extinct, and forest animals began to colonize.

Sea-dispersed species colonized all the Krakatau islands and reached an equilibrium number of species fairly quickly (Table III). Zoothoraxous species made up 14% of plants arriving between 1887 and 1897 (6 being present in 1896), 35% of those arriving between 1898 and 1908 (23 were established by 1905), and, considering only nonhuman dispersal, 40% of those arriving later. Although the animal-dispersed group of plants were in general the last to colonize, they are the group that has increased most markedly in the past 6 or 7 decades.

The Krakataus' biota is disharmonic, that is, some groups are underrepresented or absent compared to the mainland biota, and others are overrepresented. Some absences clearly are the result of the sea barrier of 13–44 km. Birds with weak powers of flight are lacking, as are terrestrial mammals other than rats, and thus so too are many trees that have seeds dispersed by terrestrial forest mammals. Plant species with fairly heavy, wind-scattered seeds are also poorly represented. In other cases the barrier is ecological—the plant succession on the islands may be either too young or too mature to provide optimal habitat for a given species. For example, the lack of old mature trees with hollows suitable as nesting sites precludes the establishment of hornbills. Or a particularly crucial plant species may be missing; thus the lack of bamboos means that bamboo bats, for example, which have very restricted roosting preferences, would have difficulty in becoming established. These barrier effects of course mean that some groups, such as pteridophytes, which have very effective spore-based dispersal, are unusually well represented.

Animals like the monitor and reticulated python probably arrived on the recovering archipelago by swimming or floating on the sea surface, while others like the paradise tree snake, blind snake, two gecko species, and a skink are more likely to have rafted on natural vegetation, and such rafts do make landfalls on the islands quite frequently (Figure 9). Termites are weak fliers and the fact that all seven species on the islands are wood or tree nesters, although over a third of the mainland's termite fauna nest in or on soil, supports the view that the Krakatau termites arrived by rafting (Table I).

Although the islands are uninhabited, four gecko species, a skink, two rat species, and a number of insects and grasses are thought to have arrived adventitiously through the sporadic visits of fishermen, scientists, and tourists.

Flight is an obvious mode of arrival for many winged insects and for birds and bats, and yet not all those

FIGURE 9 Washed-up logs on Anak Krakatau's black sand beach, 1984. Such logs may act as rafts for a number of animal species. Rakata, Krakatau's remnant, is in the background. (Photograph by David Walsh.)

capable of the journey have reached the islands, and not all those that regularly arrive have colonized. Behavioral limitations sometimes preclude colonization. Thus many birds are philopatric, that is, they do not normally fly far from their home range or territory and are thus unlikely to reach the islands, and most social bees and wasps cannot maintain their swarms over long distances and few such species have colonized. There are also ecological constraints. Lack of substantial bodies of freshwater precluded the establishment of five families of aquatic birds present in the source area of Java, and of any of the dozen or so dragonfly species that regularly visit the Krakataus.

Successful animal colonists are, in general, species with wide distributions and broad ecological tolerance.

For example, some 75% of the archipelago's present land birds are inhabitants of urban or garden areas and other disturbed habitats in southeast Asia, and the bat fauna comprises widespread species that do not have specialized roosting requirements and can tolerate disturbed habitat fairly well. Many of the insect colonists, such as bark lice, butterflies, and chloropid flies, are exploiters of ephemeral, temporary habitats or those associated with disturbed forest.

In several cases colonization is dependent on the prior establishment of other species; in a simple example, tree-nesting birds colonize after the establishment of trees. Although some animals, such as the monitor, are able to colonize very early by exploiting energy derived from outside the islands (in the form of shore crabs or turtle eggs), others require the prior establishment of their food source. Insect herbivores can survive only if their food plants are present and many have narrow food ranges, some being restricted to a single plant species. Some highly vagile butterfly species that are known to have reached the islands have not colonized; their food-plant families are absent. Similarly, parasites must have appropriate hosts. The poor early representation of brachonid parasites, for example, was probably because of the poor representation of their insect hosts, which in turn may have been the result of the late appearance of the appropriate phase in the plant succession. The koel, a nest parasite of other birds, did not colonize until after its hosts, the large-billed crow and black-naped oriole, were established. More generally, predators tended to become established late in the process, when appropriate prey was available. The carnivorous gecko, *Gekko gecko* and the lizard- and bat-eating Malay false vampire bat, as well as the serpent eagle, changeable hawk-eagle, Oriental hobby, peregrine falcon, and barn owl, were all relatively late colonists (Figure 10; see also color insert).

TABLE I Distribution of Termite Species by Lifestyle on Java and Sumatra and on the Krakataus

	H	S	Trees S	Soil	?	Total
Species on Java/Sumatra	6	6	7	5	0	24
Species on the Krakataus	5	2	1	0	1	9

Note. In comparison with the mainlands, the Krakatau termite fauna is characterized by the paucity of softwood termites [i.e., those which feed on soft wet wood and nest in the same environment (S) or in the dead part of the trunks of living trees (trees S)], the absence of soil nesters (soil), and the preponderance of hardwood termites (H), which feed and nest in hard, dry wood. [Following Yamane, Seiki, Abe, T., and Yukawa, J. (1992). Recolonization of the Krakataus by Hymenoptera and Isoptera. *Geojournal* 28(2), 213–218.]

#### IV. THE ASSEMBLY OF NEW BIOTAS ON EMERGENT VOLCANIC ISLANDS

Although the above cases of reassembly of biotas involve islands, one cannot always be absolutely sure that the reappearing biota is the result of immigration and not survival. For example, it is not known whether any plants or animals survived Long's eruption, and although there is very little likelihood of survivors of the 1883 Krakatau eruption the possibility cannot be entirely ruled out. There is one situation, however, in which there can be no doubt that newly assembling communities of land

**FIGURE 10** A juvenile Galapagos hawk on an aa lava flow, Fernandina Island, Galapagos. Avian raptors are often late colonists of volcanic islands. (See also color insert.)

organisms comprise only new colonists. This is where a volcano has emerged from the sea or from freshwater as a pristine substrate, devoid of land life; there could have been no survivors for there was no previous biota. Such cases are few and some have attracted the attention of biologists. The best known biologically are Surtsey, Motmot, and Anak Krakatau. Because these are cases of assembly of island communities *de novo*, with no possibility of recovery from surviving foci, and in all cases there has been little impact from humans, they provide rare information on dispersal as well as on the assembly of biotic components.

#### A. Surtsey

The island of Surtsey emerged in November 1963 from the submarine North Atlantic ridge some 20 km south-

west of Heimaey, largest of the Westman Islands and itself about 15 km south of Iceland. Surtsey's phreatic, explosive phase of activity lasted until April 1964, when the vent became sealed from the sea and lava flows began. This second, effusive phase ended in May 1965 but activity was resumed in 1966, producing less extensive flows. Since 1987 there has been no eruption and the island has been shrinking through erosion; it now covers 2.7 km<sup>2</sup> and is 152 m high. It is our very good fortune that biological colonization has been monitored meticulously from the start by a group of mostly Icelandic biologists led by Sturla Fridriksson, in one of the most important long-term ecological studies of the century.

Fridriksson and his team showed that objects could float to Surtsey from Heimaey in 2.5 days under favorable conditions of wind and currents, and that seeds of three coastal and three alpine plants of mainland Iceland remain viable after varying periods of immersion in seawater. Two of the coastal species tested had been found on Surtsey in beach drift only 6 months after the island's emergence; one, the sea rocket, *Cakile edentula*, was the first plant to grow on Surtsey, in 1965; the other, mayweed, *Matricaria maritima*, became established in 1972.

Between 1964 and 1972 seeds and other diaspores (plant parts that are dispersed and have the potential to produce new plants) of 38 species of vascular plants were found on Surtsey's shores; all grow in Iceland and 31 occur on Heimaey, but the 21 that grow on the Westman islands nearest to Surtsey were the most abundant. Only 6 months after Surtsey's emergence leaves and stems of lyme grass (*Leymas arenarius*) and a rush were found in beach drift, and seeds of the sea rocket, lyme grass, and *Angelica archangelica* were collected. Whole green plants of mayweed and *Sedum rosea* were found on the shore, and a mayweed plant was potted and kept alive for some time. In May 1969 mermaid's purses (the empty, chitinous egg capsules of the ray *Raja batis*) drifted ashore, and on their rough outer surfaces were seeds of 4 grass species which are common in mainland Iceland and occur on Heimaey; only 1 of them, lyme grass, is found growing on the smaller Westman islands close to Surtsey. Overall, Fridriksson believed that 3 vascular plant species probably could have arrived on Surtsey by sea from a small islet 5 km away, 2 from islets 10 km distant, and 7 from Heimaey, including the two important pioneers, lyme grass and sea sandwort, *Honkenya peploides*.

Waterborne dispersal was important in Surtsey's animal colonization also. There is good circumstantial evidence that a mite, a weevil, three species of shore flies, and a parasitic wasp of one of the flies all rafted, probably from Heimay. Grass tussocks washed ashore in 1972 and 1974 together harbored some 700 living invertebrates,

largely mites and springtails. The nature of the grit and the proportions of pollen in the 1974 tussock suggested that it came from bird cliffs on the Westman Islands.

The spores of ferns, mosses, and lichens were carried from Heimaey or Iceland's mainland in the air, and the mosses were very important ecologically (see above). All the insects found on Surtsey by 1970 were winged and included a moth, *Autographa gamma*, which migrates from Europe and is not native to Iceland. Some 77 species of flies are thought to have arrived by flight assisted by wind, and in 1966 a linyphiid spider arrived, evidently by ballooning. Springtails are wingless but some salt-intolerant species were found in moss quite far inland, suggesting the possibility of aerial dispersal also for these small flightless arthropods.

Ravens almost certainly brought in seeds of the thrift, or sea pink, *Armeria maritima*, which was found flowering in 1986 at a place where they had attempted to nest. But it is seabirds which have been of greatest importance in the colonization of Surtsey. Their excreta, dead chicks, and eggs provide minerals and organic matter, fertilizing the soil in the area of their colonies. The fulmar and black guillemot have bred regularly since 1970 and the number of vascular plant species on the island rose sharply between 1971 and 1972. By 1993, six seabird species were nesting each year and there were 30 species of plants. Almost half the plant species were restricted to bird roosting and breeding sites, and 10 to seabird colonies. Since herring gulls started to form a colony in 1985 there has been a great increase in the number of plant species; the gull carried plant material from islands of the Westman group to its nesting ground on Surtsey and fertilized the area heavily. There are now 22 plant species in the gull area, 18 of which have arrived since colonies were established. Colonization and spread of the low-growing perennial ground creeper *Sagina procumbens* have been rapid since 1985 and it is now the main pioneer of lava areas both within and outside the gull colony. Three small crowberry bushes (*Empetrum nigrum*) were found in 1993 on lava in the gull nesting ground; gulls, probably herring gulls, may have taken berries on Heimaey or, more likely, on the mainland of Iceland, 30 km away.

Within 12 years of Surtsey's emergence 60 species of migratory birds had been recorded and some were almost certainly involved in plant dispersal. In studies in 1967 and 1968 the only arriving migrants found to be carrying seeds in their gut were snow buntings of a subspecies that migrates from the British Isles to Greenland via Iceland. The seeds were of eight species, mostly common in Iceland and the British Isles, but some absent from or rare in Iceland. In a fine detective study Fridriksson's group found that the minerals in the birds' gizzards

were of a type that must have been acquired outside Iceland along with the seeds, most likely in the highlands of Scotland. Thus seeds of several species of vascular plants were brought in the gizzards of snow buntings from either the mainland of Iceland or the British Isles, probably the latter. Seeds of two species had retained their viability.

Borgthor Magnússon and his colleagues have listed a total of 44 species of vascular plants that have been recorded from Surtsey, with 35 persisting to the summer of 1995. Most of the 20 plant colonists in the first two decades were species of coastal, sandy habitats, probably dispersed by sea or birds. Fridriksson noted that although viable seeds were collected on Surtsey's shores during the first summer (1964), higher plants were not found growing until the second summer. The sea rocket, an annual, was found in 6 of the years from 1965 to 1973, and the nearest colony of sea rockets is on Heimaey. In the summer of 1966 seedlings of lyme grass were found at the high-tide mark but were destroyed by waves after a few weeks. In 1967 the sea sandwort and the lungwort, *Mertensia maritima*, were found, together with lyme grass and sea rocket. In 1969 a fifth higher plant species, scurvy grass, *Cochlearia officinalis*, had arrived, the location (bird droppings near rainwater barrels) showing that birds had been involved. In 1970 the common chickweed, *Stellaria media*, was found among pieces of egg shells, feathers, and bird droppings, and in 1971 the bladder fern, *Cystopteris fragilis*, was found in a lava cave.

As might be expected, colonization by vascular plants has been slow. Away from the bird colonies, infertile areas of lava and tephra had been colonized by 1973 by only 10 species of perennial herbs with extensive roots, such as lyme grass, lungwort, and sea sandwort, the most widely dispersed and successful plant colonist. Even by 1992 there were only 30 species, about one successful colonist per year, and the first woody plant, the crowberry, was not found until 1993. Three more new immigrants, a rush, a willow, and a *Galium* species, were recorded in 1995 in the gull colony, although establishment has not yet been reported.

Six months after Surtsey's emergence a fly was collected on the shore and in the next summer more flies and midges, two species of moth, and a mite were found. In 1966, when regular collecting began, 22 species of insects and four arachnids were recorded. The number of species increased annually, until by 1970, 158 species had arrived, almost a fifth of the Icelandic fauna. Although Heimaey was the likely source of most arrivals, some must have originated on the mainland of Iceland 35 km distant, and others, active fliers like some moths, from Europe. Only 2 or 3 species, however, had become established, and all these were carrion feeders. By 1981,

41 species of arthropods other than springtails were present, comprising an aphid (on the sea sandwort plants), a *Plutella* moth, a ground beetle and two staphylinids (rove beetles), five linyphiid spiders, two mites, an enchytraeid oligochaete, worm, and 28 species of fly representing 15 families.

### B. Motmot

Between 1953 and 1955 intermittent volcanic activity of a type that is now known as Surtseyan was reported at a point in Long Island's large caldera freshwater lake, about 5 km from the nearest shore. By 1968 an islet of tephra, Motmot, was formed (Figure 11). Lava flows in 1973 and 1974 ensured its future existence, and the islet is now about 300 m long and 50 m high. It was investigated at intervals from 1969 to 1985 by Eldon Ball and his colleagues, and in 1988 the botanists Osborne and Murphy made a short visit.

The first plants were mosses and the sedge *Cyperus polystachios*, both found in 1968. After 2 more years 13 plant species were present, including mosses, the fern *Pityrogramma calomelanos* (one of the Krakatau pioneers), two sedge species, a composite, two (perhaps three) figs,

and five other flowering plants. By 1972 there were 14 vascular plant species. Three more ferns were present (including a species of *Nephrolepis*), and six more seed plants, including a third sedge, two grasses, and a fourth fig species.

Scavenging omnivorous earwigs and carnivorous wolf spiders were among the earliest animal arrivals on Motmot. They were probably not foraging on the beach for they gradually moved inland until by 1972 they could be found over almost the whole island.

The 1973–1974 series of eruptions devastated the new flora, setting it back to a total of only three individuals, of the sedge *Cyperus cyperinus*. Invertebrates survived, however, the earwigs and wolf spiders still being abundant after the eruptions. In 1980 plant numbers were rising again and insect and spider diversity was high. In 1988, 20 species of vascular plants were recorded by Osborne and Murphy, at least 5 of which were represented in the previous flora. Wind (for ferns, grasses, and composites) and birds (figs and *Polygonum attenuatum*) were thought to be the chief modes of dispersal of the new flora, and dispersal through human activity was thought to be very unlikely.

Along with a few invertebrates, many plant propagules arrive on Motmot via the surface of the lake. However, the combination of volcanically heated beaches, chang-

FIGURE 11 Lake Wisdom, the freshwater lake in the crater of Long Island, in 1980; the islet of Motmot can be seen in the middle distance. (Photograph by Eldon Ball.)

ing water levels, and strong wave action ensures that surface transport is not a major contributor to Motmot's flora. On a floating log drifting past Motmot with soil in its roots were earwigs (not the species found on Motmot) and two ant and two spider species. Sedge seeds may have been brought by the black duck (see below) but they may also have been carried on the lake surface; sedges were also early pioneers on the Krakataus.

Wind dispersal was important. Almost half the plant species known by 1988 were probably dispersed in the air. Mosses and nine fern species, as well as four composites and two ecologically important grasses, *Saccharum robustum* and *Imperata cylindrica*, were almost certainly wind-dispersed. There is some indication that aerial fall-out of arthropods onto the island was providing sufficient sustenance for early populations of wolf spiders and earwigs (see above).

Of the 24 species of plants recorded in the 4 years after 1968, the seeds of 14 could have been brought by birds, 6 (including four figs) internally, 6 as minute seeds thought to adhere to mud on birds' feet, and 2 by becoming attached to feathers. The 20 species of the second primary succession (after the 1974 eruptions) included 8 species that could have been bird-dispersed, 4 internally and 4 in mud.

From the composition and distribution of the flora, Ball's group concluded that many plants arrived as seeds carried by the black duck, *Anas superciliosa*, which nested on the island from 1969. However, although the ducks' gut contents included many seeds of five plant species, including a sedge, no seeds could be found in the feces, so seeds adhering to the birds externally, on feathers and in mud, were the likely propagules. But Osborne and Murphy pointed out that pigeons and fruit doves are likely to be more efficient dispersers of plants like figs. Long Island has 11 species of frugivorous birds and a species of large fruit bat; doves and pigeons abound and include two species of fruit dove and two imperial pigeons which are excellent plant dispersers. Volant frugivores have not yet been reported on Motmot, however.

Two raptor species were seen on Motmot, the peregrine falcon (perhaps seeking pigeons?) and white-bellied fish eagle. Ball and Glucksman speculated that plant seeds could have been brought within the gut of birds taken by falcons and carried to the island to be consumed there. Since they made this suggestion, the Lanner falcon has been shown to be a secondhand disperser of plant seeds in this way in South Africa, and observations on Anak Krakatau indicate that peregrines may perform a similar role there.

### C. Anak Krakatau

In 1930 a tephra island, to be known as Anak Krakatau ("Krakatau's Child"), emerged from the submarine caldera resulting from Krakatau's 1883 eruption. The island persisted, grew, and was consolidated by lava flows in the 1960s. It was colonized by plants and animals, probably largely from the neighboring older islands, a kilometer or two away, themselves in process of recovery from the 1883 eruption of Krakatau. A young biota was gradually assembled, which, however, was eradicated by eruptions in 1952–1953. The colonizing process then recommenced, but damaging eruptions at fairly regular intervals have set it back repeatedly. Lava was first emitted in the 1960s and flows now cover over half the island, which is about 2 km in diameter and some 500 m high.

Since a nested pair of natural experiments in colonization was now in progress at the same site (colonization of the Krakataus from the mainland and colonization of Anak Krakatau from the older Krakataus), the experiments having started several decades apart, a number of comparative studies became possible. Anak Krakatau's continuing volcanic activity, which had no counterpart on Rakata (or on Surtsey), has complicated comparisons but has also provided replicate sequences of succession from zero or near-zero baselines.

The dispersal of sea-borne plant propagules to Anak Krakatau was studied over two monsoon seasons by Tukirin Partomihardjo. Stranded propagules of 66 plant species representing 38 families were found on the island's beaches. Disseminules of 30 species could have been derived from plants growing on the three older Krakatau island, mostly from the "core group" of coastal species present on them all, but the other 36 species must have originated from outside the archipelago, largely from Sumatra to the north. Twenty-eight of the species were already established on Anak Krakatau.

From such sea-borne propagules as these a coastal "forest" developed fairly quickly. Just inland were grasslands, the dominant grass being *Saccharum spontaneum*. In just over a decade these were succeeded by a *Casuarina equisetifolia* woodland (Figures 3–5). *Casuarina* is intolerant of shade, and on a stable substrate intrusions of some of the animal-dispersed heliophilous shrubs and trees such as small figs initiated change toward mixed forest. Further inland clumps of *Saccharum* dotted the bare ash and *Pityrogramma* and *Nephrolepis* ferns grew in the shade of lava outcrops (Figure 12; see also color insert). The present flora of about 150 species is largely the result of a classic succession frequently interrupted by eruptions.

The prevegetation colonization by animals has been discussed above. The postvegetation faunal develop-

FIGURE 12 A "pioneer" fern, a species of *Nephrolepis*, grows in the shade of a lava outcrop on Anak Krakatau. (Photograph by David Walsh.) (See also color inserts.)

ment was also of interest because at the time Anak Krakatau provided one of only two areas of fairly open habitat on the archipelago. The first birds to become established were the ground-nesting savannah nightjar and white-breasted waterhen, which would have fed upon grasshoppers, moths, skippers, and other grassland insects, as well as the collared kingfisher, which also nests without trees (in termite nests and on gully sides) and takes a variety of foods including shore crabs. The large omnivorous monitor lizard also was an early colonist. As *Casuarina* woodland developed, generalist insect/fruit eaters such as bulbuls and large-billed crows colonized, as well as arboreal insectivores and the paradise tree snake. There was a surge of colonization of avian frugivores after the island's first figs fruited in 1985, and some of the earlier colonists declined in num-

bers or became extinct. A number of fruit bats and frugivorous dove and pigeon species colonized together with about six fig species in the early 1990s as the diversification of the small forest area accelerated. Raptors finally became established in the form of the small-bird specialist the Oriental hobby, which was succeeded after doves and pigeons arrived by the peregrine falcon. The barn owl colonized and fed on the rats which arrived in the 1980s.

The colonization of this island has provided a number of insights into early successional processes but renewed volcanic activity in the 1990s has set back the process (and its monitoring) for some years.

#### V. SOME COLONIZATION COMPARISONS

The various priseres of plant colonization that have occurred on Anak Krakatau following its periodic outbursts may be compared with one another, with that seen on Rakata after 1883, and, for contrast, with that on Surtsey.

The comparison between colonization of Anak Krakatau and the older Krakatau islands is one between processes occurring at different times at almost the same place. But it was far from the same place biologically. Unlike the Krakataus after 1883, Anak Krakatau emerged into the midst of an archipelago with a biota itself selected for good colonizing ability and including potential seed dispersers—nine frugivorous bird species and two species of *Cynopterus*, small dog-faced fruit bats. Moreover, with distances from sources of only 2 km or so, these small bats and some of the smaller facultative avian frugivores could in this case easily mediate initial dispersal to the island.

Thus, in contrast to the colonization of the older Krakataus, on Anak Krakatau the animal-dispersed component of the early developing flora was substantial. On the three Krakatau islands after the 1883 eruption there was no animal-dispersed plant among the colonists within the first 3 years, but in 1896 six species were present. Zoochorous plants made up 35% (23 species in 1905) of plants arriving (i.e., first recorded) between 1898 and 1908, and, considering only nonhuman dispersal, 40% of those arriving later. In contrast, on Anak Krakatau the animal-dispersed component was 17% in the first 4 years, increasing to 38% of plants arriving in the second decade.

**FIGURE 13** The emergent island Surtsey (from the north, 1991). Surtsey and Anak Krakatau are about the same size (Surtsey is about 1500 m from east to west and is some 150 m high; Anak Krakatau is 2000 m from north to south and 190 m high) and their biotas about the same age (Surtsey from 1963, Anak Krakatau from 1957), but they differ markedly in isolation, climate, and the richness of their potential source biotas (Iceland and Java/Sumatra, respectively). (Photograph by Borgthor Magnusson.)

Surtsey is Anak Krakatau's cold-temperate analogue. The islands are about the same in their size and height (Figures 13 and 14), age, and physical isolation. Both have extensive lava shields that have ensured their permanence, and ash-covered areas that include highly mobile lowland promontories subjected to rapid marine erosion and deposition. Anak Krakatau's biota dates

**FIGURE 14** The emergent island Anak Krakatau (from the east, 1985). (Photograph by David Walsh.)

from self-devastating eruptions in 1952–1953, and there have been checks to biotic development at least three times for substantial periods. Surtsey's biota dates from its emergence in 1963, and there has been no eruption since 1967. Both have island neighbors carrying biotas that are subsets of their mainlands' biotas—the Westman Islands, the closest of which is 5 km from Surtsey, and the older pre-1883 companion islands of the Krakatau group, 2–4 km from Anak Krakatau.

The two islands differ markedly in biological isolation. The colonization of Surtsey has been slow, yet Fridriksson showed that, if water is available, plants can grow just as well on Surtsey's tephra as on other young volcanic tephra. He concluded that Surtsey's slow colonization is not due to the nature of its substrate. Surtsey's source pool of species is an impoverished one and its climate is harsh, factors which impose constraints on both the dispersal and the establishment of living propagules. For example, it was not until 1992, 32 years after its emergence, that Surtsey had the resources to support continuously resident land birds; Fridriksson informed me that in that year the snow bunting became the first land vertebrate to breed on the island. By comparison, at the same age Anak Krakatau supported over 25 species of resident land birds, paradoxically including not a single seed-eating species. Birds nevertheless played a relatively more important role in the colonizing of Surtsey by vascular plants than did both birds and bats on the Krakataus over equivalent time periods. The important birds on Surtsey are seabirds, which are not frugivorous or seed-eating, and which carry plant propagules externally. They are, of course, colonial and more numerous than the land birds of the Krakataus. Surtsey thus has a greater proportion of zoochorous plant colonists than do the Krakataus (Table II), and on Surtsey seabirds have also provided an important conduit, lacking on the Krakataus, for energy from the surrounding sea.

A significant proportion of the invertebrates colonizing Surtsey were sea-borne, and, as on Anak Krakatau, included collembolans and other insects exploiting washed-up carcasses.

The early importance of mosses on Surtsey had no parallel on the Krakataus, where they were unimportant in the early succession on ash. On Rakata (but probably not on Anak Krakatau) ferns took on an important role. Airborne invertebrates arrive on both Surtsey and Anak Krakatau in substantial numbers, and in both cases Diptera form a major component of the airborne invertebrate fauna. An animal community exploiting this airborne fallout is present on Anak Krakatau (Figure 15) but evidently not on Surtsey, although it is probably present on Motmot.

TABLE II Dispersal Spectra of Vascular Plant Assemblages<sup>a</sup>

Motmot differs from the two other emergent islands in being much smaller, only about a hundredth of their area, and having additional components of isolation. It is isolated from the sea by rings of land and freshwater, so that dispersal by sea, of great importance in the colonization of the two marine islands, particularly in the early stages of biotic assembly, can play no part at all in Motmot's colonization. Over-water dispersal has been unimportant in its colonization (Table II). Lake Wisdom is itself very isolated from possible sources of lake biota and its peripheral edges, like those of Motmot, fall off steeply. Thus few shore plant species are available for dispersal to Motmot's shores. Moreover, as noted above, Motmot's shore is very hot (the water temperature may reach 95°C in places), its wave action strong, and its water level changeable, so few of the propagules that do reach Motmot become established. Motmot's biota is thus impoverished.

After only 3 years after 1968 Motmot had two resident land birds—the black duck and Pacific swallow—but it was not until 1980 that a third resident species was recorded. The very high importance of birds as a mode of transport of disseminules to Motmot compared to Rakata almost certainly results from the short distances from the source that are involved. Moreover, for this reason and because of Motmot's small size, temporary visits by birds and bats may have played, and may continue to play, a quite important role.

## VI. ESTABLISHMENT AND COMMUNITY ASSEMBLY

In only a few cases do we know anything about the chances of successful establishment of immigrating organisms, and the early stages of integration of species into communities has been followed only rarely.

### A. Establishment Rates

The Icelandic biologists precisely grid-plotted the positions of individual plants on Surtsey, so that arrivals that failed to become established could be recorded even when they persisted for only 1 year. A total of four species failed to colonize after one arrival, but nine have failed more than once, and one has arrived as many as five times and has not yet colonized.

FIGURE 15 Anak Krakatau seen from Rakata, 1992. (Compare with Ball's photograph of Motmot in Figure 11.)

Anak Krakatau's simple early community enabled animal immigrants and sea-borne plant arrivals to be recognized and their fates noted. Over two seasons 66 plant species were found as stranded propagules on Anak Krakatau's beaches by Partomihardjo, yet less than half these (28) had already become established on the island.

In a span of 8 years of sporadic observation on Anak Krakatau for short periods, there are records of 54 animal species (25 of them vertebrates) arriving on the island, 14 of which were new to the archipelago. More than 20 of the 54 did not become established. I estimate that hundreds of individuals may have arrived over this period, many being of species new to the island and many representing failed colonization attempts.

The barriers to the establishment of waterborne propagules on Motmot have been noted above.

The crucial test of successful establishment is acceptance into an ecological community. Only rarely can the beginnings of such associations be observed.

## B. Assembly of the First Communities

The main factor affecting vegetation on the scoria of Vesuvius was found to be soil particle size, followed by soil stability. An early pioneer, *Rumex scutatus*, became dominant on the coarse mobile scoria and pumices of the 1944 eruption although it was rare in the surrounding region. On steeper slopes it was seen to facilitate the establishment of other plant species, apparently acting as a nurse plant for broom, *Bromopsis* (= *Bromus*) *erecta*, for example, which was found growing within its clumps.

It is perhaps not surprising that the beginnings of ecosystem development have been detected on Surtsey, where there are few species, colonization has been slow, and monitoring has been meticulous and regular since the island's birth.

In 1978 Fridriksson noticed that the sea sandwort, *Honkenya peploides*, a low-growing, sand-binding pioneer, and the tall lyme grass, *Leymus* (= *Elymus*) *arenarius*, appeared to be forming a simple sand dune association. Where this association is found on mainland Iceland it is succeeded by grasses (much as on the Krakataus, where the two pioneer beach creepers are sometimes succeeded by two or three grass species, although dunes are not found on the Krakataus). On Surtsey, dune height increased from 20 cm in 1980 to 1 m 10 years later. Young lyme grass plants were growing in the center of some of the sea sandwort patches, where they were better sheltered than on open ground and received a more even supply of moisture. A young lyme

grass plant was found in each of 20 patches of sea sandwort in 1983, yet no new lyme grass seedlings were found in the open ground around the patches. The number of such patches had increased to 100 in 1984 and to 166 by 1986. The patch of pioneer sea sandwort thus acts as a kind of nursery, providing favorable conditions for the establishment of a lyme grass plant within it. The parallel with *Rumex* and *Bromopsis* on Vesuvius is clear.

On Surtsey, fledglings of the great black-backed gull used the *Honkenya-Leymus* dunes for shelter in 1975 and 1976, and a pair of adults used as many as 20 sea sandwort plants as nesting material, together with the red fescue grass *Festuca rubra* and the sedge *Carex maritima*. In 1981 the association had six component species: an aphid was abundant on the sea sandworts and a collembolan (springtail) was common in the rotting, fungus-covered branches of the larger clumps.

Another "embryonic" plant association on Surtsey involved three grass species (two of *Poa* and one of *Puccinellia*) and the low-growing, creeping perennial *Sagina procumbens*. Since 1986 a colony of *Sagina procumbens* had been developing on ropy pahoehoe lava on the south of the island, where the *Sagina* and grasses were well fertilized by a herring gull colony. Fridriksson reported that the soil in this seabird breeding area had become quite fertile, with 60 mg nitrogen, 7 mg potassium, and 2.9 mg phosphorus per 100 ml of dry matter. The same association is found in mainland Iceland on cliffs and in seabird colonies, as well as around farm-houses.

Surtsey's rich moss vegetation provided a habitat for several soil animals in 1976 but this fauna seems to have been destroyed by drought in 1978 and has only partially recovered.

Birds' nests also provide a habitat for land arthropods on Surtsey. One greater black-backed gull nest contained two staphylinid (rove) beetle species, a springtail, and a mite, and the decaying materials beneath the nest were exploited by larvae of four species of flies, feeders on dung and dead organic matter. Two species of spiders, in their turn feeding on the insects, completed this community.

Thus after almost 30 years a simple and probably rather unstable ecosystem had developed on Surtsey, comprising a few species of vascular plants, seabirds, and fungi, and several species of land invertebrates. Two embryonic associations of plants and animals, one associated with slowly growing sand dunes, and another with birds' nests, had been formed. Another, involving mosses, appears to have been badly damaged but is now showing signs of repair.

## VII. THEORETICAL CONSIDERATIONS

Experiments with laboratory "microcosms," mathematical modeling studies, and the observation of natural systems all indicate that the end result of the course of development of any individual system is highly contingent on several factors. First, and most obviously, it depends upon which biotic components arrive at the new area from outside. The relative importance of various modes of immigration varies with the environmental factors that obtain from case to case, as does the rate of assembly of the biota. Miles and Walton, discussing primary succession on a mineral substrate, pointed out that since there is no seed bank, no "memory" of a previous flora (for there was none), the assembly of species depends only on their chances of dispersal. They noted that the nature and direction of early plant succession on Mount St. Helens reflect only the order of species arrival by predominantly aerial dispersal and suggested that repeatability of successions in different places at the same time or at different times in the same place is likely to be low.

On the Krakataus, however, some determinism is evident in the early stages of biotic assembly; instances at different times in the same place (on Anak Krakatau) and in different places in the same local area (on the older Krakatau islands and Anak Krakatau) show fairly high similarity. This difference from Mount St. Helens may derive from the island situation and the high predictability of sea-borne pioneers.

The composition of the assembling biota also depends on which of the arriving species become established, and this in turn may depend in part on the site of the propagule's landfall. Whereas airborne propagules may land in a variety of microsites, many of which may be unsuitable, sea-borne immigrants have a landfall on the

upper shore, which is usually a highly suitable habitat for the propagule, for it was in such a situation that its parent plant grew, to shed it into the sea. On the Krakataus a large, important group of widely distributed sea-borne plant species forms a consistent, determinate core of pioneer colonists that is repeated in several cases.

The chances of establishment of a new species also may be affected by an important biotic factor—the species that are already present, so that sequence of arrival is important. Even with the same pool of colonizing species, final outcomes—the composition of resulting biotas—will differ unless the sequence and even also the length of the interval between arrivals (colonizing interval) are identical. There are both stochastic and deterministic influences on these factors.

Seamus Ward and I have considered the relative roles of chance and determinism in this biotic aspect of species assembly in isolated habitats, both from a theoretical point of view and with regard to the Krakatau cases. A simple model predicts that the degree of stochasticity will depend in part on the relative dispersal abilities of potentially interacting colonizing species. Variation in priority will be high where two such species have similar, low, arrival rates, and variation in the interval between colonizations will depend on the dispersal ability of the second species to arrive. We concluded that early colonization should be relatively deterministic, as the assembly of Krakatau's early, pioneer sea-borne flora appears to be. Later in the colonization process both priority and the colonizing interval will be more variable. We identified possible instances of the increasing importance of chance in the later colonization of the Krakataus by large animal-dispersed forest trees and lianas. On the Krakataus the increasing importance of chance in these later stages of floral assembly is demonstrated by the fact that after a century of colonization, closely adjacent Krakatau islands, separated by only a few kilome-

TABLE III Changing Dispersal-Mode Spectra of Cumulative Vascular Plant Floras Present on Rakata (Krakataus) at Successive Survey Periods (Some Surveys Grouped)

Note. Based on Table 3b of Whittaker *et al.* (1992).

ters, developed forests dominated by quite different species.

### VIII. SUMMARY

The effect of volcanic eruptions on living communities depends on a number of factors, most importantly on the type of eruption, and at the extreme the macrobiota may be entirely extirpated. Where there is survival from refugial foci, this is usually more important than the immigration of new biotic elements in the recovery process. There are two aspects to the assembly of a new biota through the colonization of immigrants—the arrival and establishment of incoming species. In general, the plant–herbivore–carnivore sequence is followed, but there is a growing evidence that on primary substrates a guild of animals that exploit airborne organic input may precede plant colonization. Although generally colonization by bacteria and cryptogamic plants (e.g., lichens, mosses, and ferns) precedes that of seed plants, there are many instances in which seed plants were the primary colonists.

Successful establishment in some cases appears to involve incorporation into simple communities of a few interacting species. These communities are then integrated into the larger, more complex developing ecosystem. Both chance and deterministic factors are involved in colonization and the development of a new biota, and their relative importance may vary from case to case and over time within a single case of biotic renewal.

### ACKNOWLEDGMENTS

I have been greatly assisted by discussions with the following, most of whom commented on early drafts of this paper, and on whose works I have drawn freely: Eldon Ball, who encouraged me to try to further his own significant work on Motmot; Bayard Brattstrom, who provided unpublished data from his pioneer studies on Barcena; John Edwards, who sent me the

manuscript of his own excellent review on a very similar topic but focusing particularly on his own special study area, Mount St. Helens; Sturla Fridriksson, who introduced me to Surtsey and kept me up-to-date with his team's fundamentally important long-term studies there; Tukirin Partomihardjo and Rob Whittaker, whose detailed knowledge of the Krakatau's flora and masterly overview of their phytogeography must underpin all biological work on those islands; and my Australian colleague Seamus Ward, who has sharpened my appreciation of the theoretical approach to developmental ecology.

## GLOSSARY

**flood basalt** Large outpourings of basaltic lava composed of individual flows with volumes up to thousands of km<sup>3</sup>. The lava flows, erupted over a total time interval usually less than 1 million years, produce lava plateaus typically more than 1 million km<sup>3</sup> in volume and covering more than 1 million km<sup>2</sup>.

**greenhouse warming** Climatic warming caused by gases in the atmosphere, such as CO<sub>2</sub>, SO<sub>2</sub>, and methane, that absorb outgoing infrared radiation and warm the planet.

**Jurassic** Period of geologic time ranging from about 201 to 144 million years ago.

**K/T boundary** The stratigraphic boundary between rocks of Cretaceous age and rocks of Tertiary age, now dated at 65 million years ago. The boundary stratum is marked by evidence of a comet or asteroid impact, which is widely believed to have caused the extinction of some 75% of marine species and most nonmarine organisms at the end of the Cretaceous period.

**mass extinction** Simultaneous or near-simultaneous disappearance of a large number of extant species. Five major

mass extinctions, in which more than 75% of marine life and many nonmarine species died out, are recognized at the end of the Ordovician period (439 Ma); the Late Devonian period (365 Ma); the end of the Permian period (250 Ma); the end of the Triassic period (201 Ma); and the end of the Cretaceous period (65 Ma). About 20 "minor mass extinctions" have also occurred in the last 545 million years.

**Oligocene** Epoch of geologic time from 35 to 23 million years ago.

**Permian** Period of geologic time ranging from about 290 to 250 million years ago. Last period of the Paleozoic era. The Permian ended with the greatest mass extinction in the geologic record.

**sulfuric acid aerosols** Small droplets of sulfuric acid formed in the atmosphere from oxidation of sulfur-rich gases. These aerosols can form a haze in the upper atmosphere after volcanic eruptions, which can reduce incoming sunlight and cool the planet.

**Triassic** Period of geologic time ranging from 250 to 201 million years ago. The first period of the Mesozoic era.

**volcanic winter** Term used for the severe global and regional cooling that can be caused by large amounts of volcanic aerosols in the atmosphere after very large eruptions.

**E**XTINGUITION EVENTS are increasingly seen as important factors in the history of life on Earth, and recent studies suggest catastrophic causes for at

least some biotic mass extinctions. Two catastrophic processes that have been invoked are impacts of asteroids or comets and series of large volcanic eruptions. On one hand, the end-Cretaceous (65 Ma) mass extinction (the Cretaceous/Tertiary or K/T boundary) has been convincingly correlated with the impact of a 10-km-diameter comet or asteroid, and evidence of impact has been found close to the times of several other extinction events. On the other hand, the coincidence of the eruption of the Siberian flood basalt lava flow province and the even more severe end-Permian extinctions (250 Ma), and the near-coincidence of the Deccan flood basalt province (India) and the K/T extinctions, fostered speculations that flood basalt eruptions have contributed to a number of mass extinctions. Several workers compared the dates of extinction events of various magnitudes with dates of flood basalt episodes and found some significant correlations, supporting a possible cause-and-effect connection. Thus, it could be that extreme events of both extraterrestrial and terrestrial origin are responsible for many of the punctuation marks of the fossil record.

A major question regarding any possible relationship between flood basalt lava eruptions and extinction events involves the nature and severity of the environmental effects of the eruptions and their potential impact on life. Although the correlation between some flood basalt episodes and extinctions may implicate volcanism in the extinctions, it is also possible that other factors lead to the apparent association. Flood basalt episodes have been related to the inception of mantle plume activity, and thus may represent one facet of a host of geological factors (e.g., changes in seafloor spreading rates, rifting events, increased tectonism and volcanism, and sea-level

variations) that tend to be correlated, and may be associated with unusual climatic and environmental fluctuations that could lead to significant faunal changes. It has also been suggested that a coincidence of both a large impact and a flood basalt eruption might be necessary in causing severe mass extinctions, and some workers have even proposed that large impacts might in some way trigger or enhance the volcanism.

### 1. CORRELATION BETWEEN CONTINENTAL FLOOD BASALTS AND BIOTIC EXTINCTIONS

Continental flood basalt eruptions are the largest sub-aerial eruptions of basaltic composition, with known volumes of individual lava flows  $> 2000 \text{ km}^3$ . A series of these huge eruptions piles up a thick stack of basalt lava flows, creating vast provinces extending to more than a million  $\text{km}^2$  and containing more than 2 million  $\text{km}^3$  of basaltic lava. The estimated inception dates of the continental flood basalts compiled from recent sources (based on the latest high-quality  $^{40}\text{Ar}/^{39}\text{Ar}$  and U/Pb age determinations) are shown in Table I. Radiometric, paleomagnetic, and stratigraphic data all indicate that in most instances the greatest number of individual eruptions and the largest volume of lava occurred within a million years or less (Figure 1).

We can compare the ages in Table I with estimated ages of stratigraphic boundaries that involved significant

TABLE I Flood Basalt Provinces of the Last 250 Ma

Province	Age (Ma)	Volume ( $10^6 \text{ km}^3$ )	Paleolatitude	Duration (m.y.)
Columbia River	$16 \pm 1$	0.25	$45^\circ\text{N}$	$\leq 1$ (for 90%)
Ethiopian	$31 \pm 1$	$\leq 1.0$	$10^\circ\text{N}$	$\leq 1$
North Atlantic	$57 \pm 1$	$> 1.0$	$65^\circ\text{N}$	$\leq 1$
Deccan	$66 \pm 1$	$> 2.0$	$20^\circ\text{S}$	$\leq 1$
Madagascar	$88 \pm 1$	?	$45^\circ\text{S}$	$\leq 6?$
Rajmahal	$116 \pm 1$	?	$50^\circ\text{S}$	$\leq 2$
Serra Geral/Etendeka	$132 \pm 1$	$> 1.0$	$40^\circ\text{S}$	$\leq 1$ or $\sim 5?$
Antarctica	$176 \pm 1$ or $183 \pm 1$	$> 0.5$	$50-60^\circ\text{S}$	$\leq 1?$
Karoo	$183 \pm 1$	$> 2.0$	$45^\circ\text{S}$	$0.5-1$
Newark	$201 \pm 1$	$> 1.0$	$30^\circ\text{N}$	$\sim 0.6$
Siberian	$249 \pm 1$	$> 2.0$	$45^\circ\text{N}?$	$\leq 1$

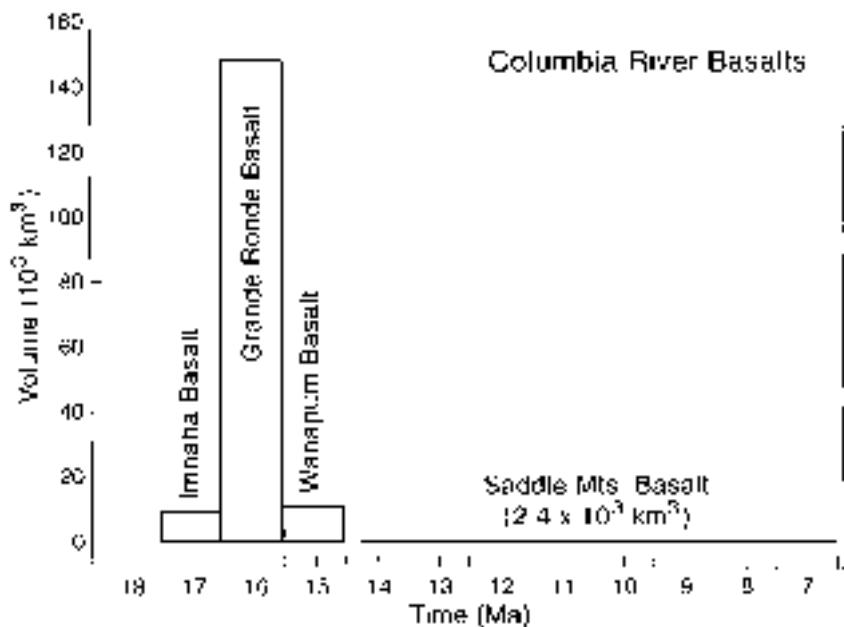

FIGURE 1 Estimate of erupted volume of Columbia River Basalts over the duration of the eruptive activity. Note that most of the magma was discharged during less than 1 million years, centered at about 16 Ma. Other flood basalt eruptions have a similar narrow age distribution.

faunal changes, dated according to the most recent geologic timescale (Table II and Figure 2).

In at least three cases, the Deccan, Newark, and Siberian flood basalts, a more direct measure of correlation with mass extinction boundaries is possible. For exam-

ple, the Deccan Traps Flood Basalts of India contain >50 recognized flows in 1200-m sections in the best exposed region around Mahabaleshwar. The Deccan lavas were previously believed to have been erupted over a long period of time ranging from ~80 to ~30 Ma,

TABLE II Flood Basalt Episodes and Faunal Events

Flood basalt episode	Age (Ma)	Stratigraphic boundary	Age (Ma)
Columbia River	$16 \pm 1$	Early/Mid-Miocene	16.4
Ethiopian	$31 \pm 1$	Early/Late Oligocene	30
North Atlantic	$57 \pm 1$	Paleocene/Eocene (Thanetian/Selandian)	54.8 (57.9)
Deccan	$66 \pm 1$	Cretaceous/Tertiary	$65.0 \pm 0.1$
Madagascar	$88 \pm 1$	Cenomanian/Turonian (Turonian/Coniacian)	$93.5 \pm 0.2$ (89 $\pm$ 0.5)
Rajmahal	$116 \pm 1$	Aptian/Albian	$112.2 \pm 1.1$
Serra Geral/Etendeka	$132 \pm 1$	Jurassic/Cretaceous (Hauterivian/Valanginian)	$142 \pm 2.6$ (132 $\pm$ 1.9)
Antarctica	$176 \pm 1$ or $183 \pm 1$	(Aalenian/Bajocian)	$(176.5 \pm 4)$
Karoo	$183 \pm 1$	Early/Middle Jurassic	$180.1 \pm 4$
Newark	$201 \pm 1$	Triassic/Jurassic	$205.7 \pm 4$
Siberian	$249 \pm 1$	Permian/Triassic	$248.2 \pm 4.8$

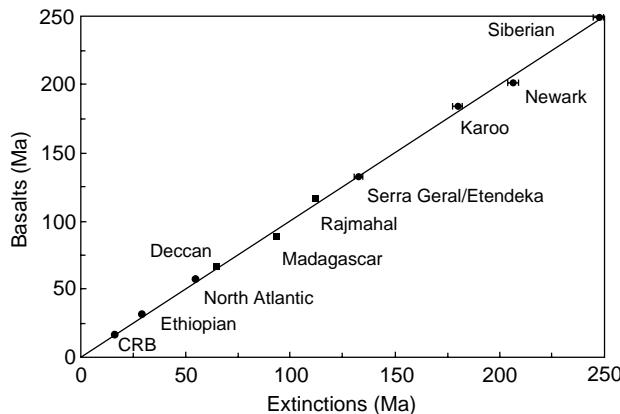

FIGURE 2 Possible correlation of flood basalts and extinctions/faunal changes. This graph uses 16.4, 30, 54.8, 65, 93.5, 112.2, 132, 180, 206, and 248.2 Ma ages for faunal changes (see Table II).

based on the large range of K/Ar age determinations. Redating of the basalts using refined  $^{40}\text{Ar}/^{39}\text{Ar}$  techniques, however, indicates that the vast bulk of the thick stack of flows was erupted over a period of only about 500 ky, bracketing the time of the Cretaceous/Tertiary boundary. Most recently, the K/T boundary impact fallout layer has been reported to lie in sediments interbedded within the Deccan lavas, supporting the radiometric dating and paleomagnetic results that indicate that the eruptions began prior to the K/T boundary.

In the case of the Newark Basalts of eastern North America, the pollen changes that mark the Triassic/Jurassic boundary have been located just below ( $\leq 40$  ky) the first lava flows. For the Siberian Basalts, the paleontological evidence has been interpreted as placing the time of the Permian/Triassic mass extinction within the lowest lava suite. The probability that three major episodic volcanic events that typically last  $\leq 1$  m.y. should occur within 1 m.y. (to be conservative) of major mass extinction boundaries during the last 250 Ma (of which there are  $\sim 12$ ) is about  $\sim 10^{-4}$ . For a few other basalts precise dating and paleomagnetic work suggest correlations with boundaries involving lesser faunal and floral changes. For example, the Ethiopian Basalts, recently dated at  $31 \pm 1$  Ma, may correlate with the faunal changes that mark the Lower/Upper Oligocene boundary, dated at close to 30 Ma. The Karoo Basalts, recently dated at  $183 \pm 1$  Ma, might correlate with the boundary between the Early and Middle Jurassic, at  $180.1 \pm 4$  Ma, which is also marked by a faunal turnover event.

## II. ENVIRONMENTAL EFFECTS OF FLOOD BASALT ERUPTIONS

Several kinds of environmental effects of flood basalt eruptions have been suggested, including climatic cooling from sulfuric acid aerosols, greenhouse warming from  $\text{CO}_2$  and  $\text{SO}_2$  gases, and acid rain. Indirect environmental effects include changes in ocean chemistry, circulation, and oxygenation, especially from basaltic volcanism associated with large submarine oceanic plateaus that may represent flood basalt volcanism in an oceanic environment. Before we proceed to evaluate these effects, however, we briefly examine the nature of flood basalt volcanism and estimate the amounts climatically active gases these volcanic events can release into the atmosphere.

### A. The Style of Flood Basalt Eruptions

The style of eruption of flood basalt lavas is an important determinant in the atmospheric and climatic effects of these events. In fissure-fed basaltic lava flow eruptions, the volumetric eruption rate is a critical parameter in determining the height of fire fountains over active vents, the convective rise of the volcanic gas plumes in the atmosphere, and hence the climatic impact of an eruption.

Flood basalt eruptions were originally envisioned as flowing as turbulent sheets 10 to 100 m thick that covered large areas in a matter of days. By contrast, it is now believed that flood basalts are erupted mainly as fissure-fed pahoehoe flows that inflate to their great thicknesses during the time that they reach their great extent. This suggests relatively slow emplacement of the flows over longer periods of time, most likely years to decades. Yet, average eruption rates must still have been higher than in any historic eruption except perhaps the extremes of some Icelandic lava outpourings. For example, the time required to emplace a large ( $1000-2000$   $\text{km}^3$ ) lava flow at the peak output rate (about  $1.4 \times 10^7$   $\text{kg/s}$ ) of the largest historical lava flow eruption, the 1783 Laki (Iceland) event, would be  $\geq 10$  years.

### B. Climate Cooling

Climatic cooling at the Earth's surface attributed to volcanic eruptions is primarily a result of the formation and spread of stratospheric  $\text{H}_2\text{SO}_4$  aerosols. These small

droplets are formed from sulfur volatiles (largely SO<sub>2</sub>) injected into the stratosphere by convective plumes rising above volcanic vents and fissures. The sulfuric acid aerosols have a residence time in the stratosphere of several years, where they backscatter incoming sunlight. Fine volcanic ash also lofted into the stratosphere largely settles out of the atmosphere in less than 3 months.

Basaltic eruptions are commonly effusive in character, last much longer, and are much less explosive than silicic eruptions of comparable volume. They are commonly considered to be much less effective in lofting volatiles to significant altitudes, where stratospheric aerosols could be produced. Observations and model calculations suggest, however, that the high eruption rates during the (~15 km<sup>3</sup>) 1783 Laki basaltic fissure eruption in Iceland produced high fire fountaining (~600 to 1450 m), so that convective plume rise above the fountains could have attained altitudes up to 13 km above sea level (Figure 3). In support of this estimate, observations of the widespread sulfurous haze over Europe in 1783, and a marked sulfuric acidity peak in Greenland ice in 1784, suggest that the eruption plume reached the tropopause over Iceland (~9 km), and intruded into the base of the stratosphere. For the much larger volume lava flows typical of flood basalt episodes, the models of convective plume rise also indicate that sulfur-rich eruption plumes could reach the lower stratosphere.

Moreover, basaltic magmas are usually very rich in dissolved sulfur (commonly with concentrations of >1500 ppm sulfur), and therefore the release of sulfur-rich gases from a large basaltic eruption can be much higher than that from an explosive silicic eruption of equal volume. For example, studies of the Laki lava flow and ash indicate that the magma originally contained ~1700 ppm of sulfur, and the eruption could have released ~125 MT of SO<sub>2</sub> (65% during the first 2 months of intense activity) from the vent and lava flows (1 MT = 10<sup>12</sup> g). This could have created about 160 MT of high-altitude H<sub>2</sub>SO<sub>4</sub> aerosols, and about 50 MT of local aerosols in the Icelandic troposphere.

The atmospheric effects of the Laki eruption were severe and quite widespread, supporting the creation of at least some stratospheric aerosols. Haziness and dimming of sunlight were noticeable in 1783–1784 in Europe (Figure 4), and the so-called “dry fog” was reported in North America and as far east as China. Climatic cooling followed, and the winter of 1783–1784 was the coldest winter recorded in the eastern United States in a 225-year record.

The observed sulfur content of basaltic magmas and evidence of degassing of the lava flows suggest that the sulfur release from a large flood basalt eruption of ≥1000 km<sup>3</sup> volume [such as the Roza Flow of the Columbia River Basalts (14.7 Ma)] can be about 10,000

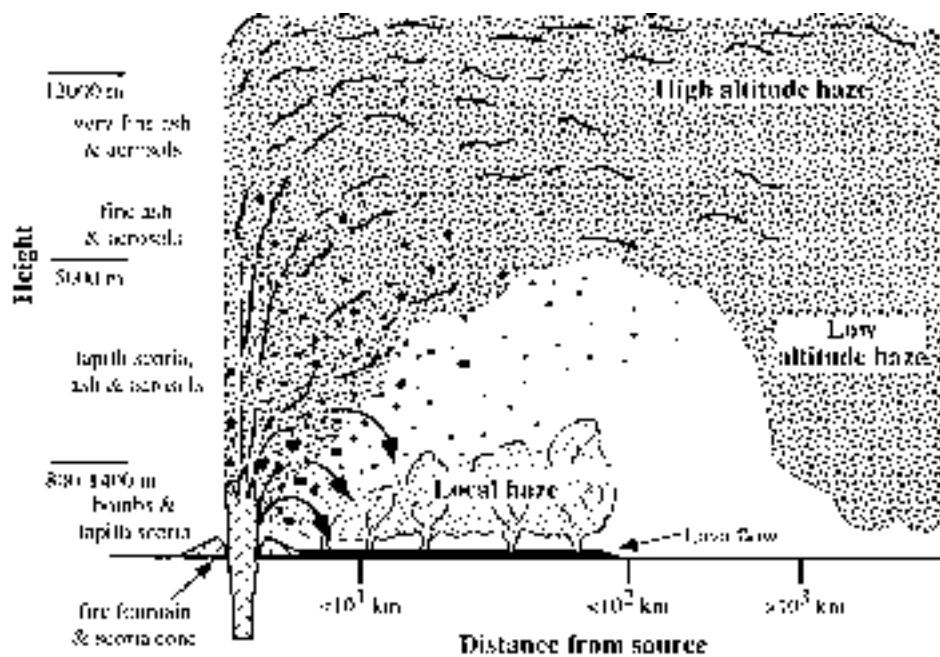

FIGURE 3 Eruption column height and levels of atmospheric injection of ash and aerosols from the 1783–1784 Laki (Iceland) eruption. Information obtained from calculations and observations. [After Thordarson and Self, unpublished.]

MT of  $\text{SO}_2$ , along with significant amounts of HF and HCl. At maximum eruption rates for Laki, the Roza eruptions would have produced lava fountains  $\geq 1.5$  km in height, and created a convective column rising  $\geq 15$  km above the vents. If the Roza eruption went on for 10 years, the annual aerosol burden in the atmosphere could have been greater than 1000 MT per year, with a portion going into the lower stratosphere. This would be enough to produce a large increase in the opacity of the regional and perhaps hemispheric atmosphere.

The conversion of such a large amount of  $\text{SO}_2$  to  $\text{H}_2\text{SO}_4$  would have probably greatly depleted stratospheric  $\text{H}_2\text{O}$  and OH, which at present consists of about 1000 MT globally, but a large amount of water could have been injected into the stratosphere by the eruption plumes. Some have suggested that self-limiting physical and chemical effects in very dense aerosol clouds might mitigate severe volcanic perturbations. It may be, however, that some features of dense clouds prolong the lifetime of aerosols in the upper atmosphere, as evidenced by the extended 6-year ice core acidity peak possibly related to the Toba (Indonesia) explosive eruption of 74,000 years ago. More accurate modeling of dense stratospheric aerosol clouds, and their effects on atmospheric dynamics and chemistry, is needed.

Volcanic aerosols at all altitudes should cool the Earth's surface, with maximum cooling effects from low-level tropospheric aerosols. In most volcanic eruptions, however, tropospheric aerosols have a very short lifetime of about a week before they are washed out of the lower atmosphere. A flood basalt eruption could release such large amounts ( $\sim 1000$  MT) of sulfuric acid aerosols, however, that a regional tropospheric aerosol cloud might be maintained despite washout. Climate cooling might also lead to suppression of atmospheric convection, so that rainout might be less effective at removing the aerosols.

Historic stratospheric aerosol clouds such as from the eruptions of El Chichón in 1982 and Pinatubo in 1991 have typically shown an atmospheric lifetime of a few years, so that the ocean–atmosphere climate system did not have a chance to come to equilibrium with the short-lived volcanic perturbation. Thus, these historic eruptions that created on the order of tens of MT of stratospheric aerosols are associated with surface coolings of only a few 10ths of a degree Celsius in the 1 or 2 years following the eruption (although a prompt cooling in the month after the eruption, probably related to volcanic ash in the atmosphere, has also been noted). Studies using a global climate model (GCM) suggest that if maintained for 50 years, a stratospheric loading of only about 10 MT of aerosols would lead to a  $5^\circ\text{C}$  global

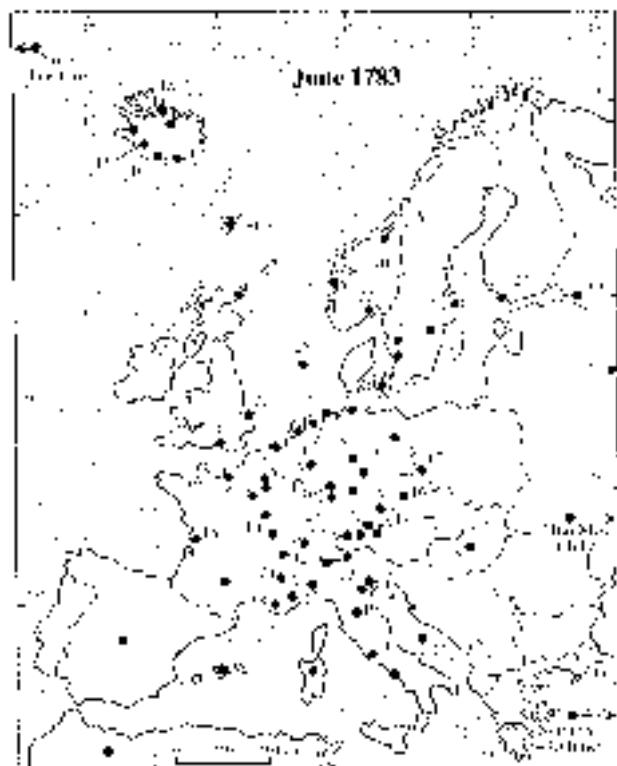

cooling. Therefore, if flood basalt eruptions were continuous at the average activity level for decades, significant cooling of climate is possible through involvement of the oceans.

Basaltic eruptions can also have episodes of more explosive activity. Laki, for example, produced ash estimated to have been about 3% of the total erupted volume. Some continental flood basalt eruptions are known to have been accompanied by more explosive volcanism. The North Atlantic Basalts were apparently coincident with a series of 200 or more basaltic ashes, equivalent to a magma volume of several thousand cubic kilometers. These explosive basaltic eruptions probably involved hydrovolcanic processes, and the widespread ash in the atmosphere could have led to some cooling.

### C. Greenhouse Warming: Carbon Dioxide and Sulfur Dioxide

Greenhouse warming caused by large emissions of carbon dioxide from flood basalt volcanism has also been suggested as a cause of climatic change leading to mass extinctions. For example, based on published estimates of the  $\text{CO}_2$  weight fraction of basaltic magmas, the fraction of  $\text{CO}_2$  degassed, and the volume and timing of the Deccan eruptions, it has been estimated that from  $\sim 6$  to  $20 \times 10^{16}$  mol of carbon dioxide could have been released over a period of several hundred thousand years. Results of models designed to estimate the effects of this increased  $\text{CO}_2$  on climate and ocean chemistry suggest, however, that the total increase in atmospheric  $p\text{CO}_2$  would have been less than 200 ppm, leading to a predicted global warming of less than  $2^\circ\text{C}$  over the period of eruption of the lavas. It is unlikely that such a small and gradual warming would have been an important factor in mass extinctions of life.

Another possible source of greenhouse warming from flood basalt eruptions is  $\text{SO}_2$  gas emissions. The Laki eruption showed that prolonged basaltic fissure eruptions can create large, persistent downwind plumes of  $\text{SO}_2$  gas and  $\text{H}_2\text{SO}_4$  aerosols in the lower atmosphere. During the summer of 1783 in Europe, while the sulfurous dry fog hung in the air, the weather was stifling. Historical reports of acrid odor, difficult breathing, dry deposition of sulfate, and vegetation damage indicate especially high  $\text{SO}_2$  concentrations in the lower atmosphere from mid-June to early August (Figure 4). The July 1783 temperatures in Western Europe were up to  $\sim 3^\circ\text{C}$  warmer than the long-term average, and contemporary reports describe the weather as hazy, hot, and

**FIGURE 4** The inferred dispersal of the Laki haze (dry fog) of 1783, from contemporary reports. Dots indicate locations of observations; numbers give dates of observation in June 1783. [After Thordarson and Self, unpublished.]

very dry, but with frequent thunderstorms and hailstorms of unusual intensity.

The average concentration of  $\text{SO}_2$  in the atmosphere over Western Europe in July 1783 could have been up to several ppm (background values are  $\sim 1$  ppb), and calculations suggest that the greenhouse effect of the  $\text{SO}_2$ -rich volcanic haze could have led to significant regional short-term warming. The even greater emissions of  $\text{SO}_2$  from flood basalt volcanism could have led to more severe regional warming events that might have affected flora and fauna over wide areas.

#### D. Acid Rain

Acid rain from flood basalt eruptions is another possible environmental effect. For the historic Laki eruption, the local haze over Iceland contained high concentrations of sulfuric acid, causing skin lesions in animals and humans. Grass growth was stunted, trees were killed, and 50% of livestock perished from fluorine poisoning. The re-

sulting "haze famine" led to the death of  $>20\%$  of the Icelandic population, and acid rain effects were also reported from Northern Europe.

Calculations for flood basalts suggest that  $\text{H}_2\text{SO}_4$ , HF, and HCl release from a typical eruption of  $\sim 1000 \text{ km}^3$  could have been about  $10^{14}$  mol. If spread worldwide, this acid would give  $\sim 0.2 \text{ mol/m}^2$ , and if deposited over a year, then the daily acid fallout would be  $\sim 5 \times 10^{-4} \text{ mol/m}^2$ . If the eruption lasted  $\sim 10$  years, however, the daily deposition would be only  $\sim 5 \times 10^{-5} \text{ mol of acid}$ .

For comparison, total current anthropogenic sulfur release is about  $10^{14} \text{ g}$  per year, or about  $10^{12} \text{ mol H}_2\text{SO}_4$  equivalent. Total global annual rainfall at present is  $\sim 5 \times 10^{17}$  liters. As a rough estimate, if  $1 \times 10^{14} \text{ mol H}_2\text{SO}_4$  (equals  $\sim 2 \times 10^{14} \text{ mol of H}^+$ ) is added to this precipitation, the result is  $\sim 4 \times 10^{-4} \text{ mol/liter of H}^+$ , equivalent to a pH of  $\sim 3.7$ . The acidity of rainfall nearer to the flood basalt eruption would be higher (lower pH), and rainfall at distant sites would be less acidic (higher pH). Although it seems clear that local or regional effects of acid rain from flood basalt eruptions could have been considerable, global effects are much less likely.

#### E. Other Environmental Perturbations

Several other less well-constrained extinction mechanisms for flood basalt volcanism have been suggested. In the case of the Siberian Flood Basalts and the Permian/Triassic extinctions, it has been suggested that the volcano-nism caused the release of vast quantities of methane from hydrates that had accumulated on adjacent high-latitude shelf areas, leading to greenhouse warming. In other scenarios, the addition of volcanic  $\text{CO}_2$  into the atmosphere was proposed to contribute to global warming and overturn of anoxic ocean bottom waters, and perhaps create physiological problems for land animals. As discussed above, however, it is very unlikely that the flood basalt volcanism could have produced enough  $\text{CO}_2$  by itself to lead to these conditions.

It has also been suggested that large-scale ocean-plateau volcanism, such as that which created the Ontong Java Plateau and the Caribbean volcanic province in the Cretaceous period, could have altered ocean chemistry through the oxidation of material in hydrothermal effluents and stimulation of primary productivity in the surface oceans by release of hydrothermally derived iron. Such a submarine volcanic scenario has been proposed as a cause of global ocean anoxia at times of Cretaceous extinction (e.g., the Cenomanian-Turonian mass extinction at 93 Ma).

---

### III. FLOOD BASALTS AND IMPACTS: POSSIBLE CONNECTIONS

Several authors have explored the possibility that flood basalt volcanism might be triggered or enhanced by the occurrence of large comet or asteroid impacts. Rough calculations implied that large impacts (impactors of  $\geq 10$  km diameter) could excavate initial transient cavities deep enough to result in decompression melting in the upper mantle, with ensuing volcanism along deep fractures that penetrated the lithosphere. To date, however, there is no firm evidence that impacts can directly induce terrestrial volcanism, and convincing evidence for local large impacts has not been reported at the sites of flood basalt eruptions. Thus, a direct connection seems unlikely.

Is an indirect connection possible? Energy considerations suggest that the impact of a large (several kilometer-diameter,  $\sim 10^{18}$  g) asteroid or comet traveling 20 to 60 km s<sup>-1</sup> releases  $\sim 10^{23}$  to  $10^{24}$  J. Even with a low seismic efficiency of about  $10^{-4}$ , the total seismic energy would be  $\sim 10^{19}$  to  $10^{20}$  J, and such an impact is estimated to produce an earthquake with a Richter magnitude  $\geq 10$ . Furthermore, the impact energy is delivered over a very short time period, and thus the rate of energy input into the terrestrial system is orders of magnitude greater than the rate of energy release from terrestrial tectonic processes. Lithospheric stresses created by updoming from a rising mantle plume might be released during such a global seismic event, leading to the kind of rapid decompression melting thought to be required to produce flood basalts.

More recently, calculations indicate that focusing of seismic waves from large impacts can also produce relatively large stresses at their antipodes (and perhaps other caustics) on the Earth, possibly causing lithospheric fracturing and deposition of heat in the upper mantle, that might help to induce or increase ongoing volcanism. Some evidence for this idea comes from finite-element modeling and studies of volcanic centers (e.g., Alba Patera) antipodal to large impact basins on Mars. The Deccan Province was erupted as India sat above the Reunion hot spot, which today lies at about 21°S, 55°E. Reconstructions, however, place the large ( $>150$ -km diameter) end-Cretaceous Chicxulub impact structure in Yucatán at  $\sim 20^{\circ}\text{N}$ , 70°W, in the Late Cretaceous, 55° in longitude from the antipodal position from the Reunion hot spot. For the Deccan, at least, the evidence suggests that the eruptions began prior to the large Chicxulub impact, and thus it looks as though

that impact could not have triggered the initiation of volcanism.

The wealth of physical evidence for an extraterrestrial impact or impacts at the K/T boundary, and the close timing of many of the extinctions with the worldwide impact ejecta layer, suggests that the primary cause of the K/T mass extinctions was the collision of an asteroid or comet with the Earth. If, indeed, some species of life died out prior to the large impact event, then the Deccan eruptions might be implicated. Some critics of the impact interpretation, however, have attempted to attribute all of the important components of the K/T boundary layer to volcanism. Suggestions that the anomalous iridium at the boundary was a product of Deccan volcanism are ruled out by the generally low iridium values in the Deccan lavas, in soils and weathering profiles between flows, and in K/T boundary sections on the Indian subcontinent. Furthermore, despite arguments to the contrary, experimental and observational evidence clearly shows that shocked quartz and stishovite cannot be produced at the pressures characteristic of volcanic eruptions, and the K/T tektite glass has features incompatible with a volcanic origin. If volcanism did contribute to the end-Cretaceous extinctions, it did not produce these forms of evidence.

---

### IV. EXPLOSIVE VOLCANISM AND EFFECTS ON LIFE

Explosive volcanic eruptions can definitely produce global aerosol clouds in the stratosphere, and historic explosive events, such as Tambora in 1815 and more recently Pinatubo in 1991, have had significant short-term climatic effects. Thus, it is also worthwhile to consider the environmental effects of the largest known explosive eruptions.

#### A. The Toba Eruption and Volcanic Winter

The largest ( $\sim 2800$  km<sup>3</sup> of magma) explosive eruption of the last few hundred thousand years was the  $\sim 74,000$  year B.P. Toba eruption (Indonesia). Toba occurred during a relatively rapid interglacial-glacial cooling and

sea-level drop, which may have played a role in triggering the eruption. Stratospheric dust and aerosols ( $\sim 1000$  MT) could have accelerated the cooling by causing a “volcanic winter” with global temperature decreases of 3 to  $5^{\circ}\text{C}$ , and  $\sim 10^{\circ}\text{C}$  during the growing season at mid-to-high latitudes for a year or more, with possible longer term climatic effects. Ice core studies indicate that the Toba aerosols remained in the stratosphere for the unusually long time of  $\sim 6$  years.

Botanical studies suggest that very cold-sensitive tropical vegetation would be affected disastrously by abrupt low-latitude cooling. Furthermore, computer model simulations show that reduction of early growing-season temperatures by  $\sim 10^{\circ}\text{C}$  can kill  $\geq 50\%$  of temperate to sub-Arctic evergreen forests, and severely damage the surviving trees. Temperate deciduous trees, and other less cold-hardy vegetation, are expected to fare even worse. These results suggest a global ecological crisis, with reductions in standing crops of plants and animals. Evidence for such abrupt environmental changes in the aftermath of Toba might be detectable in high-resolution records (e.g., lakes and bogs) and ice cores.

Although no major extinctions are seen at the time of Toba’s blast, human genetic studies indicate that prior to  $\sim 50,000$  years ago the human population suffered a severe bottleneck (perhaps only 4000 to 10,000 individuals for  $\sim 20,000$  years), followed by rapid population increases, technological innovations, and spread of humans “out of Africa.” The predicted environmental and ecological effects of the Toba eruption lend support to a possible connection between that volcanic event and the human population bottleneck, and other faunal/floral changes are predicted.

# ERUPTION RESPONSE AND MITIGATION

Scores of volcanoes will continue to erupt (about 55 to 70 being active each year) and will thus continue to pose a significant risk as the world's population grows and we rely increasingly on technology for the basic needs of civilization. However, some of the same technologies that improve life, such as the Global Positioning System (GPS), have also led to improvements in forecasting of eruptions. Better data, plus improvements in the use of data, have led to increasingly effective responses to eruptions and mitigation of their hazards.

One of the main tools for monitoring is seismology. Nearly every eruption is preceded by an increase in earthquake activity, and eruptions are accompanied by a continuous vibration of the ground known as volcanic tremor. The opening chapter of this section, Seismic Monitoring, discusses the use of seismology in eruption forecasting and monitoring in general. The chapter includes case studies of eruptions at Mount St. Helens, Kilauea, Ito-Oki, Pavlof, and Pinatubo.

Deformation of the ground, such as bulging, doming, or the formation of cracks, is also frequently found prior to eruptions. Further, if new magma is injected beneath a volcano, gravity changes may occur because new mass is being added. Finally, when rock is heated near its Curie temperature, its magnetization decreases. The following chapter, Ground Deformation, Gravity, and Magnetics, discusses modern techniques of measuring deformation, gravity, and magnetic signals and their use in monitoring volcanoes and eruption forecasting. Case histories include Sakurajima, Krafla, Colima, Mount St.

Helens, Campi Flegrei, Poas, Etna, White Island, and Aso volcanoes.

In addition to earthquakes and deformation, volcanoes typically show signs of increased heat or changes in degassing prior to eruptions. These may be measured from the Earth's surface or from satellites if the signal is strong enough. During eruptions, plumes of ash and gases rise and may then travel great distances downwind. The next chapter, Gas, Plume, and Thermal Monitoring, examines the monitoring of gases, heat, and plumes and illustrates these with examples from Mount St. Helens, Pinatubo, Showa-Shinzan, Usu, Vulcano, Long Valley caldera, Galeras, Masaya, Etna, Popocatepetl, El Chichon, Spurr, Erebus, Lascar, and others.

Each type of data may be handled and interpreted individually, but experience has shown that much more can be learned when various data sets are combined. Indeed, closely monitored eruptions with many data sets provide much of the basis for progress in volcanology. The chapter Synthesis of Volcano Monitoring describes how various types of data contribute to an evolving understanding of the activity of volcanoes. The sequence of geological, geochemical, and geophysical events is different for different types of eruptions. These ideas are illustrated using detailed case studies from Mount Etna and from Soufriere Hills (Montserrat).

Once scientists agree about the meaning of the data (and even if they disagree), a series of communications need to occur between scientists and those responsible for emergency response. The actions that need to be taken, appropriate for the current or expected hazards, need to be identified and assigned to the right people. The content and distribution of warning messages, maps, videos, alert levels, etc., are the focuses of the chapter Volcano Warnings. Concepts are illustrated using examples from two volcanoes that have erupted, Mount St. Helens and Pinatubo, and one that has not, Long Valley caldera.

Although most eruptions are small, any eruption can pose a risk if people or structures are close to the volcano. Large eruptions, in contrast, affect nearby populations

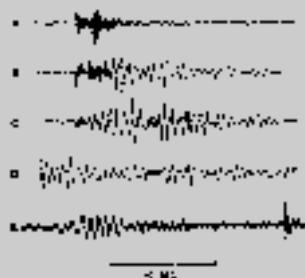

with certainty and have many effects at great distances. In each case, the perception of the events, and the response of society, will dictate whether an eruption is benign or whether a disaster will occur. The next chapter, Volcanic Crises Management, discusses elements of volcanic crises management, drawing on experiences at El Chichon, La Soufriere (Guadeloupe), Popocatepetl, Nevado del Ruiz, and others.

Past eruptions have left deposits that can be studied to learn about the type and distribution of specific volcanic hazards. Further, contemporary eruptions at similar volcanoes may be studied to learn about the general effects of hazards. Once these are identified, coherent strategies may be developed to help mitigate risk. Some of these are direct, such as building dams to protect areas from mudflows. Some are longer term and less direct, such as land use zoning. Others are indirect and strategic, such as setting appropriate rates for insurance. These and other related topics are discussed in the chapter Volcanic Hazards and Risk Management.

When an eruption occurs or is about to occur, the need for information suddenly becomes acute. Much of the needed information can be prepared ahead of time; indeed, the in-between periods last much longer than the eruptive periods. Effective strategies for education and intervention are the subjects of the final chapter of this section, Risk Education and Intervention. Although few studies have been done on the subject, the authors of this article assess the effects of a brief school-based intervention program that they conduct at three schools following the 1995 eruptions of Mount Ruapehu, New Zealand.

Although volcanoes will continue to erupt, knowledge of their behavior and effects, and adequate monitoring programs, can greatly reduce the risks from future eruptions. People can coexist with volcanoes provided they do so intelligently.

## GLOSSARY

- anomaly** An observation that differs from normal or expected values.
- deterministic** A statement of the likelihood of an event based on a physical model and measurements.
- forecast** A general description of future events, including rough estimates of time, location, and likely activity.
- precursor** A geological event that occurs prior to an eruption and is related to the preparation processes of the forthcoming eruption.
- prediction** A specific description of future events, including time, size, type, location, and formal errors for each.
- probabilistic** A statement of the relative likelihood of an event based on study of a population of similar events that have occurred in the past.
- reduced displacement** The root-mean-square (rms) amplitude of volcanic tremor multiplied by the distance from

the station to the source. This has the effect of correcting data to a common reference point.

**seismic network** A group of seismic stations that are deployed in a region for the purpose of detecting and locating earthquakes.

**seismic station** A set of instruments including a seismometer (buried in the ground), cables, batteries, solar panels, amplifiers, radios, and antennae located in an enclosure nearby.

**spectrogram** A plot of frequency in hertz (Hz) of seismic signals as a function of time. Typically the strength of the signal is shown as a color or shading.

**swarm** A group of many earthquakes of similar size occurring closely clustered in space and time with no dominant main shock.

**telemetry** The set of instruments and communications that send a data signal from their source to a distant data acquisition system. May include radio, microwave, telephone, and satellite components.

**S**EISMOLOGY IS AN important and effective tool for monitoring volcanoes and forecasting eruptions. In the past 2 decades there have been over 25 successful forecasts. Well-monitored volcanoes have six or more local seismic stations within 15 km and several regional stations (>15 km) which are able to detect volcanic earthquakes of  $M \geq 0$  under the volcano.

The recording of several years of background seismicity is important to establish a baseline for evaluation of possible precursors. Four main types of events are recorded: high-frequency earthquakes, low-frequency earthquakes, explosion earthquakes, and volcanic tremor. Surface events such as rockfalls, avalanches, and mudflows are also recorded. Volcanic earthquakes prior to eruptions generally occur in swarms; have maximum sizes of  $M < 5$ ; include many events with similar waveforms; have high  $b$  values; increase in numbers before eruptions; and occur beneath or near the site of eruptions. Many swarms follow a regular sequence consisting of the following components: background, swarms of high-frequency events, relative quiescence after the peak rate, low-frequency events, volcanic tremor, eruption, and deep earthquakes following eruption. This sequence reflects systematic changes in locations of earthquakes and in the dominant physical processes.

#### I. INTRODUCTION—HISTORY AND ORGANIZATION

Seismic monitoring is the systematic checking of the status of seismic activity at a volcano. Monitoring attempts to associate key diagnostics, such as rates, types of earthquakes, and changing locations, with physical processes involved in the movement of magma. This can be done probabilistically by comparing current activity at the volcano of interest with comparable past activity at similar volcanoes. It can also be done deterministically when a particular process can be associated with seismic signals with a high degree of confidence. Seismic monitoring can help determine if a volcano: (1) is in a background or restful state; (2) is restless; (3) shows precursory activity; (4) has begun

TABLE I Selected Early Volcano Observatories and Observations with Seismometers

Volcano	Country	Date	Type of instrument
Vesuvius	Italy	1856	Mechanical

A cable carries the signal to a custom-designed hut which houses the batteries, antenna, and electronics. Solar panels are mounted on the top left of the hut, which faces south. (Photo by S. McNutt.)

to erupt; (5) is actively erupting; (6) is ending an eruption; or (7) is returning to a background state. Seismic monitoring is fairly effective alone, but is better utilized as one component of an integrated monitoring effort.

Nearly every recorded volcanic eruption has been preceded by changes in seismic activity beneath or near the volcano. For this reason, seismology has become one of the most useful tools for eruption forecasting. Early observatories (Table I) included seismometers that were at first crude mechanical devices, but were later upgraded to more modern electromechanical types (see Figure 1). At the present time, approximately 200 of the world's volcanoes are seismically monitored (about one-third of the 538 volcanoes that have erupted in historic times). Volcanoes that are actively erupting draw atten-

tion both publicly and scientifically, and over half of these are seismically monitored. A good example of this is Montserrat, West Indies, which is active at the time of this writing. There have been a number of generally successful forecasts during the last 2 decades (Table II), although the exact criteria for claiming success and the levels of precision have been variable.

A key development in monitoring during the last 20 years has been the proliferation of modern computers, which has led to dramatic improvements in speed and precision in locating earthquakes as well as in determining properties of seismic waves, often in "near real time." For example, many digital data acquisition systems record at 100 samples per second, so arrival times can be measured to the nearest 0.01 as opposed to 0.1 for old paper records and 0.05s for film recorders. This precision, together with close station spacing, has the

effect of improving location accuracy, and the best located earthquakes have formal errors as low as 50–100 m horizontally and 100–300 m vertically.

Electronic data bases have greatly facilitated the storage and manipulation of large data sets, which in turn have facilitated the use of data-intensive forms of analysis. An example is seismic tomography, which uses data from thousands of earthquakes to produce 3D images of earth structures. Automation of many tasks has improved the ability to analyze many types of data in near real time, which leads to better methods of both forecasting and characterizing eruptions in progress. For example, near-real-time (several minutes after the fact) reduced displacement measurements and spectrograms measure time-domain amplitudes and frequency-domain amplitudes automatically. Both of these produce time series (see below) which are routinely interpreted in terms of changing volcanic processes. The plots now can be produced automatically and posted to the World Wide Web, so anyone with a computer and modem can view them.

## II. SEISMIC INSTRUMENTS AND NETWORKS

Most seismometers used to monitor volcanoes are located on the flanks at distances within 15 km (Figure 2). About a third of the monitored volcanoes have at least one station within 1 km of the active vent. Modern networks generally consist of six or more stations. Station spacing of a few kilometers enables better detection of small earthquakes and generally small location errors (<0.5 km). Data are usually telemetered to a common site and recorded on drum recorders as well as on digital computers.

Many tasks are now automated on computers and run in near real time, which means the data are available for viewing a few minutes after the fact. For example, when an earthquake occurs, there is an abrupt increase in the signal level at several stations at nearly the same time. This feature is exploited by algorithms that look for an increase in the short-term average (STA) of 0.5–1.0 seconds above a long-term average (LTA) of 30 seconds to 1 minute at a certain LTA/STA threshold, such as a factor of four. When the algorithm is triggered, a file is opened and 1 minute or so of data are written for all stations of a given network. This type of strategy is efficient because only the data that matter—from the earthquake—are kept, in compact form.

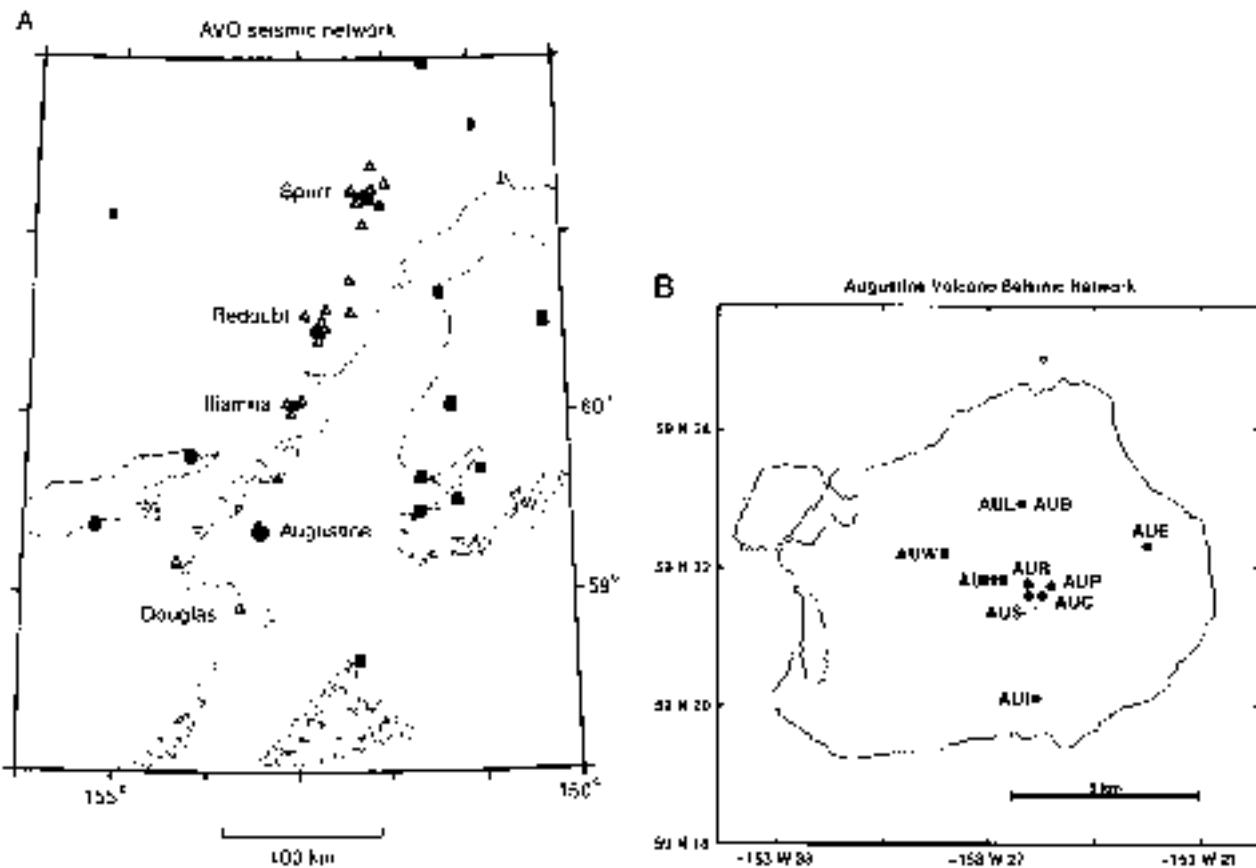

FIGURE 2 (A) Map of local (open triangles) and regional (solid squares) seismic stations in the Cook Inlet region of Alaska. Clusters of stations are located near each of the five active volcanoes. (B) Map of local seismic stations near Mount St. Augustine. Most well-monitored volcanoes have similar networks of six to eight stations.

To retain small events and emergent signals like tremor, several observatories continuously record digital data. A number of volcanoes are monitored indirectly because a nearby (>15 km) seismic station is part of a larger regional seismic network. Maps showing distributions of seismic stations near several volcanoes in Alaska are shown in Figure 2. Topography, telemetry, and ease of access often determine the exact location of stations.

Most seismometers at volcanoes are short-period (1 s) vertical instruments which record useful data between about 0.7 and 30 Hz. They consist of a magnetic mass suspended on a spring, surrounded by a coil of wire. When the mass moves in response to ground motion, a current is generated in the coil. Modern three-component, digitally telemetered, high-dynamic-range, broadband seismometers record over a much wider band of frequencies (0.02 to 50 Hz). These instruments also have a mass and spring, but the coil that senses the motion is connected to a feedback circuit which sends a current through another coil exactly to oppose the

motion. Thus the mass is held fixed, and the feedback current is proportional to the ground motion. Such broadband seismometers also have a much higher dynamic range, up to 145 dB, as opposed to about 40 dB for analog telemetry. Temporary deployments of these broadband instruments have become common recently, and permanent deployments of 1 to 10 instruments at well-monitored volcanoes are becoming more widespread. Microphones are often added to seismic stations to add an additional independent data channel. They are used to record air waves from explosions and other features of the radiated sound field; they also measure atmospheric pressure fluctuations from wind and storms.

Volcano observatories vary widely in location and sophistication. The simplest observatories may be a small observation hut, with a single seismograph recorded on paper on a revolving drum. Many larger observatories are located near volcanoes at distances of several tens to several hundreds of kilometers, and seis-

mic data from local and regional stations are telemetered to them by cable, radio, and telephone. Some observatories are colocated with universities or other research organizations. These may be hundreds of kilometers from the volcanoes of interest, yet the vast array of modern communications available today make such facilities common and economical. They are, further, safe from large eruptions which may affect closer facilities. There are approximately 90 members of the World Organization of Volcano Observatories (WOVO) as of this writing, most with some kind of seismic monitoring capability.

The distance from an earthquake to a seismic station and the magnification of the station are the main factors

that determine the magnitude detection threshold, that is, the smallest signals that can be recorded. Typical magnifications at volcanoes are 5000 to 50,000, and the corresponding magnitudes of detection are about  $M = 0$  to  $M = 1$  for the 1- to 15-km distances involved. It is desirable to record the smallest earthquakes possible, but because volcanoes often have high noise levels, this is usually achieved by putting stations close to the vent rather than operating more distant stations at higher magnifications.

The largest events in swarms preceding most eruptions typically have magnitudes of  $M = 2$  to  $M = 3$ . However, many larger events have occurred at volcanoes, especially calderas (Table III), and some of these

TABLE III Selected Large Earthquakes Near Volcanoes

Volcano	Year	$M_{\max}$	Comment
Arenal	1968	4.5	Pre-eruption
Asama	1916	6.3 $M_s$	No eruption
Aso	1975	6.0	No eruption
Bandai	1888	5	Triggered eruption
Bezimianny	1956	5.0	Pre-eruption
Fernandina	1968	5.7 $M_s$	Caldera collapse
Gorely	1985	$\leq 6$	Posteruption (8 months)
Ito-oki	1989	5.5	Pre-eruption
Jan Mayen	1954	5.8	No eruption
Kalapana	1975	7.1 $M_s$	Shallow thrust
Katmai	1912	7.0	Posteruption
Long Valley	1980	6.2 $M_L$	4 earthquakes with $M \geq 6$ , no eruption
Miyake-jima	1962	5.9	Strong swarm
Miyake-jima	1982	6.4 $M_{JMA}$	Swarm 20 km deep
Miyake-jima	1983	6.2 $M_s$	During eruption
Mt. St. Helens	1980	5.2 $M_s$	Triggered eruption
Mt. Usu	1910	5.5	Pre-eruption
Mt. Usu	1943–1944	5.0	Pre-eruption
Mt. Usu	1977	3.7	Pre-eruption
Mt. Usu	1977–1980	4.3	Emplacement of cryptodome
Pinatubo	1991	5.7	Co-eruption
Sabancaya	1991	5.6 $M_s$	10 km NE of summit
Sakurajima	1914	7.0 $M_s$	10.5 hours posteruption, depth 13 km
Sheveluch	1964	5.5	Pre-eruption
Showa-Shinzan	1944–1945	3.8	Dome emplacement
Unzen	1792	5–5.5	Accompanied collapse

Note.  $M_{\max}$ , maximum magnitude;  $M_s$ , surface wave magnitude;  $M_L$ , local (Richter) magnitude; and  $M_{JMA}$ , Japan Meteorological Agency magnitude.

are large enough to be hazardous in their own right. Magnitude 4 to 5 earthquakes are common at volcanoes with large deformations in the form of doming, bulging, and sector collapses; events associated with the latter may reach  $M = 5.5$ . To date no definitive correlations have been found between the size of preceding earthquakes and the volume or explosivity of the resulting eruption.

A seismometer in the vicinity of a volcano will typically record seismic signals from four sources: the volcano, local earthquakes ( $< 15$  km), regional earthquakes ( $> 15$  km), and teleseisms (generally  $> 600$  km). Part of the job of the seismologist is to recognize and discriminate among these. It is especially helpful to record data from several stations at regional distances of 50–200 km to aid in the identification process. Two examples illustrate why these are helpful. At Nevado del Ruiz volcano, Colombia, in November 1985 and later, many earthquakes from the Bucaramanga nest, a persistent deep source of earthquakes beneath Colombia, appeared on seismograms from stations near the volcano. The Bucaramanga event seismograms resembled many of the volcanic events, and their occurrence created confusion. At Spurr volcano, Alaska, in 1992, the seismic signal for two eruptions began gradually but the third began sharply and its onset looked like that of a regional earthquake. However, the pattern of arrival times and relative amplitudes at local versus regional stations quickly revealed that the event was an eruption at the volcano.

In general, there are many more small earthquakes than large ones. This is a consequence of the fact that the size distribution of earthquakes obeys a power law, which in seismology is of the form  $\log_{10}N = a - bM$ , (where  $N$  is the cumulative number of events,  $M$  is magnitude, and  $a$  and  $b$  are constants) and is known as the Gutenberg–Richter relation. The slope, or  $b$  value, determines the relative number of large versus small events. While for tectonic earthquakes the  $b$  value has typical values of 0.9 to 1.0 worldwide, more extreme values have been observed at volcanoes. High-frequency events have values ranging generally between 0.6 and 1.3, but low-frequency events have  $b$  values of up to 3.0. This means, for low-frequency events, that small earthquakes dominate, and also implies that the source size is restricted. Determination of the  $b$  value for volcanic earthquakes is an important diagnostic tool for identifying changes in seismicity.

At volcanoes, most earthquakes occur at depths of 10 km or less. Deeper events are common but the number of events is considerably smaller. A trend recently observed at several volcanoes is that deeper earthquakes

(10–40 km) occur after major phases of eruption. It is thought that these events are occurring in response to stress changes caused by the removal of magma at depth. The cumulative energy of deep quakes may be proportional to the volume of magma erupted.

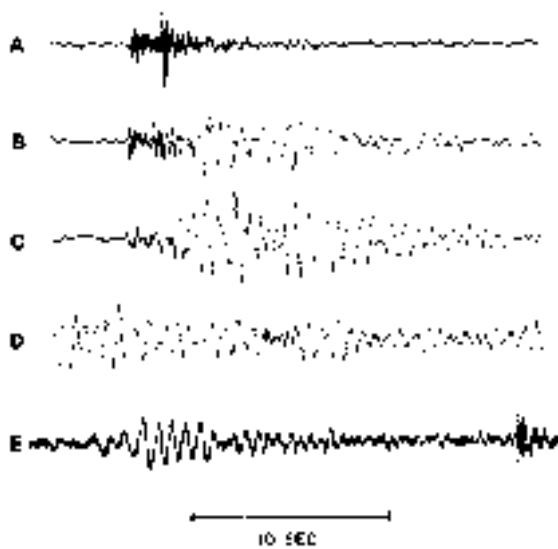

It is important to keep track of the amplitude of the ground shaking, so calibration information for each seismic station is stored and used to help determine earthquake magnitudes and the reduced displacement of continuous signals such as volcanic tremor. These “normalized” measures allow comparison between different volcanoes. Similarly, several observatories compute spectrograms—plots of the frequency of ground shaking versus time—to help identify low-frequency events and to help distinguish between earthquakes, noise, and other types of signals.

Some volcanic signals have gradual onsets or very long durations (hours to days or more). For these events, traditional location methods, which depend on measuring arrival times for  $P$  and  $S$  waves, cannot be used. New techniques use data from dense networks or “arrays.” Here, the stations are very close, a few tens to hundreds of meters apart, so it is possible to see the same wave coherently on all the stations (the wave need not be a first or prominent arrival). Because the physics of waves are well known, it is possible to determine what type of wave is present, which direction it is coming from, and how fast it is moving. All these provide information about the sources. Thus, dense arrays can be used like antennae to discern certain features of specific types of seismic waves even when the signals are weak or noise is present. Array methods look at different features of seismograms and thus extend the information available for analyses.

---

### III. TERMINOLOGY AND TYPES OF VOLCANIC EARTHQUAKES

Active volcanoes are the sources of a great variety of seismic signals. Traditionally, volcanic earthquakes have been classified based on seismogram appearance into four different types: high-frequency or A-type, low-frequency or B-type, explosion quakes, and volcanic tremor. This classification scheme works very well at a large number of volcanoes. For monitoring, it is important to quickly recognize different types of events and the exact terminology is less important. Other local signals, such as those caused by glaciers or landslides, are also recorded at volcanoes, and need to be distinguished

**FIGURE 3** Typical waveforms of volcanic earthquakes. (A) High-frequency or volcanotectonic earthquake, 6.8 km depth, Redoubt volcano, station RED, 8 km from the vent. (B) Hybrid or mixed-frequency event, -0.6 km depth (0.6 km above sea level), Redoubt volcano, station RED. (C) Low-frequency or long-period event, -0.4 km depth, Redoubt volcano, station RED. (D) Volcanic tremor, Redoubt volcano, station RED. (E) Explosion quake, Pavlof volcano, station PVV, 8.5 km from the vent (note prominent air-wave arrival). [After (A–D) Power, J., et al. (1994). *J. Volcanol. Geotherm. Res.* **62**, 69–94; and (E) McNutt (1986).]

from the volcanic events. Although the original classification included restricted depth ranges for various earthquakes, these have often been relaxed because of improvements in location accuracy and better understanding of source and propagation effects. Examples of volcanic events are shown in Figure 3.

### A. High-Frequency Events

Most high-frequency events are thought to be caused by shear failure or slip on faults, and differ from their tectonic counterparts only in that they occur predominantly in swarms at volcanoes. High-frequency events have clear P and S waves, and dominant frequencies are 5–15 Hz. A typical small high-frequency event is shown in Figure 3A.

### B. Low-Frequency Events

Most low-frequency events are thought to be caused by fluid pressurization processes such as bubble formation

and collapse, and also by shear failure, tensile failure, or nonlinear flow processes which occur at very shallow depths for which attenuation and path effects play an important role. These events often have emergent P waves, lack S waves, and have dominant frequencies between 1 and 5 Hz, with 2–3 Hz most common. An example of a low-frequency event is shown in Figure 3C.

### C. Hybrid Earthquakes

Some earthquakes share attributes of both high- and low-frequency events. These are called hybrid events, and may represent a mixture of processes. For example, the event shown in Figure 3B displays the high-frequency onset of a high-frequency event, but the later part of the signal (the coda) is similar to low-frequency events.

### D. Explosion Earthquakes

Explosion quakes accompany explosive eruptions, and many are characterized by the presence of an air-shock phase on the seismograms. There is a partitioning of energy at the source; part of the energy travels through the ground as seismic waves, and part travels through the air as acoustic or air waves. The air wave then couples back into the ground near the seismometer. The air wave also shows up clearly on microphones or barographs. An example of an explosion quake is shown in Figure 3E.

### E. Volcanic Tremor

Volcanic tremor is a continuous signal with a duration of minutes to days or longer. The dominant frequencies of tremor are 1–5 Hz (2–3 Hz is most common), similar to low-frequency events, and many investigators have concluded that tremor is a series of low-frequency events occurring at intervals of a few seconds. Harmonic tremor and spasmodic tremor are two special cases of more general volcanic tremor. Harmonic tremor is a low-frequency, often monotonic sine wave with smoothly varying amplitude, and spasmodic tremor is a higher-frequency, pulsating, irregular signal. An example of volcanic tremor is shown in Figure 3D.

## F. Very-Long-Period Events

Over the past decade broadband seismometers have been deployed at volcanoes. These have the ability to detect a wider frequency band, particularly at the low end (down to  $f = 0.016$  Hz, or a period of 60 s). A new class of events called very-long-period (VLP) or very-low-frequency (VLF) events have been observed at some volcanoes. Observations to date show events with periods of 3 to 20 s originating from shallow depths of 1.5 km or less under several active volcanoes including Kilauea, Stromboli, Aso, Sakurajima, and Satsuma-Iwojima. The VLP events at these volcanoes have been associated with either eruptions or vigorous fumarolic activity, and the observed events have fairly small amplitudes.

## G. Superficial Events

Seismometers located on volcanoes may record a variety of local signals caused by shallow processes. These include nonvolcanic processes such as glacial events, shore ice movement, and landslides, as well as volcano-related processes such as outburst floods and lahars, pyroclastic flows, and rockfalls from crumbling lava domes.

- *Glacial events.* High-latitude and/or tall volcanoes are frequently covered by glaciers. Glaciers produce seismic events along the ice–rock boundary, and within the ice when cracks and crevasses form. Seismograms from such events resemble those for low-frequency (LF) volcanic events.

- *Shore ice events.* Ice forms from seawater when the air temperature falls below 10°F. Large blocks of such ice gather on the shores of Augustine Island, Cook Inlet, Alaska, and move around as the tides ebb and flood. When the blocks collide or break, they produce seismic events because the blocks are coupled to the ground. The individual ice events resemble LF volcanic events, and the events occur in swarms of a few hours duration because of the tides.

- *Landslides.* Avalanches and landslides of various sizes occur on volcanoes. Those associated with partial melting of ice and snow mainly occur in the spring and summer. The main avalanche or landslide generates a seismic signal of several minutes duration, depending on the size and runout. The amplitude varies with the amount of material, with larger avalanches generating stronger seismic signals.

- *Rockfalls.* Rockfalls are a special type of landslide in which one or a few pieces of bedrock become detached

and free fall. They are especially common at the edges of volcanic domes and at volcanoes with very steep slopes or cliffs. In the summer of 1995 workers at Mount Spurr, Alaska, observed rocks more than 1 m in diameter falling several hundred meters and impacting on the crater floor. The corresponding seismograms showed strong local signals lasting more than 1 minute.

- *Pyroclastic flows.* Pyroclastic flows are products of explosive eruptions and consist of particles of hot molten rock and gases which move rapidly over the ground surface. Collapses of volcanic domes can also produce pyroclastic flows. These latter events were characterized by complex seismograms which have been modeled as a sequence of forces. First, rock is removed from the dome (the dome moves up slightly in response); second, the falling rock collides with the slope below (an impact); and third, the rock breaks apart and the fragments continue to move down the slope as an irregular flow. These seismograms last several minutes and may contain high frequencies, and the larger flows are associated with larger amplitude signals.

- *Outburst floods and lahars.* The surface melting of ice and snow, or heavy rains, may cause floods and lahars (volcanic mudflows). Similarly, a volcanic eruption under a glacier will melt the ice, and the flooding that subsequently occurs is called a jokullhaup. All these floods or lahars cause long-duration seismic signals that resemble volcanic tremor, except that the signal is stronger near the flow channel, as opposed to tremor, which is stronger nearer the volcanic vent.

Seismic monitoring requires regular checks of data at times of interest, and preparation of plots and maps to display data so that anomalies may be identified and interpreted. For example, counts are often made of the number of earthquakes of each type per hour or day. These are especially helpful to identify small events which increase in numbers before eruptions. Maps and cross sections are made of all locatable earthquakes at periodic intervals such as a day or week. Locatable events must be large enough to show up on three or more stations, so these are fewer in number than countable events. Spectra may be computed for background signal and earthquakes to look for the onset of low-frequency events or tremor. Signal amplitudes are determined to distinguish storm noise from possible tremor, and to track tremor once it starts.

All the seismic data are combined with other data on a regular basis, and attempts are made to develop a working hypothesis of what is physically occurring to cause the observed signals. Such hypotheses or conceptual models are continually revised as conditions change.

These are the link between the raw data and the science. In the remainder of this article it is assumed that the seismic events have been properly identified and classified.

#### IV. FORECASTING ERUPTIONS

The main goals of seismic monitoring of volcanoes are to know the present status of a volcano, to forecast eruptions, to estimate the size of eruptions in progress, and to understand the physical processes that are occurring. Seismic monitoring can help determine if a volcano: (1) is in a background or restful state; (2) is restless; (3) shows precursory activity; (4) has begun to erupt; (5) is actively erupting; (6) is ending an eruption; or (7) is returning to a background state. The primary focus of this article is forecasting eruptions. For this, goals are estimating the date and time, the place, the size and type, and the likely duration of eruptions. A variety of observations have a bearing on these problems.

##### A. Seismicity Rates and Background

Volcanoes nearly always have a high background level of seismicity. Thus, a baseline of measurements of at least a few years duration is usually necessary to characterize and understand background seismicity. The background may consist of several different types of events, which are related to different processes. Typical background rates of seismicity are a few to a few tens of events per day, depending on the locations and magnifications of the seismic stations. In contrast, the rates

of seismicity before and during eruptions are typically several tens to several hundreds or more events per day, and include larger-magnitude events. Many successful eruption forecasts have been made based on an increase in seismicity above previously recorded background levels. However, the main physical processes that cause seismicity are those associated with magma intrusion. Thus, there will always be a false alarm rate because some intrusions remain at depth whereas others reach the surface and erupt.

In terms of trying to assess the *type* of eruption prior to its onset, previous eruptive activity is a better guide than any seismic feature yet identified. This is true for all of the case studies discussed in Section VI except for Ito-oki in 1989, which formed a new vent. For the formation of new volcanoes, such as Paricutin, Mexico (1943), Surtsey, Iceland (1963), or Novarupta, Alaska (1912), geology of the surrounding area is a better guide than earthquake activity to determine the type of impending eruption.

##### B. Statistics of Volcanic Seismicity

Statistical information on many volcanoes, swarms, and eruptions provides a broad perspective to evaluate potential precursors (Table IV). It is helpful to have such information available during a seismic crisis to have an idea of the possible range of activity. However, a comparison of seismic activity at Kilauea and Krafla demonstrates a potential pitfall. Both of these volcanoes produce basalt, and fissure eruptions are common at each. For Kilauea, of 73 swarms studied, 31% accompanied eruptions, 42% accompanied intrusions, and 27% were associated with inflation episodes. Except for harmonic

TABLE IV Parameters of Volcanic Eruption Seismic Precursor Case Histories

Volcano name	Date	VEI <sup>a</sup>	Swarm duration (days)	Time since previous eruption (years)	Precursor event type <sup>b</sup>	Precursor maximum magnitude
Mount St. Helens	5/18/80	5	59	123	H, L, T	5.0
Kilauea	1/3/83	3	99	0.25	H, L, T	4.2
Ito-oki	7/13/89	2	53	—	H, L, T	5.5
Pavlof	9/16/96	3	5	8	L, T	0.5
Pinatubo	6/15/91	6	70+	600	H, L, T	4.3

<sup>a</sup> Volcanic explosivity index.

<sup>b</sup> H, high-frequency or volcanotectonic earthquakes; L, low-frequency or long-period earthquakes; and T, volcanic tremor.

tremor generated near an erupting vent, intrusions and eruptions were seismically indistinguishable. This suggests that the only difference between an intrusion and an eruption is the magma level compared to ground level. At Krafla, similar numbers were obtained for 20 swarms which included volcanic tremor and occurred in association with deflation episodes; 9 swarms accompanied eruptions and 11 occurred during intrusions. However, the first 5 were intrusions and the last 6 were eruptions; thus the statistics changed substantially as a function of time. Here the magma level was presumably lower for the intrusions and higher for the eruptions.

### C. Volcanic Tremor

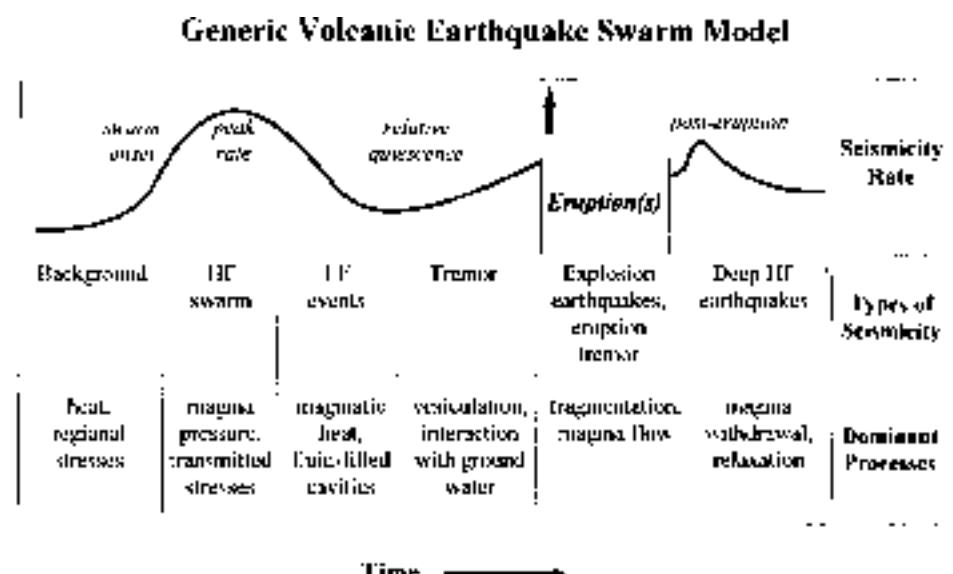

Volcanic tremor (Figure 3D), which has several possible mechanisms, is an especially common short-term precursor to eruptions. Tremor was the most common short-term precursor in a recent study of 132 historical cases of phreatic eruptions. This suggests a close link between tremor and hydrothermal processes (tremor known to be related to hydrothermal processes is weaker than that associated with magmatic activity, although frequencies are similar). Tremor was the most consistent short-term indicator of impending eruptions in a study of 200 calderas worldwide. This study did not distin-

guish between different tremor mechanisms. While most tremor episodes accompany eruptive activity, about 20% precede eruptions on a time frame of 10 days. This value of 20%, however, did not distinguish between different tremor mechanisms. Nevertheless, in spite of different mechanisms, clearly volcanic tremor is a common and important precursor to many eruptions.

## D. Generic Volcanic Earthquake Swarm Model

Common observations suggest a general model of earthquake activity at volcanoes. The model, which is termed a generic volcanic earthquake swarm model, is shown as a time series in Figure 4. Seismicity rates, types of events, and dominant processes are indicated in the commonly observed temporal sequence. Variations in the involvement of groundwater, as well as variations of parameters such as magma composition, temperature, rate of flow, and volatile content, can explain many of the observed differences from this model of seismic activity at different volcanoes.

In the generic model, high-frequency earthquakes reflect shear fracture of the country rock in the vicinity of volcanoes in response to increasing magmatic pressure. Since magma movement at depth may occur over large

**FIGURE 4** Schematic diagram of the time history of a generic volcanic earthquake swarm model. Seismicity rates are shown along with the main types of events observed at each stage. Some ideas about dominant processes are presented at the bottom of the figure. [After McNutt, S. (1996). Page 99–146 in “Monitoring and Mitigation of Volcanic Hazards” (Scarpa/Tilling, eds.). Springer-Verlag, Berlin/Heidelberg.]

distances and long periods of time, the durations of high-frequency swarms are long. At shallow depths of 1 to 3 km, several significant changes occur. First, gases begin to exsolve from the magma, changing its mechanical behavior and, hence, its ability to transmit or reflect seismic waves. For example, exsolution of volatiles will increase the viscosity and lower the acoustic velocity. A seismic event generated by resonance of a magma-filled cavity would thus be richer in lower frequencies. Second, the magma may encounter groundwater, modifying the shallow hydrothermal system and removing some of the available magmatic heat by conduction and advection. Most low-frequency events and tremor originate at shallow depths, and several models for their origin involve fluids, either water, magma, exsolved volatiles, or all three. Tremor caused by boiling of water is generally weaker than tremor involving magma movement. Third, open cracks are found above 3 km depth in the earth, permitting venting of excess pressure. This may explain the relative quiescence after the peak rate of a swarm as well as the inverse relation between high-frequency events and tremor.

The upper 1 to 3 km are small distances compared with depths to magma chambers (5–20 km) or crustal thicknesses (about 35 km). Thus, if vertical magma ascent rates are constant, then durations of low-frequency event swarms and tremor sequences will be shorter than those of high-frequency events simply because the distances are smaller. Deep earthquake swarms following eruptions probably reflect stress changes associated with partial evacuation of magma chambers deeper than 5 km.

Relative seismic quiescence following an initial seismicity peak occurred in 25% of a worldwide sample of 192 swarms. While quiescence 25% of the time may seem too low a percentage to be included in a generic model, it is included because of its importance in terms of eruption forecasting and identifying physical processes. Factors that may cause quiescence include strain hardening; high temperatures near the brittle–ductile transition; increased water content (e.g., groundwater) lowering effective stress; or a reduction in strain rate. It is common for low-frequency events and tremor to occur after seismicity rate peaks, during times of relative quiescence. This may be explained by gradual shoaling of the source, particularly magma interacting with groundwater or exsolution of volatiles.

Each volcano is unique in its seismic behavior, but the observations suggest that variations in a few parameters such as those discussed above may account for the main differences. Minor variations in each of several parameters may greatly affect one observed parameter, such as swarm durations. The durations of earthquake swarms

are characterized by a log-normal distribution with a mean of 5 days (Figure 5). No definitive correlations exist between the duration of a swarm and the size or type of eruptive activity. This is not surprising given the ranges of sizes, rates, compositions, and types of structures observed.

Recently, parameters of 700 volcanic earthquake swarms have been compiled into an electronic data base called the Global Volcanic Earthquake Swarm Database (GVESD). The data base has one table of basic information on each volcano, such as type of lava, height, and location; one table on eruptions, including volume, time of occurrence, and type; and a table of swarm parameters such as duration, number of earthquakes, depths, and magnitudes. Using electronic search commands, it is possible to find all known cases of earthquake swarms that fit a particular profile. For example, we can search for the cases that last 3 weeks, have 60 events per day, and a largest event of  $M = 3.3$ . The “answer” is a list of similar swarms which can then be analyzed to determine whether eruptions occurred, how long they lasted, etc. These answers are probabilistic in that they look for a likelihood of something happening based on past occurrences. Such information is complementary to simultaneous efforts to determine and to constrain what is happening physically at a volcano.

## E. Other Methods

Several recent works have addressed analytical techniques and instrumental or computational methods of reducing volcano seismic data. One method of analysis is based on the materials science approach of estimating failure criteria. An observable parameter, such as strain or seismicity, is fit to the equation

$$\Omega^{-\alpha} \ddot{\Omega} - A = 0, \quad (1)$$

where  $A$  and  $\alpha$  are constants,  $\Omega$  is the observed quantity, and the dot refers to differentiation with respect to time. This method has been shown to be successful in several volcano applications in retrospect, but not beforehand. These included the March 1982 eruption of Mount St. Helens, the April 1960 eruption of Bezymianny, and the 1987 summit eruption of Izu-Oshima. The method predicts the time of the eruption onset.

The RSAM (Real-Time Seismic Amplitude Measurement) and SSAM (Seismic Spectral Amplitude Measurement) systems are rapid analysis tools that have been developed by the U.S. Geological Survey. They are similar to the  $D_R$  and spectrogram techniques described

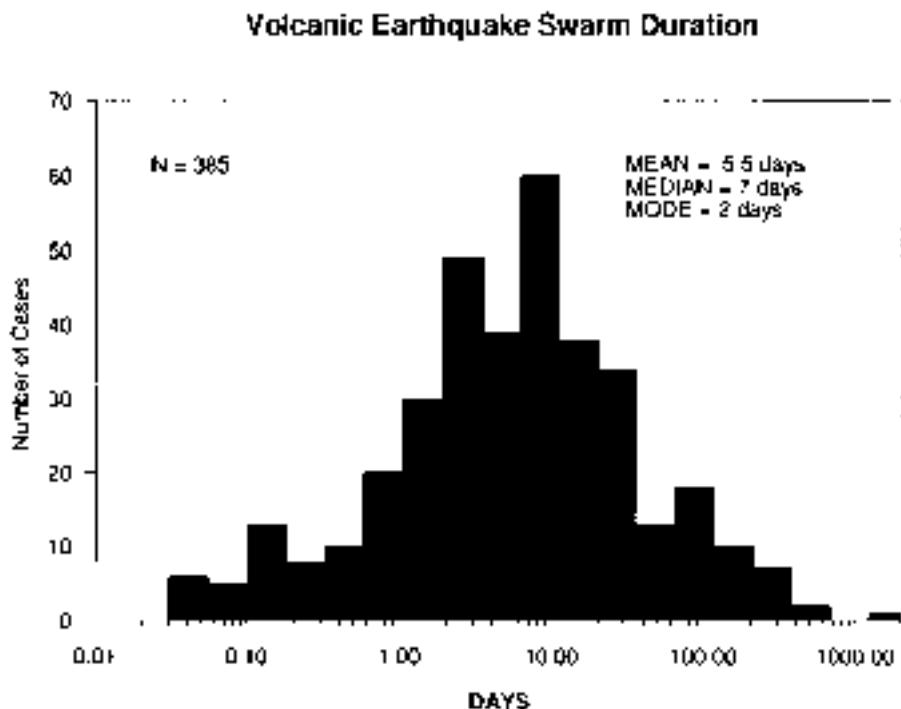

FIGURE 5 Histogram of volcanic earthquake swarm durations. The horizontal axis is logarithmic, and the numbers shown represent the middle value of each bin. The data form a log-normal distribution with a mean and median of 5.5 and 7 days, respectively. [After Benoit, J., and McNutt, S. (1996). *Annali Geophys.* **33**, 221–229.]

below. The RSAM system provides consecutive 1- or 10-minute averages of absolute seismic amplitude or energy for each seismic station, regardless of event type. RSAM data are generally plotted as time series for each individual station. The SSAM system determines the average spectral amplitude for 16 user-defined frequency bands. Calculations are performed once per minute for each individual seismic station. SSAM data are generally displayed using time-frequency-amplitude plots where the intensity of the signal corresponds to an 11-step gray or color scale. Both of these monitoring tools are useful for quantitatively determining the gross features of seismicity automatically and quickly during crises when detailed manual analyses are not possible. RSAM and SSAM are especially useful digital recording techniques when signals are continuous or when signal amplitudes on visual drum recorders begin to overlap, or exceed the physical dynamic range of analog recording, so that reliable amplitudes cannot be easily obtained.

RSAM data from four volcanoes have been analyzed using an automated curve-fitting scheme. The same exponential equation was objectively selected to best fit pre-eruption normalized RSAM data from dome-build-

ing eruptions at Mount St. Helens and Mount Pinatubo, suggesting that a common process is acting regardless of the details of the seismicity. Selected portions of premonitory seismicity at Redoubt, Mount Spurr, and Pinatubo also showed exponential increases with different durations. The best-fit equation is of the form

$$\text{NORMALIZED_RSAM_COUNT}(t) = a + b \exp(-t/c), \quad (2)$$

where  $\text{NORMALIZED_RSAM\_COUNT}(t)$  is the normalized RSAM value at time  $t$ , and  $a$ ,  $b$ , and  $c$  are parameters determined by the curve-fitting program. This approach aims at identification of an aggregate process which does not depend on specific types of earthquakes or their relative times of occurrence.

## V. CHARACTERIZING ERUPTIONS IN PROGRESS

Forecasting eruptions has received dominant focus as a goal of volcano monitoring, especially when the volcano

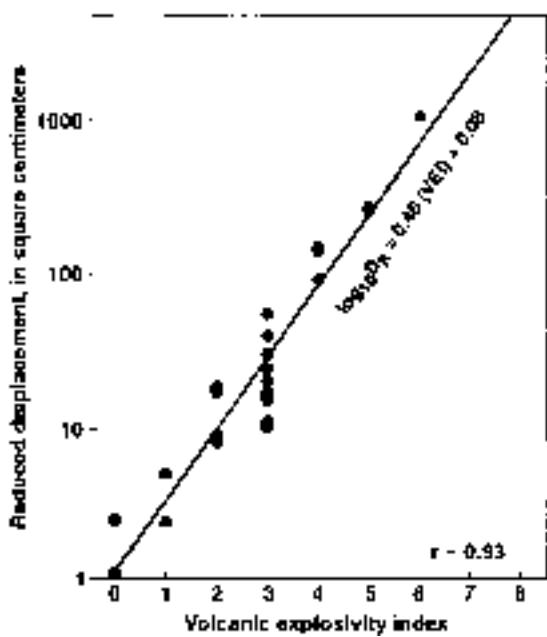

FIGURE 6 Volcanic tremor reduced displacement versus the volcanic explosivity index (VEI) of Newhall and Self (1982). *J. Geophys. Res.*, **87**, 1231–1238. The plotted line is a regression fit to the data. [After McNutt, 1994.]

is located near population centers. However, characterization of eruptions in progress, including estimates of tephra volume, height of ash column, and end time of eruption, is also of importance for hazard mitigation, particularly regarding aviation. Progress has been made recently to estimate the volcanic explosivity index (VEI) based on tremor reduced displacement ( $D_R$ ) measured during eruptions (Figure 6). The computed relation is

$$\log_{10}(D_R) = 0.46(\text{VEI}) + 0.08. \quad (3)$$

Reduced displacement is a method of normalizing volcanic tremor to a common scale. For body waves (e.g., P waves and S waves) the formula is

$$D_R = \frac{A \cdot r}{2\sqrt{2}M}. \quad (4)$$

For surface waves (e.g., Rayleigh waves, Love waves, and PL waves) the formula is

$$D_R = \frac{A\sqrt{\lambda r}}{2\sqrt{2}M}, \quad (5)$$

where  $A$  is amplitude in centimeters peak-to-peak;  $r$  is distance from source to seismic station in centimeters;  $M$  is seismograph magnification at the tremor frequency;

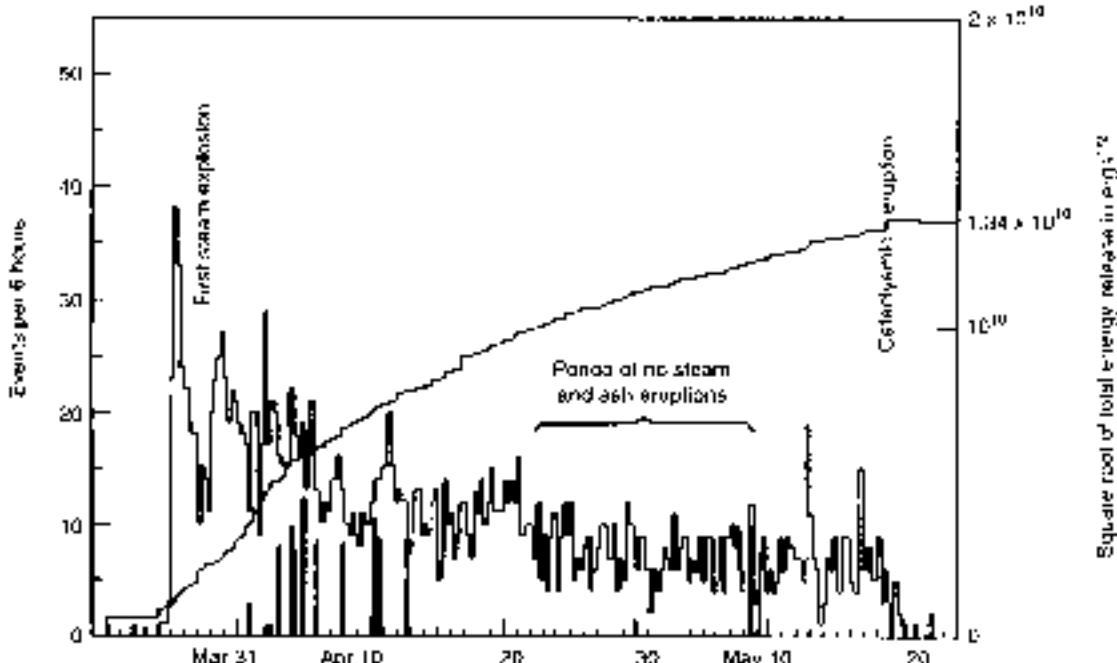

FIGURE 7 Counts of Mount St. Helens earthquakes larger than magnitude 2.5 per 6 hours (histogram), volcanic tremor (vertical solid lines, length proportional to tremor duration), and square root of cumulative energy release (irregular curve) from March 20 to May 24, 1980, Universal Time. [After McNutt, S., and Beavan, J. (1984). *J. Geophys. Res.* **89**, 3075–3086.]

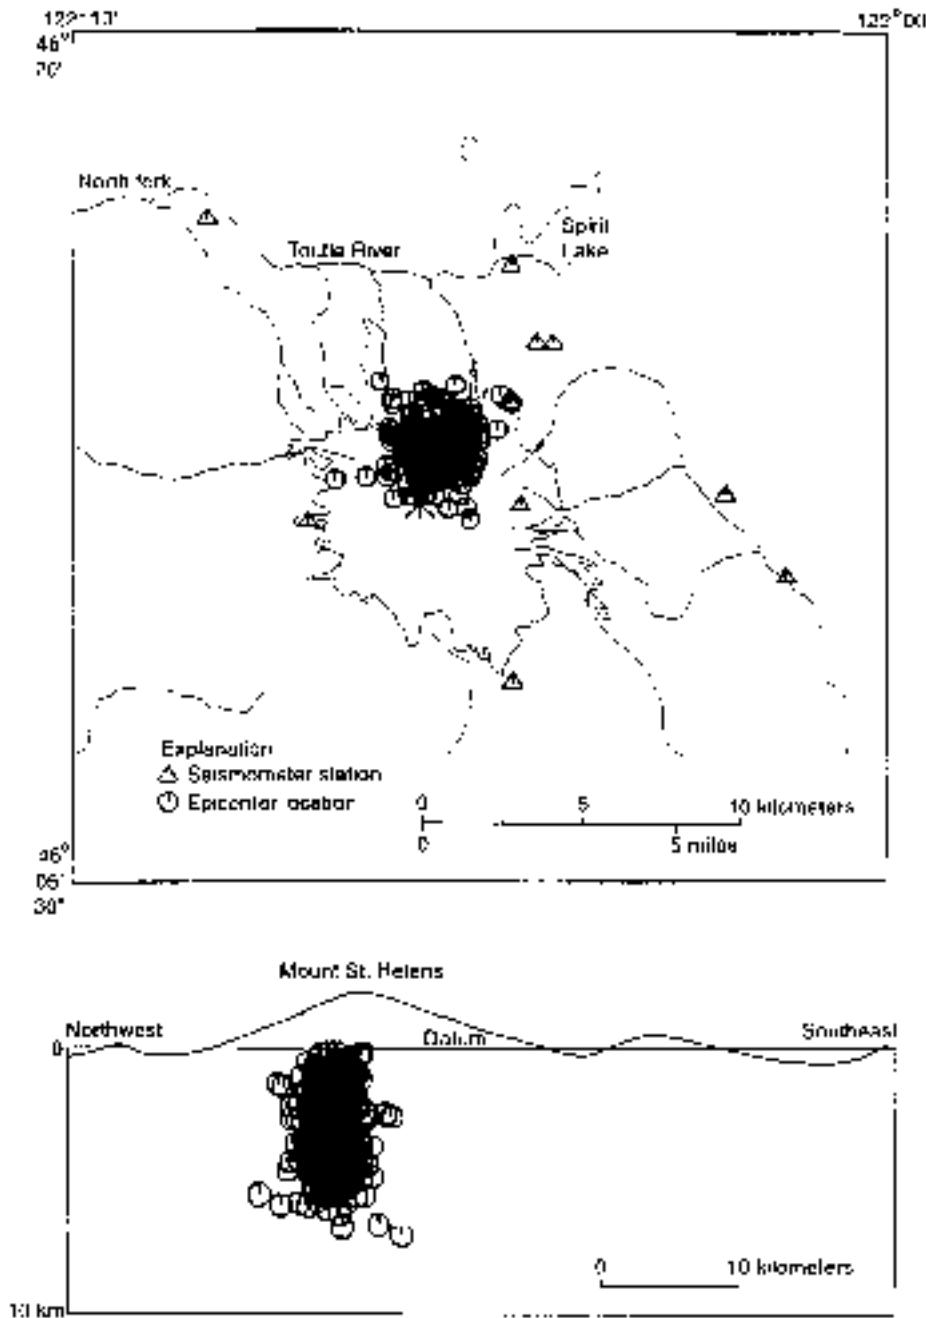

FIGURE 8 Epicenter map and cross section of seismicity from March 27 to May 18, 1980, at Mount St. Helens volcano. Contour on map is 4000 ft.; datum for cross section is average elevation of seismic stations, approximately 3000 ft. [After Endo et al., 1981.]

and  $\lambda$  is tremor wavelength in centimeters.  $2\sqrt{2}$  is the root-mean-square (rms) amplitude correction.

Such information is helpful for estimating plume heights and tephra volumes. The ends of eruptions can be estimated as coinciding with the end of strong tremor associated with eruptions. In many cases tremor declines

more or less exponentially on a timescale of minutes to tens of minutes and returns to background levels. In some cases, eruptions of ash end but weak tremor continues for days in association with hydrothermal activity.

The ends of eruption sequences, which may last months to years, are more difficult to determine than

the ends of individual eruption pulses, which last a few hours to days. Generally volcanic tremor ceases altogether and the number of earthquakes per unit time decreases regularly. Volcanic earthquake swarms decline with a similar power law decay to aftershocks, except that the timescale is often longer.
