Mount St. Helens, Washington, USA, produced a large explosive dacite eruption, including a lateral blast, on May 18, 1980, following 59 days of increased seismicity. On March 20, 1980, an  $M = 4$  earthquake occurred, followed by many smaller events. Activity increased, reaching eight  $M \geq 4$  events in a single hour on March 25. Phreatic eruptions began on March 27. The earthquake sequence eventually included over 10,000 earthquakes, including high- and low-frequency events and volcanic tremor (Figures 7 and 9). Most events were located at depths of 3–7 km beneath the north flank of the volcano, the site of the eventual eruption (Figure 8). There were no immediate precursors in the hours before the climactic eruption. However, the shaking from a  $M = 5.1$  earthquake initiated the eruption by causing a sector collapse which uncapped the volcano. Deep (5–20 km) earthquakes began shortly after the eruption and lasted for several days. Later smaller eruptions were generally preceded by swarms of small earthquakes lasting several hours to several days.

### B. Kilauea, January 1983

Kilauea volcano, Hawaii, is a shield volcano with a summit caldera and rift zones to the southwest and east. Earthquakes are numerous and are associated with all three of these features, as well as with a deeper nearly horizontal fault on the south flank of the volcano (Figure 10). New magma typically rises from depth near the summit, causing earthquake swarms and inflation, and then either erupts near the summit or moves laterally into the east rift zone, accompanied by summit deflation. A fissure eruption began on the east rift zone on January 3, 1983, near Napau Crater, extending 8 km downrift toward Puu Kamoamoa. Prior to this, earthquake swarms had occurred on September 26 and December 9, 1982, near the summit, followed by an intense swarm

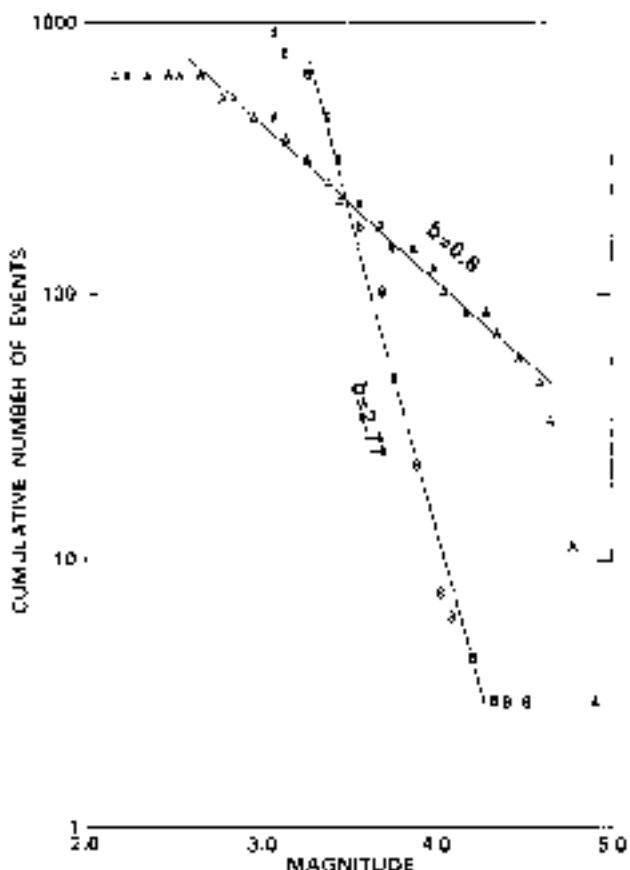

FIGURE 9 Frequency-magnitude relations for high-frequency (A) and low-frequency (B) earthquakes at Mount St. Helens. Regression lines fit to selected portions of the data produce the  $b$  values indicated. [After Endo *et al.*, 1981.]

on the upper east rift from December 30, 1982, to January 6, 1983 (Figure 11). Most of the earthquakes were shallow, between depths of 2 and 4 km, and the largest was  $M = 4.2$ . Volcanic tremor first occurred weakly, and then was strong at frequencies of 5 to 10 Hz at the time of fissure opening. Later, tremor was predominantly 2.5 Hz with bursts of stronger activity paralleling the behavior of intermittent high lava fountains. After the initial fissure eruptions, the volcanic activity localized south of Puu Kamoamoa (Figure 10) and formed a new cone called Puu Oo. In July 1986, activity shifted to a lava lake 3 km downrift. The eruption is continuing as of this writing, and is Kilauea's longest historical eruption.

### C. Ito-oki, July 1989

A submarine eruption occurred offshore of the Izu Peninsula, Japan, on July 13, 1989, following 53 days of in-

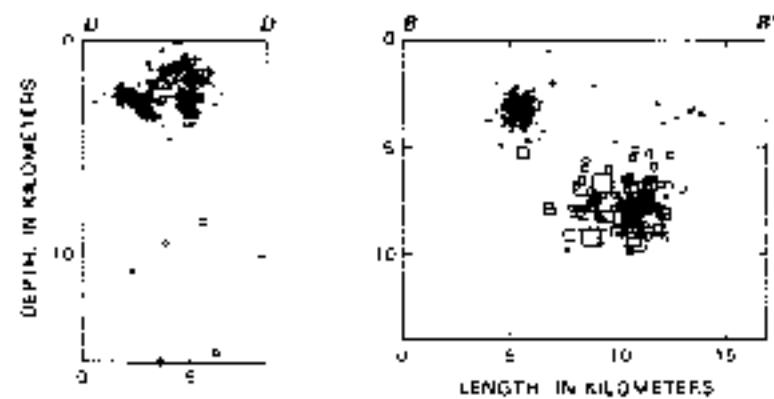

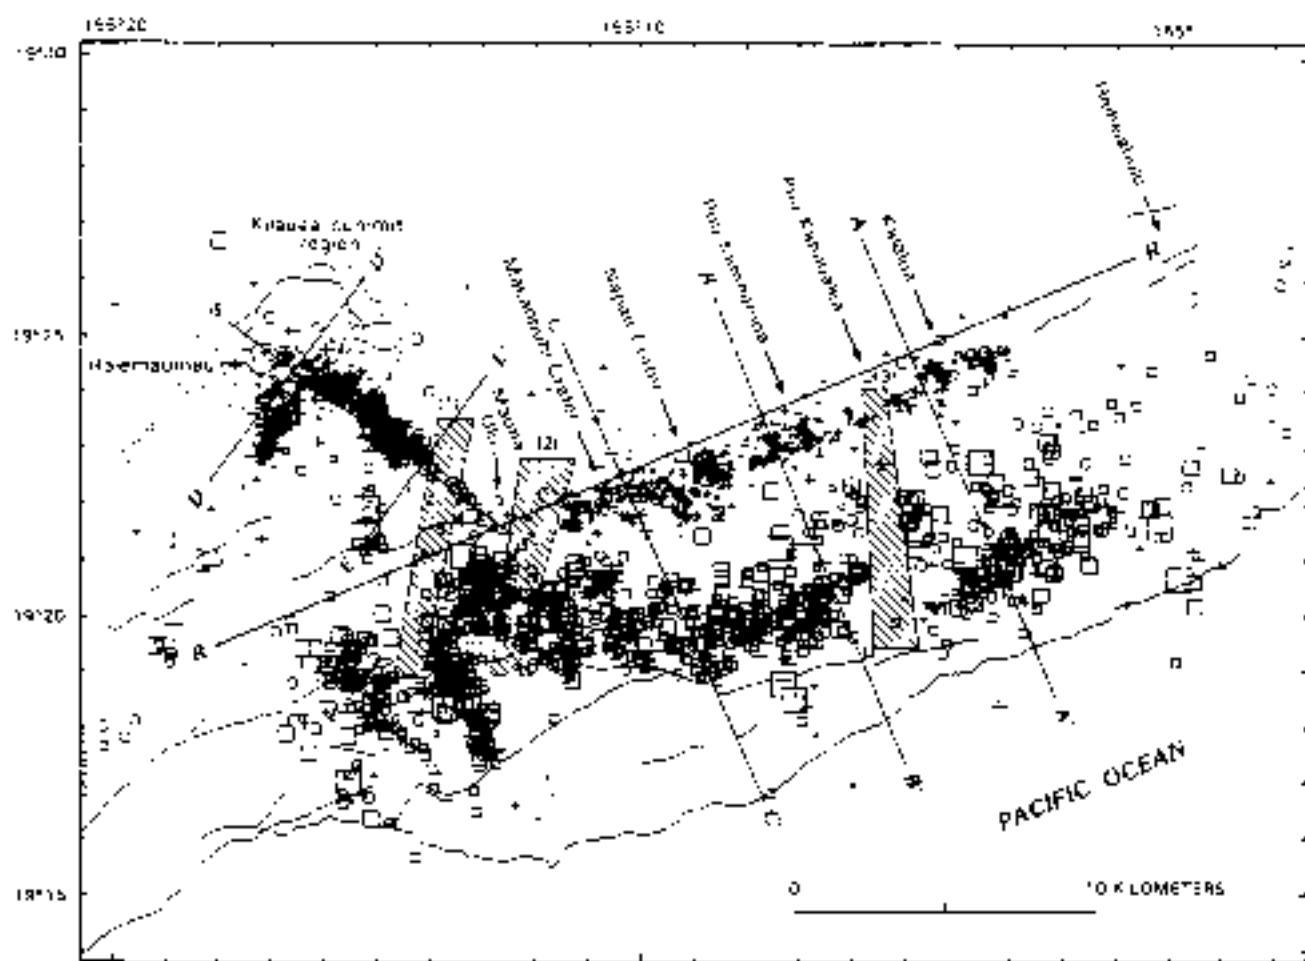

FIGURE 10 (Top) Map of Kilauea volcano and the east rift system showing earthquakes less than 15 km deep for the period September 1982 to January 1983. Shallow earthquakes ( $<5$  km) are shown as crosses, and deeper earthquakes ( $>5$  km) as squares; symbol size is proportional to magnitude. Note the concentrated shallow seismicity near Kilauea's summit and the more diffuse seismicity along the east rift zone. The deeper events occur mostly on a nearly horizontal fault. The January 3 eruption began near Puu Kamoamoa. Zones free of earthquakes are shown with cross hatching. Lines labeled A-A', B-B', etc., show cross sections. (Bottom) Two cross sections (see map) showing the depth distribution of earthquakes near the summit and near the eruption site. [After Koyanagi et al., 1988.]

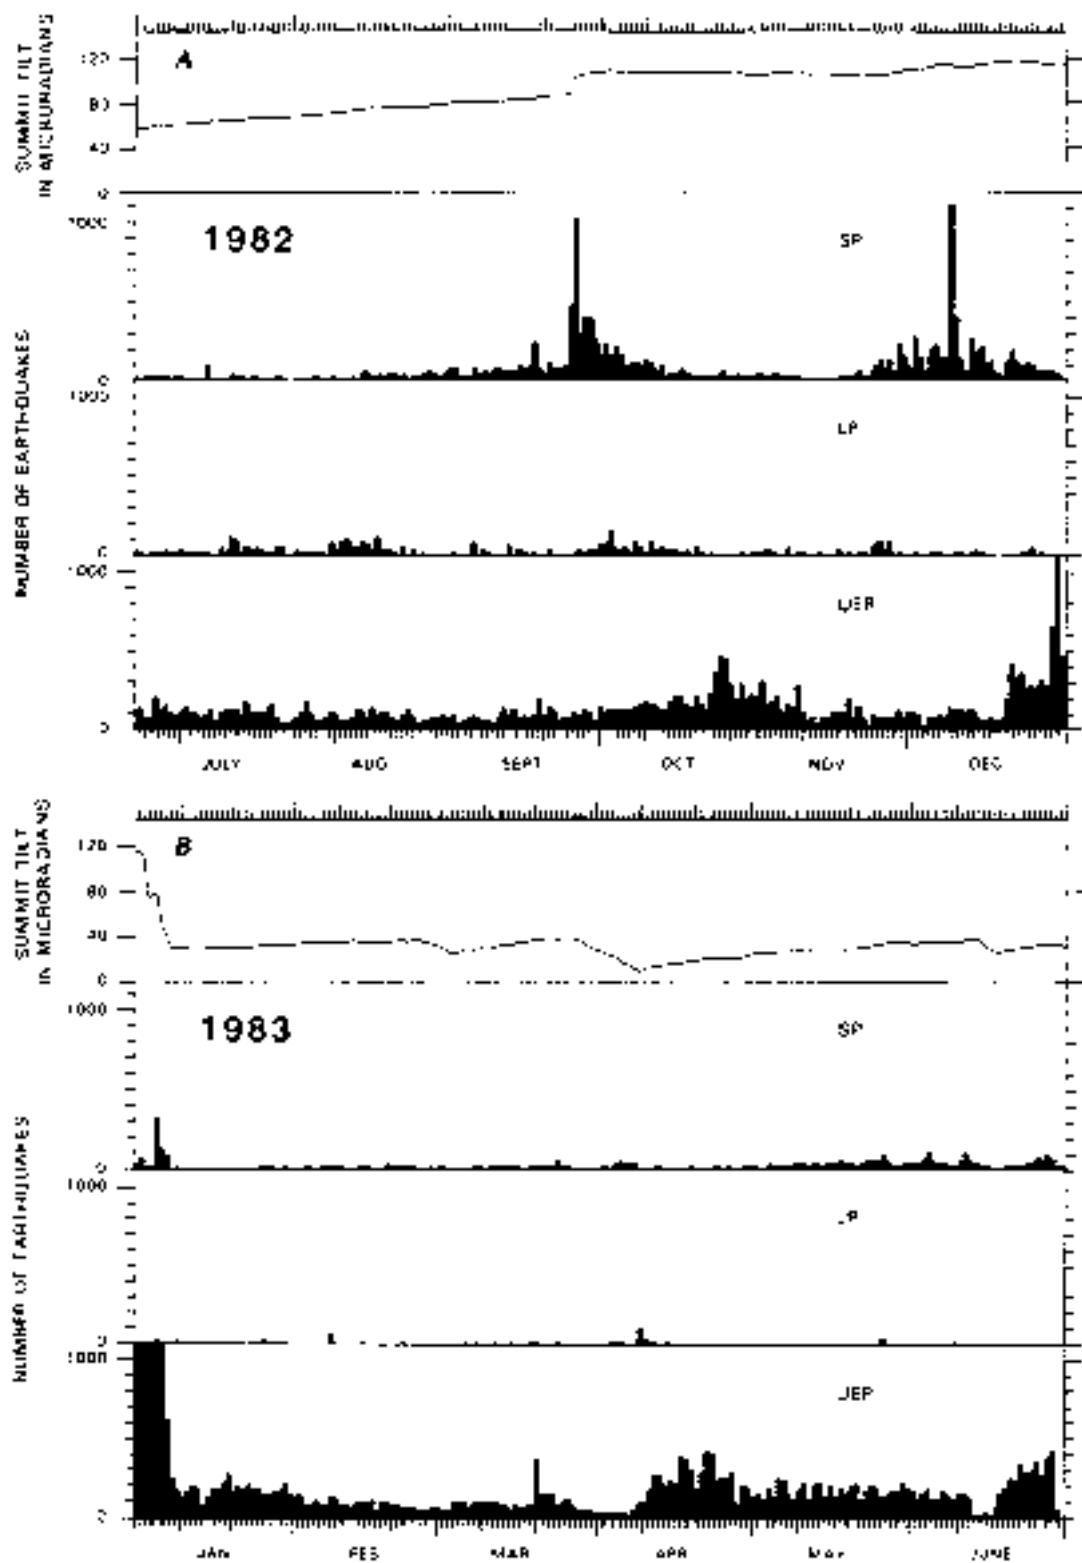

FIGURE 11. Summit tilt and daily number of earthquakes at Kilauea summit and upper east rift (UER) for the periods (A) July to December 1982 and (B) January to June 1983. Summit earthquakes are divided into short-period (SP) and long-period (LP) types based on their waveforms. Note the summit swarms in September and December, and the strong UER swarm just before the eruption of January 3, 1983. Summit deflation typically accompanies the migration of magma into the east rift system. [After Koyanagi et al., 1988.]

creased seismicity. An earthquake swarm occurred May 22–26, and then subsided. On July 2 earthquake activity resumed. Earthquake counts increased first, followed by the largest event of the sequence, a  $M = 5.5$  event on July 9. After this event, the number of earthquakes decreased, and then low-frequency events appeared, followed 2 days later by the occurrence of volcanic tremor (Figure 12). After 1 day of relative quiescence the eruption began, accompanied by visible boiling at the sea surface. This eruption was accompanied by unusually strong tremor. Seismicity occurred sporadically in the days following the eruption. The seismicity associated with the eruption was embedded in the high seismicity characteristic of the surrounding area (Figure 13).

#### D. Pavlof, September–December 1996

Pavlof is the most active volcano in North America and has had over 40 eruptions since 1760. It is monitored by a network of six seismic stations within 11 km, and three others from 33–40 km. An eruption report was received on the morning of September 16, 1996, from residents of Cold Bay, 37 miles to the Southwest. This

was a surprise to scientists because no significant precursors had been seen on seismic records, which were partially obscured by a storm in the area. Later analyses showed that the small-scale seismicity had actually increased on September 11, which was only revealed after digitally filtering the data (Figure 14) to remove storm noise. The eruption lasted continuously from September 16 to December 4, declined, and then had two stronger bursts on December 10–12 and December 27–29 (Figure 15). The challenge during this eruption was not to forecast the onset, which was missed, but to quickly determine escalations of activity that represented more explosive phases of the eruption. These occurred five times (Figure 15). The data were analyzed automatically in near real time (a few minutes) to determine reduced displacement and this was used to establish an alarm threshold of  $6 \text{ cm}^2$ . Further, spectrograms were determined and were used to help identify explosions and escalations in tremor (Figure 16).

#### E. Pinatubo, June 1991

Pinatubo volcano, Philippines, produced a dacitic caldera-forming eruption on June 15, 1991, which was the

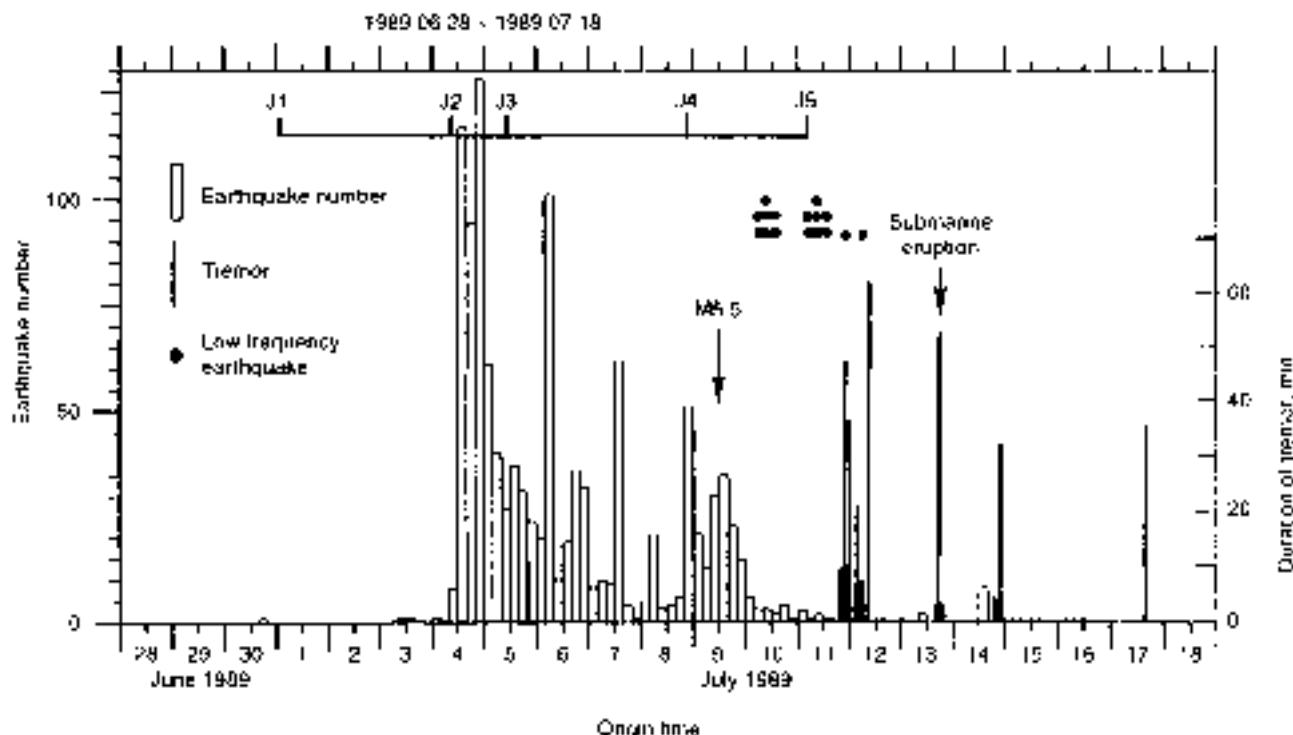

FIGURE 12. Crustal seismicity associated with the 1989 Ito-oki submarine eruption. Number of earthquakes per 4 hours, duration of tremor events, periods of crustal movement (J1–J5), and occurrence of low-frequency earthquakes are indicated. [After Ueda, 1993.]

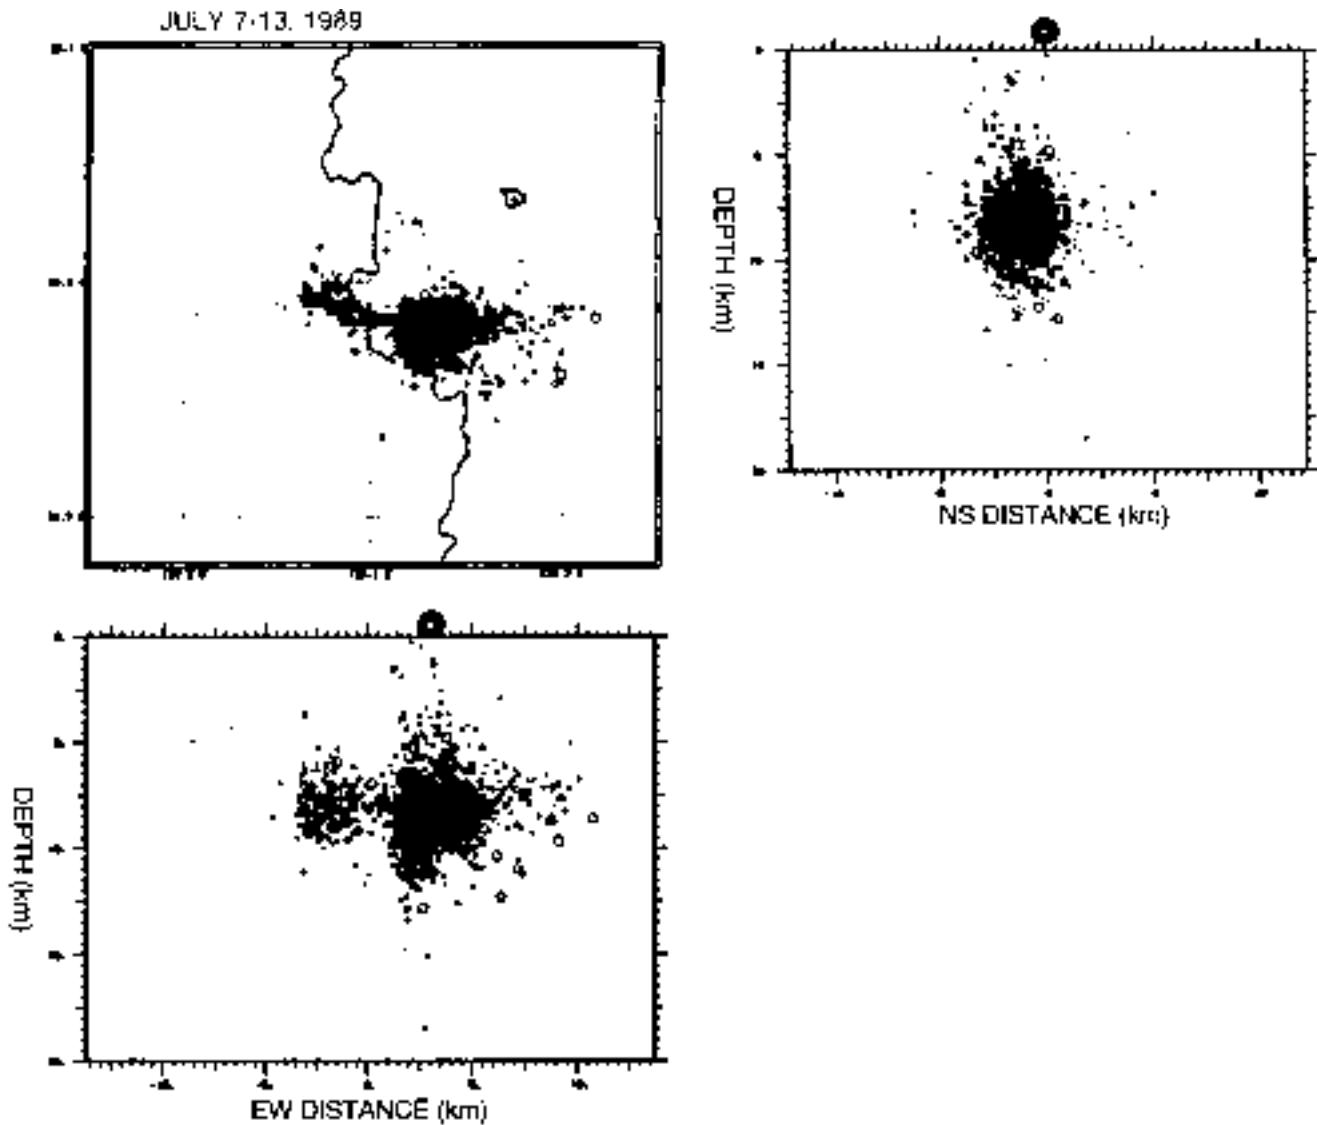

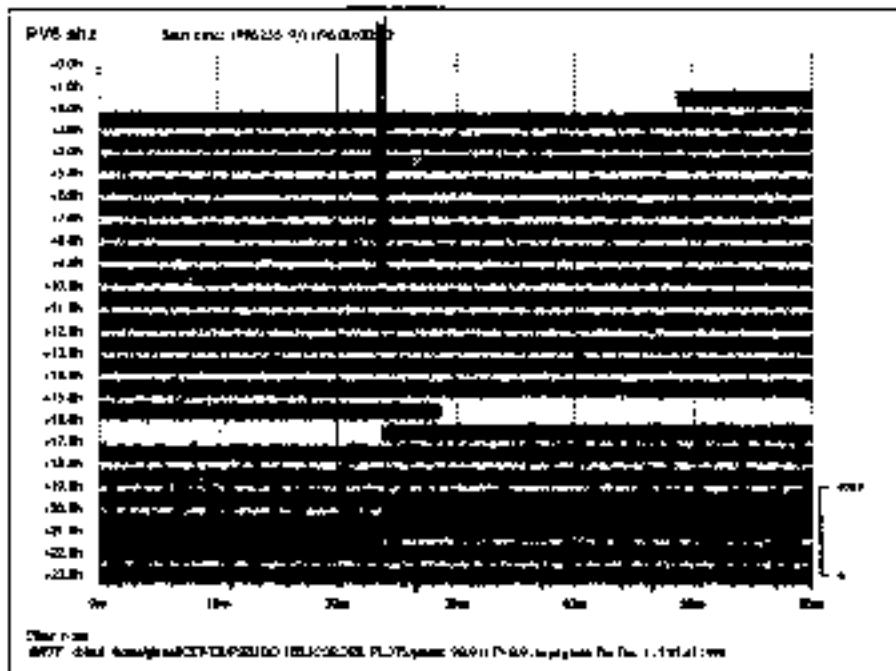

FIGURE 13 Map and cross sections of hypocenters in the vicinity of the July 1989 Ito-oki eruption. The submarine eruption produced the topographic feature known as Teishi Knoll (large round symbol). [After Matsumura et al. (1991). *J. Phys. Earth* **39**, 93–106.]

largest explosive eruption worldwide in 79 years. The eruption produced about  $10 \text{ km}^3$  of tephra, generated an eruption column to a height of 33 km, and affected global climate for several years. Seismicity increased 2 months or more before the eruption and was generally shallower from June 1 to 12 (Figures 17 and 18). The exact start date is not known because seismometers were not installed until after phreatic explosions on April 2, 1991. Epicenters were located about 5 km northwest of the volcano until June 3, when activity shifted to beneath the northwest flank near the summit (Figure 18).

Tremor began on June 3 and a small dome was emplaced June 7. Two episodes of stronger tremor occurred several hours before the first dacite Plinian explosion, which occurred June 12. This was followed by a strong swarm of low-frequency events and tremor. The climactic caldera-forming eruption occurred on June 15 (Figure 19). Following this, the volcano entered a phase of periodic smaller eruptions lasting about 3 weeks. Large deeper earthquakes, up to  $M_s = 5.7$  and to 25 km depth, occurred over an area out to 20 km from the summit starting at the time of the climactic eruption.

### unfiltered helicorder plot

### filtered helicorder plot

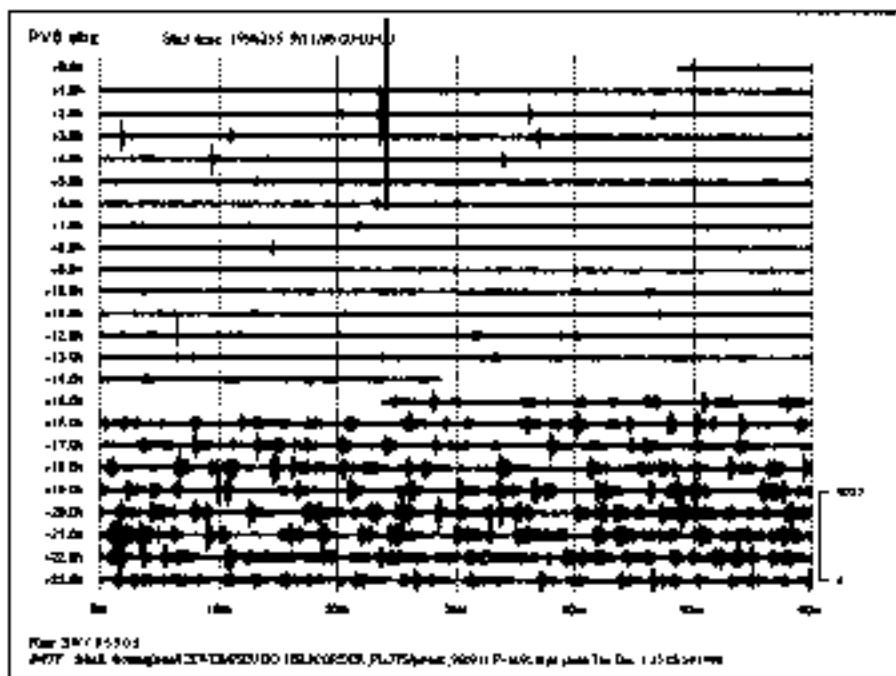

FIGURE 14 Unfiltered and filtered digital seismograms from station PV6 at Pavlof volcano, September 11, 1996. Each record is for 1 day, one line per hour. The unfiltered seismogram shows only noise with variable amplitude. The lower seismogram was filtered to remove noise below 0.8 Hz and above 5 Hz. It shows the rapid onset of a swarm of small earthquakes that occurred a few days before the eruption. (Courtesy G. Thompson.)

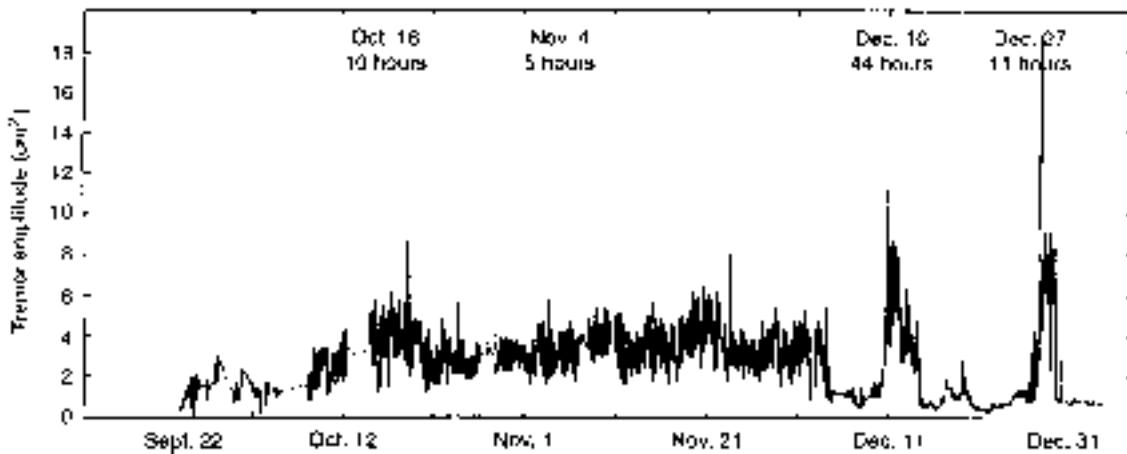

FIGURE 15 Plot showing the normalized amplitude (reduced displacement) of volcanic tremor during the 3.5 months of the 1996 Pavlof eruptions. Stronger tremor accompanied more explosive phases of the eruption on October 18, November 4 and 23, and December 10 and 27, 1996.

## VII. CONCLUSIONS

Several of the observations and conclusions presented in this chapter deserve additional emphasis. First, it is very important to have a sample of background seismicity of several years duration to serve as a benchmark for comparison of possible precursors. This requires establishing a seismic network or at least a single station before a volcano shows signs of reawakening. Second, a variety of recording methods are necessary to emphasize different features of the data. These may include drum recorders, event-triggered computers, continuous digital recording, spectrograms, and reduced displacement plots (or RSAM and SSAM). Third, three-component and broadband seismometers are necessary to properly analyze many signals. These provide improved monitoring at the time, and much needed data for later analysis to understand the physical processes. Broadband, high-dynamic-range seismometers are particularly important because existing instruments always saturate for large eruptions, and because energy at long periods ( $\geq 1$  s) is simply not seen on standard short-period seismometers. Thus our current understanding does not incorporate either the full spectrum or high-amplitude near-source effects. Fourth, monitoring strategies need to be flexible and should not rely exclusively on a single process or type of signal. In spite of better understanding and greatly improved data quality and precision, volcanoes are still capable of new and unexpected activity. Finally, false alarms are inevitable. These may be reduced as

patterns and processes become better understood, but the fundamental processes that are monitored using seismology are common to both intrusions and eruptions. Progress toward probabilistic methods may help overcome this obstacle.

Volcano seismology has matured in the last 2 decades, helped by the advent of computers and detailed study of many eruptions of different types and sizes. And yet, despite the extraordinary increase in amount and precision of knowledge, there is no guaranteed method for forecasting eruptions. Rather, volcanoes remain complex structures for which a great variety of behaviors are possible. Several general patterns of seismic activity and physical models have been discussed here, yet these may be overlooked during crises. This happens for two main reasons. First, during crises there simply is not time to perform many detailed analytical or research tasks. For this reason, most monitoring tasks are designed to be simple and reliable, and hence less prone to error. Many can be automated. Second, scientists tend to be conservative in their decision making, and crises are poor times to test new hypotheses. Rather, the best observations which are built on the most secure, previously published foundation will guide response. This trend sometimes delays response, but prevents unacceptably high false alarm rates.

Although seismology is a powerful tool in terms of eruption monitoring, it is nowhere near as powerful alone as it is when combined with other techniques. These include visual observations, geodesy, gas sampling, satellite images, and others. Nevertheless, seis-

mology is the backbone of most volcano observatories, and a strong seismic monitoring program generally results in effective hazard mitigation. Future efforts will undertake to provide a more physical basis for eruption forecasting, and to continually search new and existing high-quality data sets for better diagnostics. Such data, and well-trained and experienced scientists, will help reduce the potential for disasters at dangerous volcanoes.

## GLOSSARY

- earth tides** The change in gravity at the surface of the Earth caused by the relative movement of the Sun and Moon.
- GPS** A surveying technique that uses signals from a series of artificial satellites to determine position on the Earth's surface.
- gravimeter** Sensitive geophysical instrument used for measuring the relative acceleration due to gravity.
- microgravity** Technique using gravimeters at the limit of precision to measure gravity differences of the order  $10^{-6}$ – $10^{-8} \text{ ms}^{-2}$ .

**microgravity network** Array of stations used in a microgravity survey.

**piezomagnetic** Magnetic properties of rock produced by stress.

**proton precession magnetometer** A geophysical instrument which exploits the property of protons (usually water or hydrocarbon is used as a proton source) whereby their magnetic moment vector aligns itself parallel to an applied field. When the applied field is switched off, the magnetic moments precess (like a spinning top) about the remaining (Earth's) magnetic field. The frequency of the precession is proportional to the strength (magnitude) of the field, which provides a measure of the prevailing Earth's magnetic field strength.

**SAR interferometry** Synthetic aperture radar (SAR) interferometry is a powerful remote sensing technique for measuring the distance to the Earth's surface. It requires that the surface is imaged by the radar at least twice from almost the same position in space. The property measured is the phase of the reflected radar signal. The differences in phase between the two images produce interferometric fringes that will represent both the topography of the surface and any changes in position of the surface during the period between the acquisition of the two images. Thus it is possible with this technique to measure both the gross topography of volcanoes at a

scale of 10 m and the dynamic changes of surface at the centimeter scale.

**P**RECursors to volcanic eruptions include changes in the physical properties (e.g., density, temperature) of rocks beneath the surface. If these properties are measured and monitored, they can give some indication as to the likely magnitude and nature of the following eruption. Local changes in subsurface density may be produced by magma movements (intrusion/withdrawal) and by variations in the degree of magma vesiculation. These changes can be detected by measuring variations in the acceleration due to gravity. Variations on the order of 10s to 100s of  $\mu\text{Gal}$  are typical, where  $1 \mu\text{Gal} = 10^{-8} \text{ ms}^{-2}$ . These magmatic processes may also induce changes in the total magnetic field strength. Magnetometers regularly deployed on volcanoes measure field strength to 0.1 nanoTesla and fluctuations of a few nanoTesla to a few thousand nanoTesla are typical. Ground deformation also accompanies volcanic processes such as subsurface magma movements. Deformation may be horizontal (opening cracks) and vertical and ranges from millimeters to meters in scale. Measurements are made using surveying levels, electronic theodolites, and more recently the satellite-based methods of GPS and SAR interferometry. Measurements of gravity, magnetic fields, and ground deformation can also be made during and between eruptions, providing information on the processes going on inside a volcano when it is not erupting.

---

## I. PRINCIPLES OF GROUND DEFORMATION MONITORING

For many volcanoes, ground deformation is among the most useful indicators of the general state of the volcano and any impending eruption. The work of the Japanese scientist Mogi, published in 1958, marks the beginning of modern deformation studies on volcanoes. His model describes the effect at the surface of an increase in pressure of a small, spherical source in an infinite elastic half-space, simulating the effect of increasing magma pressure within a buried magma chamber before an eruption. Despite the fact that volcanoes are not strictly elastic in behavior, nor are their surfaces flat and horizontal, many volcanoes show behavior surprisingly close

to Mogi's model, particularly on a scale of several kilometers. Mogi applied his model successfully to Sakurajima volcano, Japan, and Kilauea volcano, Hawaii.

Recent developments of Mogi's model have included the effects of volcano topography in three dimensions and other nonspherical, non-axisymmetric-shaped magma chambers.

Until recently, deformation was measured at permanent markers by surveying methods such as leveling (which gives relative vertical height), distance measurement and theodolite angular measurement (which give horizontal measurements of position), and dry tilt (which gives ground tilt only). In the past few years, GPS has overtaken theodolite and distance measuring as the fastest and most precise way of measuring horizontal position.

Once a network of fixed stations has been established and measured on a volcano, the detection of displacements due to ground deformation will depend upon a later remeasurement of the same stations. The deformation is then usually expressed relative to one of the stations in the network (the reference station), normally the station furthest from the volcanically active areas, and preferably off the volcano altogether. However, using GPS, it is now possible to refer movement to stations hundreds of kilometers away which may thus introduce irrelevant tectonic movement of the reference stations. As a general rule, reference stations should be close to the area studied without being actually involved in the movement under investigation.

It takes a finite amount of time to occupy all the stations on a volcano using these surveying methods—typically from a couple of days to a month, depending upon the methods used, the size of the measuring network, the manpower available, and the weather. It is therefore not usually practicable to measure the network more than once a month; financial and logistic considerations often mean that once or twice a year is nearer the norm for many volcanoes.

Surveying methods complement electronic tiltmeters on volcanoes very effectively, in that they provide a high spatial resolution, which combined with the high time resolution of tiltmeters can provide an overall picture of events taking place within the volcano. They are particularly suited to studies of internal structure, and also to long-term monitoring of ground deformation. As a predictive tool, they have been effective in predicting position, as well as giving an indication of the likelihood of future eruptions.

Electronic tiltmeters use a different approach. They measure ground tilt continuously, but at one place only,

so that although the progress of changing tilt can be recorded from minute to minute, there is no information on what is happening between tilt stations; nor is it necessarily true that the tilt site is representative of the whole volcano. However, for volcanoes with fluid magma of low viscosity, such as the Hawaiian or Icelandic volcanoes, tiltmeter records can provide immediate information on events within the interior of the volcano. Episodes of magma injection, for example, can be followed in detail as they unfold, and increasing ground tilt can be used to help predict the time of an impending eruption.

Newly developed satellite techniques such as GPS and SAR interferometry have the potential of bridging the gap between tiltmeters and surveying methods. SAR interferometry, like ground surveying, is capable of providing a map of altitude changes, and can do so every time the satellite passes over. At present, this technique has been attempted using satellites which have been able to overfly the same region of the Earth every month or so, but there is no reason why future satellites could not increase this coverage to as often as necessary for key volcanoes, thus approaching tiltmeters in temporal coverage, with the advantage that information can be derived at any point on the volcano. Permanent GPS stations have now been installed on some volcanoes and volcanic areas which provide continuous information on how the edifice is deforming with time. If enough of these are installed, then they can replicate ground deformation surveying, but with the advantage that, like tiltmeters, they can do so continuously, thus providing the ideal monitoring system, the only drawback being the high cost of GPS receivers.

## II. TECHNIQUES USED IN THE FIELD

### A. Precision Leveling

Leveling is the most accurate method of deriving changes in relative heights on a volcano. It was first used in this way in Japan, to investigate the 1910 eruption of Usu volcano and the 1914 eruption of Sakurajima volcano, but did not come into use as a regular monitoring tool until 1965 at Kilauea volcano, Hawaii. In its simplest form, leveling involves the use of a vertical graduated measuring staff and an instrument called a level, consisting of a telescope with a central crosshair set up to read exactly horizontally. Figure 1 illustrates the method of precision leveling between two fixed markers on a volcano. Using this technique, accuracies of 0.8 mm over 1 km are obtainable.

### B. Conventional Ground Surveying

Both trigonometric leveling and trilateration (determining angles between sets of markers), sometimes combined, were in use to measure horizontal and three-dimensional changes in position of networks of benchmarks at volcanoes prior to about 1995. Distances were measured by EDM (electronic distance measurement), and heights determined from vertical angles read with a theodolite. However, the proliferation of GPS satellites and advances in GPS techniques have made these methods of deformation measurement largely obsolete, ex-

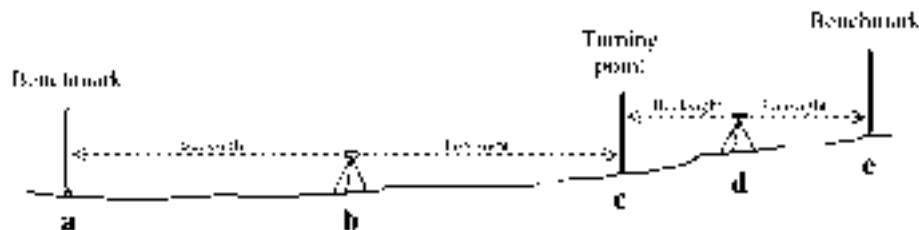

FIGURE 1 Diagram of leveling procedure. The staff is set up over the reference benchmark a, and the level at b. The value on the staff at the horizontal crosshair seen through the level is read and noted down; this first value is the backsight. The staff is then moved forward to a temporary position c, known as a turning point, where it is placed on the ground, not on any fixed station, and the staff value read and recorded again. This forward observation is called the foresight. The instrument is then moved to position d, and the staff at c (now the backsight) is read again. Finally, the staff is set up over the second benchmark e, and the foresight read. The difference in height of e relative to a is the sum of all the foresight values minus the sum of all backsight values. In this example, only one staff turning point is required at position c, but in practice any number of turning points can be used between the two permanent benchmarks. The speed of leveling depends upon the steepness of the slope, steeper slopes requiring shorter sights, as well as the distance between the two points to be measured.

cept where the higher costs of equipment have as yet precluded this, or where dangerous activity prevents occupation of a remote station. Among traditional surveying methods, only precise leveling now remains more accurate than GPS as a volcano monitoring technique.

### C. GPS

GPS is now the most accurate way of measuring horizontal position over large distances. Signals from a series of satellites (at present about 30) are processed by a receiver on the ground which determines the distance to each satellite and derives its position on the Earth's surface. Because of continuous signal scrambling for military reasons, absolute positions are only accurate to tens or hundreds of meters, but by using two dual-frequency receivers in the same region, the scrambling is virtually the same and so relative positions between the two can be obtained to accuracies of a few millimeters over tens of kilometers, depending on satellite configurations at the time of measurement. Vertical positions are never so accurate as horizontal positions because the satellites are only on one side (above the instrument) and so the configuration is far worse.

A great advantage of GPS (Figure 2) is that it can be

**FIGURE 2** Wild dual-frequency GPS receiver in use near the summit of Mount Etna volcano, Sicily. The sensor is set up vertically above a ground marker, and the data stored in the handheld controller. Another receiver is left running at a base station at the start of the day's work. With occupation times between 15 minutes and 3 hours (depending on satellite configuration and distance between the receivers), the relative position and height of the two receivers can be determined with a precision of a few millimeters.

carried out in any weather, including rain, snow, fog, and high winds, which would preclude conventional surveying altogether. Like ordinary trigonometric surveying, when measuring a network of points a strong triangulation net should be constructed with good redundancies, so that error ellipses can be calculated. Displacement can then be distinguished from the various sources of error. For the highest accuracies, lines and stations should be observed for longer than 24 hours at a time, but logistical constraints on inaccessible volcanoes may preclude this. A more practical procedure may be to ensure that stations are reoccupied on different days and times of day, when the satellite positions are completely different.

### D. SAR Interferometry

Synthetic aperture radar (SAR) interferometry by satellite, a technique being developed at present, can provide information on ground deformation at any point on the volcano without the need to deploy any instrumentation on the ground at all. Two satellite radar images taken on different orbits but from almost the same point in space are compared. The differences in phase between the two images produces interferometric fringes that will represent both the topography of the surface and any changes in position of the surface during the period between the acquisition of the two images, that is, any deformation that has taken place in the interval. One of its disadvantages is that the displacements are measured in the satellite vector only, normally approaching the vertical but not necessarily so. The results can be affected by atmospheric changes (humidity, pressure, etc.), and vegetation and snow cover preclude measurement at present, though algorithms may eventually be developed to overcome these problems. Early attempts to use the technique on volcanoes of high topographic relief were also dogged by errors associated with subtracting the topography. Highest accuracies achievable depend upon the wavelength used; heretofore this has been just under 3 cm.

The end product of SAR interferometry is an interferogram: essentially a map of the volcano showing interference fringes which correspond to contours of displacement in the satellite direction between two radar images. The technique promises to be particularly important for remote or rarely monitored volcanoes where no other means of deformation monitoring is possible.

### E. Dry Tilt

Dry tilt is the colloquial name given to a method of measuring changes in tilt of the ground which employs the same optical instruments as leveling. The technique came to be known as "dry tilt" by way of contrast with the end state of those making water-tube tiltmeter measurements.

In its simplest form, a dry tilt station consists of at least three benchmarks arranged in a roughly equilateral triangle with sides of about 50 m. The level is set up in the center, and the staff placed on each of the three benchmarks in turn with their relative altitudes measured to a high precision. Next time the station is measured, any tilt of the ground in the intervening period will show up as a slight change in relative altitudes of the three benchmarks.

Dry tilt stations must always be regarded as a poor second to leveling, as they provide no information on altitude changes at widely separated parts of the volcano, and the same limitations apply as for tiltmeters. However, the advantage of dry tilt stations is that they are cheap and quick to measure, and can be occupied several times a day during periods of crisis. For poorly funded or infrequently visited volcanoes, they are a simple means of providing rudimentary information on deformation, for example, where heavy forest cover precludes SAR interferometry.

### F. Tiltmeters

Various kinds of tiltmeter have been deployed on volcanoes, the first being a horizontal pendulum seismometer that proved to be an effective tiltmeter installed at Kilauea volcano, Hawaii, in 1912. Borehole tiltmeters can now be bought off-the-shelf, and have been installed at many volcanoes to provide a continuous record of deformation. The choice of site is important, as most tiltmeters are affected to some degree by temperature and rainfall. Installation in a temperature-stable underground vault is the best location for most types of tiltmeter, though lava tubes have also been used as a naturally available alternative. Most sensitive tiltmeters also suffer a "running-in" period when a constant tilting occurs, sometimes for several months, before the signal settles down.

These problems are largely overcome when hydrostatic level tiltmeters are used which have a much longer baseline and so escape the anomalies consequent upon measuring tilt essentially at one spot. Tiltmeters sensitive enough to record Earth tides can be installed without the need for temperature-stable vaults.

Problems with tiltmeters as a means of measuring deformation are that they do not measure relative altitude change nor horizontal deformation. Instead they provide a measure of ground tilt only at individual sites. If, for example, tilt at such sites around the volcano is always away from the summit, it is assumed that the summit is rising. However, such a deduction has to be based on the assumption that the intervening ground between the tiltmeters is behaving in the same way, and this may not be the case, particularly in highly faulted terrains.

---

### III. CASE HISTORIES OF DEFORMATION

Ground deformation on volcanoes may be due to several causes. These include: (1) inflation/deflation of a buried magma storage zone, (2) injection of a dike or sill which may or may not be an eruption conduit, (3) subsidence due to lava loading, gravitational settling, or spreading of the whole volcano, and (4) slope movement caused by slope creep prior to failure or by magma pressure variations on steep slopes. Combinations of these causes frequently occur to produce a complex pattern of deformation.

#### A. Sakurajima Volcano (Japan, 1914)

After a large eruption in 1914, leveling benchmarks around Sakurajima volcano, which had been installed and leveled in 1895 as part of a country-wide survey, were resurveyed in June 1914. The results showed a broad, roughly circular subsidence of more than a meter and at least 60 km wide, not centered on the volcano itself, but roughly concentric with the center of Kagoshima Bay, an old caldera. These results were analyzed by Mogi, who found that when plotted against the distance from the center of subsidence, the data fitted very closely to the deformation expected from elastic deformation caused by a buried source, from which he was able to develop his model.

The Mogi model predicts that

$$\Delta d = \frac{3a^3 Pd}{4\mu(f^2 + d^2)^{3/2}}$$

$$\Delta b = \frac{3a^3 Pf}{4\mu(f^2 + d^2)^{3/2}},$$

where

- $a$  = radius of the source sphere
- $P$  = change in hydrostatic pressure in the sphere
- $f$  = depth to the center of the sphere
- $\mu$  = Lamé's constant
- $d$  = radial distance on the surface from point above source
- $\Delta d$  = radial horizontal displacement of a point at the surface
- $\Delta h$  = vertical displacement of a point at the surface

Mogi found that the Sakurajima data were consistent with a depth to source ( $f$ ) of  $10 \pm 1$  km (Figure 3).

### B. Krafla Volcano (Iceland, 1978)

The Krafla fissure swarm in northern Iceland began erupting in December 1975 after 230 years of dormancy. There were nine eruptions in the following 9 years. The accompanying deformation patterns showed repeated inflation and deflation sequences, essentially of the Mogi type, centered on the 9-km-wide Krafla caldera. It appears that a magma chamber was being supplied with magma over this 9-year period, and that the consequent steady inflation of the chamber was punctuated by about 20 rapid deflation events. During these deflation events, vertical fissures crossing the area widened and filled with magma from the reservoir, forming dikes which extended rapidly to distances up to 50 km from the caldera center. Eleven of these dikes did not reach the surface, but remained as intrusions.

Characteristic ground deformation can be expected on the ground surface above a vertical or near-vertical dike undergoing dilation during emplacement. In general, points on either side of the dike will displace away from the dike, normal to its long axis, as it inflates. The vertical displacement increases rapidly with distance from the dike, reaches a peak value, and then decreases slowly toward an asymptote of zero displacement (Figure 4a). In the case of vertical dikes, this displacement is symmetrical about the center of the dike. For near-vertical dikes, displacements are greater on the side in the direction of dip and the point which experiences zero displacement is above the uppermost tip of the dike rather than its center. Horizontal ground strain is the first derivative of this displacement with respect to distance. Its peak tensile value occurs above the tip of the dike, and then decreases rapidly, through zero at the peaks of the displacement, to a relatively low compressive strain which then asymptotes back to zero (Figure 4b). The exact shape of the displacement against distance

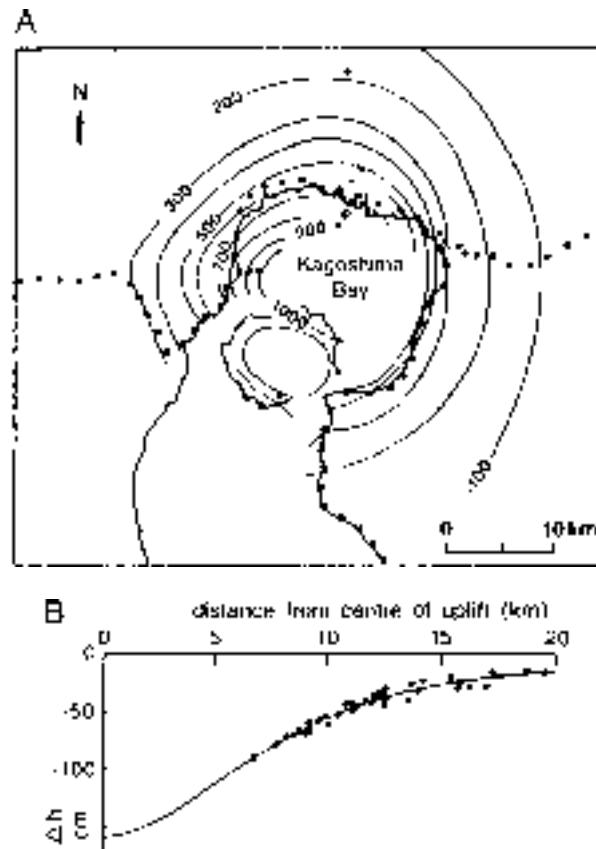

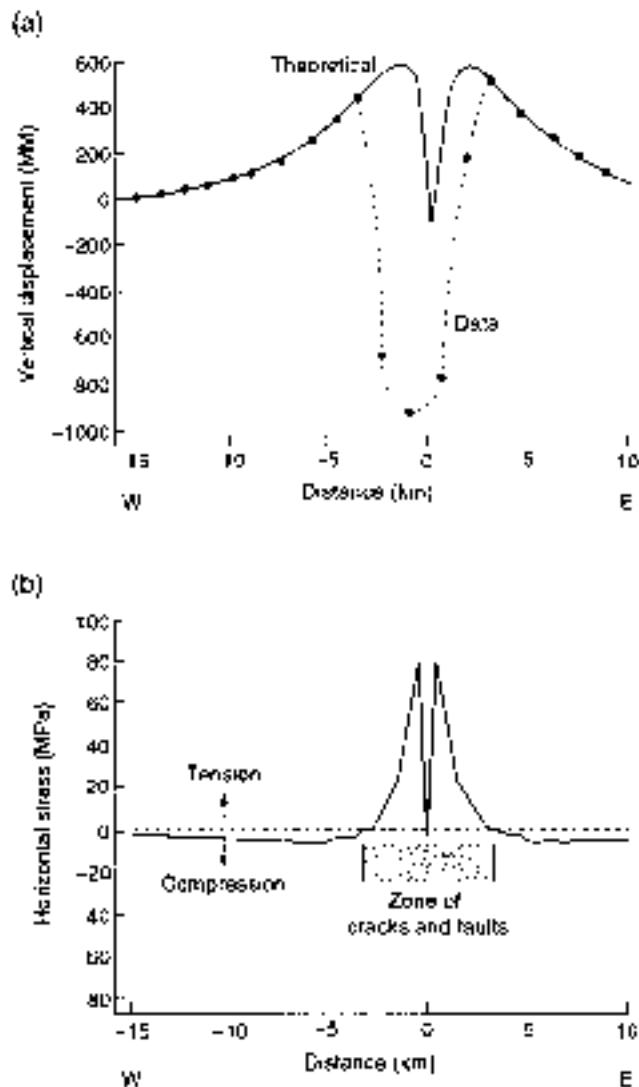

FIGURE 3 (A) Map and diagram of a deflation episode at Sakurajima volcano, Japan, measured between 1895 and June 1914, just after the voluminous eruption of that year. The map above is overlaid with contours of deformation at 100-mm intervals, interpolated between values of vertical displacement measured at benchmarks around the volcano. A benchmark distant from the volcano has been used as a zero reference. Below vertical displacement is plotted against distance from the volcano in Kilometers. The black dots show displacement at individual benchmarks, while the curves show the theoretical displacement expected from a buried pressure source according to Mogi's (1958) model. The center of deflation lies not at the volcano itself, but in the center of Kagoshima Bay, the adjacent caldera. The curve in (B) is for a pressure source at a 10-km depth.

curve depends upon the depth, height, and angle of dip of the dike.

Models so far derived have been two-dimensional, that is, they apply to a dike of infinite length and constant cross section, located at a constant distance from a plane surface in a semi-infinite homogeneous isotropic elastic medium. By contrast, a real dike is of finite length and has a varying cross section, and its path may be curved. Its depth may vary beneath an irregular topography and the material surrounding it will be a mixture of magmatic products. All of these factors will influence the displace-

**FIGURE 4** (a) Plot of vertical displacement against distance from a dike emplaced during a rifting event north of Krafla volcano, Iceland, on 7 January 1978. Data points closely follow the theoretical curve (solid line) for a vertical dike whose center lies at a 3-km depth, and whose height is 5.5 km. The fit is good apart from close to the dike itself, where tensional stress is calculated to be very high [see (b)]. (b) Calculated horizontal stress in MPa plotted against distance from the dike modeled in (a).

ment of a point on the surface as the dike inflates or deflates, and cause it to deviate from the theoretical curve. However, measurements of real dike-emplacement events like those at Krafla show that the observed displacements can be remarkably close to the simplified models, suggesting that these deviations are not too important in practice (Figure 4a).

Analysis of the measured vertical displacements associated with one of the intrusive events at Krafla (that of 7

January 1978) indicated that the intrusion was consistent with a vertical dike 5.5-km in height, whose center lay at a depth of 3 km. The measured values in Figure 4a depart from the theoretical curve only near the dike itself, where the theoretical horizontal stresses are tensile, and many faults and cracks were visible at the surface, indicating that in this zone, the ground was not behaving elastically, so would not be expected to conform to the model.

This kind of analysis can be used to build up a record of positions of injected dikes within a volcano which can aid in studies of subsurface structure and future eruption prediction.

#### C. Colima (1982–1997)

The loading, compaction, or gravitational distortion of the volcanic pile by recent volcanic products may cause subsidence of more than a meter per year in extreme cases at some volcanoes. In the case of Colima volcano, Mexico, subsidence of the entire volcano has dominated the deformation pattern at least since 1982 when the first ground deformation network was installed.

Colima has been in more or less continuous dome-building eruption for decades, yet despite this dome growth, deformation measurements have shown continuous subsidence roughly centered on the summit. Leveling stations 1 to 3 km distant from the summit have subsided nearly 1 cm per kilometer per year radially on average. Recent measurements between 1994 and 1997 show a greater subsidence of 2 cm per kilometer per year near the summit and 5 cm per kilometer per year at the edge of the dome (Figure 5). Subsidence continued even through the period of rapid dome extrusion and lava flows in 1991. It probably results from compaction and elastic/plastic deformation of the edifice, which is a steep-sided cone reaching to 3880 m.

#### D. Mount St. Helens (1980)

As a volcano builds up by the steady accumulation of lavas and pyroclastics, its slopes become progressively steeper, and there comes a time when it becomes an unstable structure. If eruptions continue, this instability may ultimately resolve itself in slope failure, where a large section of the volcanic edifice may peel off and slide downslope in a sector collapse. The most famous example of this kind of event was the Mount St. Helens eruption of 18 May 1980, where nearly 3 km<sup>3</sup> of the northern slopes of the volcano collapsed and slid off the volcano, taking the pressure off the magma beneath and

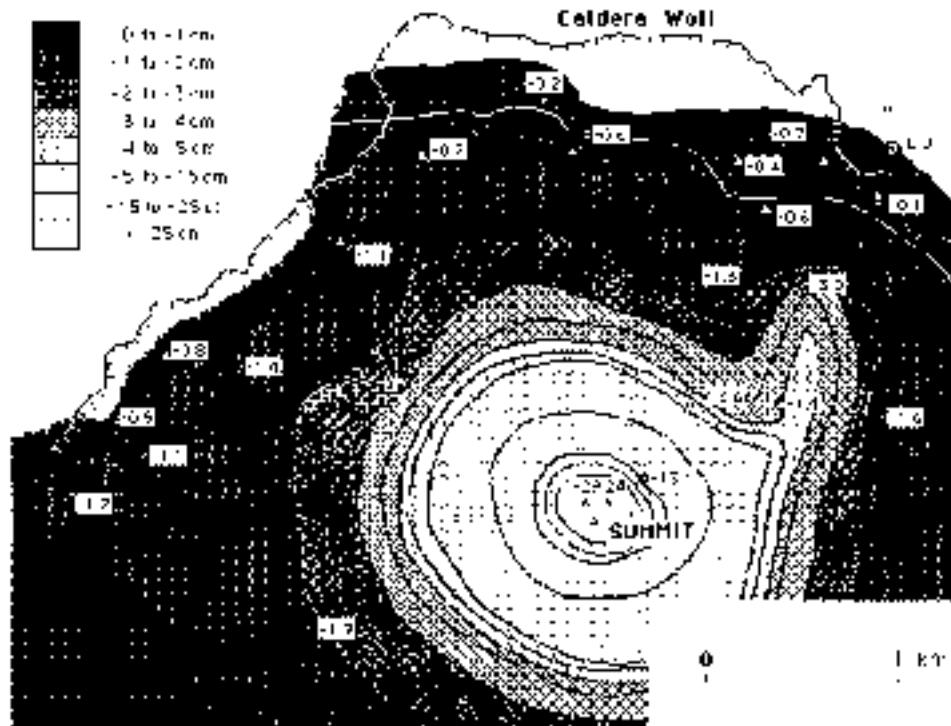

FIGURE 5 Subsidence concentric to the summit of Colima volcano, Mexico, measured between 1994 and 1997. The relation to the topography, and the continuous nature of the subsidence since 1982, suggests that compaction and downwarping due to loading of the volcano is responsible for most of this movement.

provoking a large pyroclastic eruption. A similar event occurred at Bezymianny volcano, Kamchatka, in 1956. At Bandai San volcano, Japan, in 1888, a large slope failure occurred without a concurrent pyroclastic eruption, probably because the volcano was inactive and no magma had been present near the surface.

Before such catastrophic events occur, slope creep and other precursory movements may take place on the unstable slope and may be capable of indicating both where and when failure will take place. The best monitored eruption of this type was that of Mount St. Helens in 1980.

Slope movements prior to the event were enormous—so great that they were first detected not by sensitive instruments but from air photographs, where the enormous changes were plainly visible. Air photographs had been taken the previous year, on 15 August 1979, and were taken again on 7 and 12 April 1980 and 1 and 12 May 1980.

Between each of these dates, there was subsidence close to the summit, and broad inflation about 1 km downslope on the northern flank. The amount of subsidence had totaled more than 70 m by May 12, the subsiding area forming an expanding trough or graben

on the north side of the summit aligned approximately east–west. This graben was 1.5 km long and grew from 360 m wide on April 7 to about 600 m wide on May 12. The inflation further down eventually raised some areas more than 150 m above the pre-eruption topography (Figure 6), forming a prominent bulge which became increasingly obvious down the northern flank. This bulge measured nearly 2 km in diameter, with a zone of maximum uplift that moved northward as time progressed.

Dry tilt stations were also set up and measured frequently during the crisis, and in some cases showed large short-term fluctuations in tilt, measured at up to 50  $\mu$ rad per hour on April 10th.

At the same time, distance measurements to reflectors installed at several points on the upper slopes of the mountain showed that stations on the bulge were moving north at a fairly constant rate of up to 2.5 m per day. Many reflectors were in fact moving in an almost horizontal direction or even slightly downhill, though the fact that this carried them north into regions well above the pre-eruption slope made them appear as inflated areas on the topographic difference maps.

Sector collapses and the associated pyroclastic flows

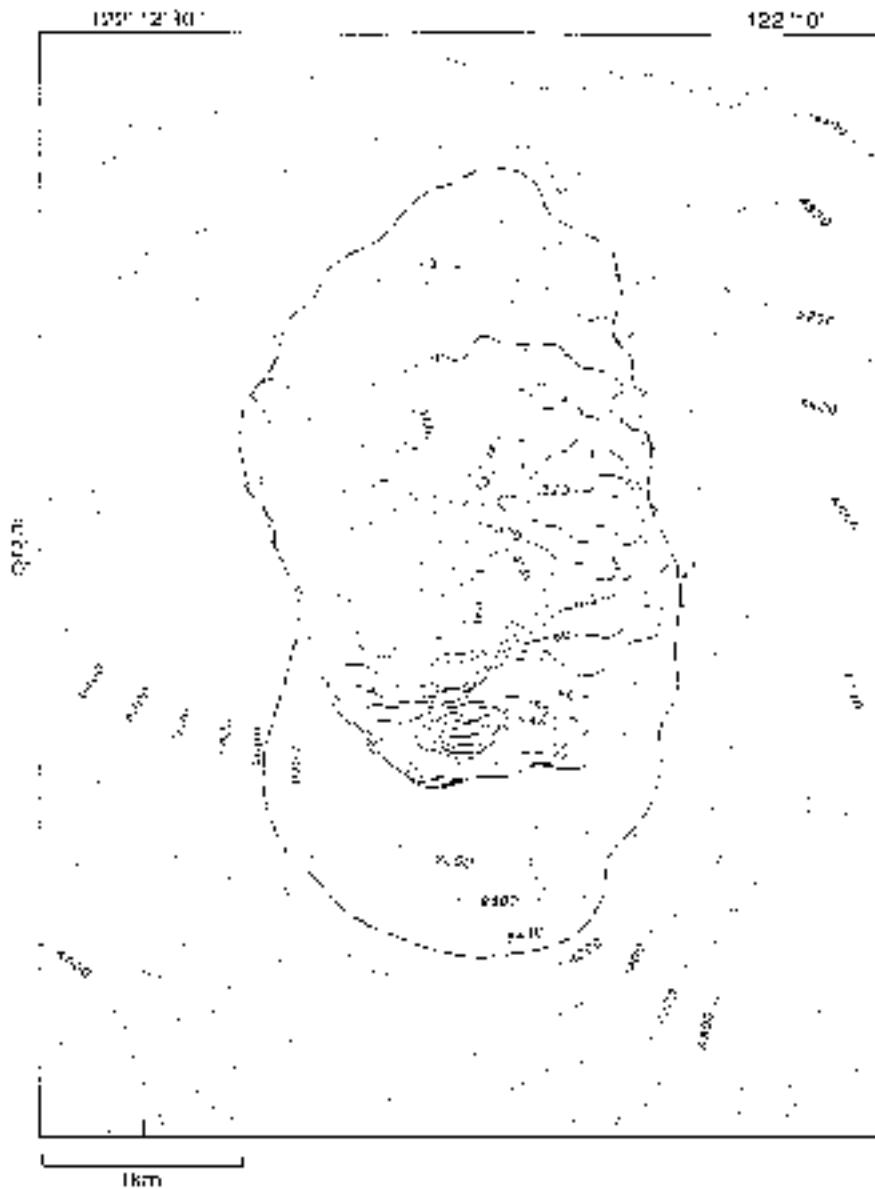

FIGURE 6 Map showing topography (dotted lines) and elevation changes in feet (solid lines) between 15 August 1979 and 12 May 1980 at Mount St. Helens volcano, USA, before the catastrophic slope failure and pyroclastic eruption of May 18. The bold dashed line shows the position of the crater rim that formed in the May 18th eruption.

that may accompany them are among the most potentially dangerous and destructive types of volcanic activity as they occur suddenly and progress very rapidly, and are capable of wiping out towns as far as 100 km distant from the volcano in some cases. The Mount St. Helens eruption of 18 May 1980 is the only example of sector collapse on a volcano where monitoring has been carried out both before and after the event, and as such contains important information to bear in mind when facing pos-

sible future sector collapses on other volcanoes. As far as deformation goes, it seems that the enormous rates of ground movement began only 8 weeks before the eruption, and continued at a fairly constant rate until the moment of eruption. This indicates a different behavior from slope creep observed before some types of slope failure, where a progressively increasing rate of deformation is observed, which can be used to predict the time of failure.

#### IV. PRINCIPLES OF GRAVITY MONITORING

The acceleration due to gravity at the Earth's surface is approximately  $9.8 \text{ ms}^{-2}$ . Gravity varies by  $7000 \mu\text{Gal}$  ( $7 \times 10^{-5} \text{ ms}^{-2}$ ) between mountains on the equator (where the Earth's radius is greatest) and sea level at the poles. Modern gravimeters can measure gravity differences (either between different places or at one place through time) to about 1 in  $10^8$ ; in other words, variations as small as  $0.00000001 \text{ ms}^{-2}$  can be detected. Such variations occur naturally over the face of the Earth due to lateral heterogeneities in the density structure. Thus buried dikes, feeder pipes, and even magma chambers can be identified by making a map of the variations in gravity, provided there is a density contrast between the subsurface structures of interest and the surrounding rock. Local variations in gravity occur due to contrasts in subsurface mass distribution and in elevation (gravity decreases vertically at roughly  $308 \mu\text{Gal m}^{-1} = 3 \times 10^{-6} \text{ ms}^{-2}$ ; this is called the free-air gradient).

The most common type of gravimeter used on volcanoes basically comprises a mass on a spring (Figure 7). A complex array of gears provides a very accurate measure of the force that needs to be applied (mechanically or electronically) to the mass to return the spring to its original length within the prevailing gravity field. Calibration of the instrument allows differences in the measured force (either between stations on a network or with time at one place) to be expressed in terms of gravity differences. Gravity measurements are usually made at ground level, although instruments have been

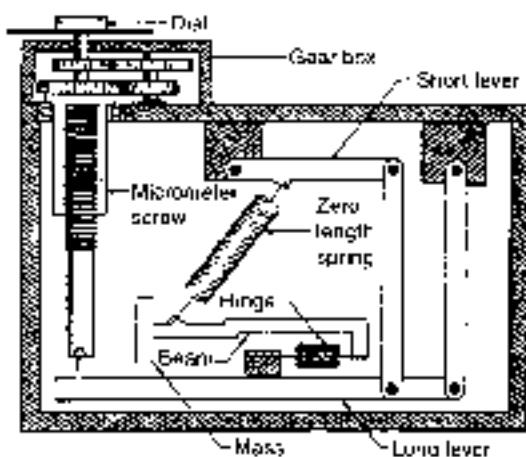

FIGURE 7 Basic operating mechanism of a LaCoste and Romberg gravimeter.

developed to operate on the seabed, from a ship, and on an airplane.

#### V. TECHNIQUES USED IN THE FIELD

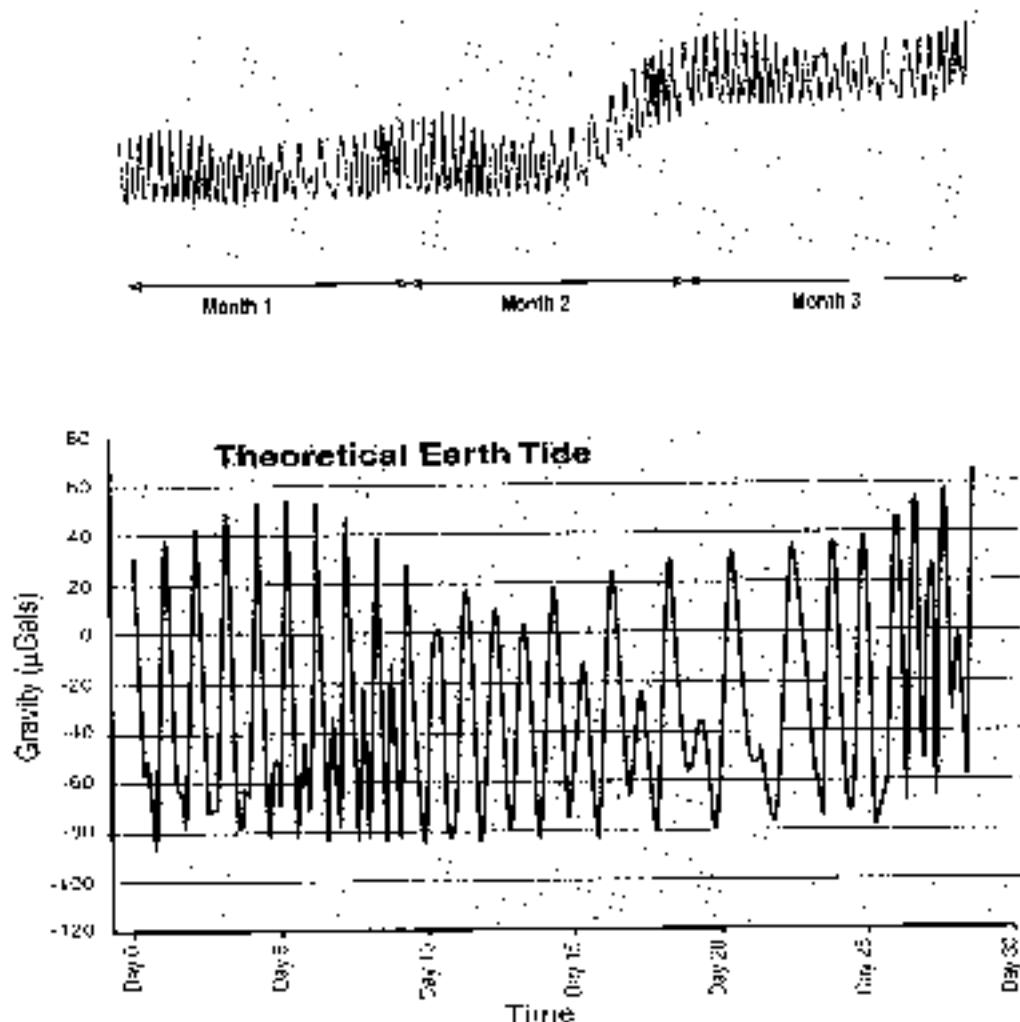

##### A. Earth Tides

The Earth tides are variations in gravity caused by the relative movement of the Sun and Moon. On large water masses, these bodies produce the familiar ocean and river tides. On land, the solid mass of the Earth also deforms in response to the varying gravity pull of the Sun and Moon.

For any point on the Earth's surface, Earth tides vary by up to  $400 \mu\text{Gal}$  peak to peak with a maximum rate of change of about  $60 \mu\text{Gal hour}^{-1}$  ( $1.8 \times 10^{-10} \text{ ms}^{-2}$ ). For any time, the Earth tides can be computed (Figure 8); any deviations from the tide, called residual gravity changes, are due to instrumental effects or external processes such as ground deformation and volcanic activity. It is usual to have a continuously operating GPS receiver adjacent to a tidal gravimeter so that the effects of elevation changes can be constantly monitored. A volcano tide, which would be a volcanically induced residual, is expected to be present if large subsurface volumes of magma are free to move.

This is a relatively new technique for monitoring volcanoes and there are only limited examples of its use. The potential is enormous though, once unwanted "noise" such as changing groundwater levels and the effect of tremor on the instrumentation have been removed. A gravimeter operating in a remote location (telemetering data to an observatory) can provide valuable information on subsurface processes without any risk to human operators.

There are two ways in which the Earth tides on a volcano can be analyzed usefully. The first is to record the tides and then to determine the "delta factor" or the amount by which the predicted tide needs to be multiplied to produce the observed tide. The amplification is needed because the tidal prediction calculations assume a solid Earth. The elasticity of the real Earth means that it responds to the tides differently from a solid spheroid. Variations through time of the delta factor preceding eruptive activity, for example, can then be interpreted in terms of changes in the elastic properties of the volcano. Another way of investigating the Earth tides is to subtract the observed tide from the computed tide and to study the residual tide. For this

**FIGURE 8** The top graph shows a sample of continuous gravity measurements at a hypothetical volcano over a 3-month period. The Earth tide signal dominates until the end of month 2, when a volcanic event causes a steep gravity increase. The theoretical Earth tide for month 2, such as might be measured at a reference station at the foot of the volcano, is shown beneath.

second approach, a delta factor is assumed, although changes in this factor through time may become apparent.

#### B. Microgravity

Microgravity monitoring involves the measurement of small changes in the value of gravity at a network of stations. Microgravity is becoming increasingly recognized as a valuable tool for mapping out the subsurface mass redistributions that are associated with volcanic activity. As for all types of gravity work, it is essential

for the unambiguous interpretation of the data that any changes in elevation are measured at the same time as the gravity measurements are made. Gravity values are tidally corrected (the effects of the computed Earth tides are removed) and then the data are usually expressed relative to the value of gravity at a base or reference station which is preferably outside the area of volcanic activity and interest. The network is then remeasured some weeks, months, or years later, or after some volcanic event has occurred. The tidally corrected gravity difference at each station relative to the base station must then be corrected for any elevation changes that have taken place. Any residual gravity changes are due to subsurface density changes.

### C. Absolute Gravity

The most common method for determining the absolute value of gravity in volcanoes involves measuring the rate of fall of a mass. A laser interferometer is used to track the vertical rise of a corner cube reflector propelled vertically upward and its subsequent fall. The instrumentation is expensive, very heavy, and only transportable by vehicle. It is also complex to use, taking a day or so for one value to be measured, and the technique is therefore not often used. However, the advantage of absolute gravity values is that, unlike relative gravity values, there is no dependence on reference to a base station that may or may not be stable. Earth tides, elevation, and even atmospheric pressure will influence the value of gravity determined; these effects must be removed before an absolute value is obtained.

The absolute value of gravity has been measured at the oldest volcano observatory in the world, at Vesuvius, Italy. The first measurement was made in 1986 and the second in 1994. The first value obtained was  $980,133,453 \pm 4 \mu\text{Gal}$ , and 8 years later the value was  $980,133,396 \pm 3 \mu\text{Gal}$ . This approximately  $60-\mu\text{Gal}$  gravity increase is consistent with the results of microgravity surveying in the area, which showed a similar increase relative to a reference station away from the volcano. Similar results on Etna and elsewhere have shown small changes, but to date there have only been two or three measurements made at each volcano.

---

## VI. CASE HISTORIES OF GRAVITY CHANGES

Microgravity surveys have been made at active volcanoes since the 1950s, but tidal gravity, with its requirements of continuous power, accurate time keeping, and large volumes of data output, has only been a realistic option for volcano monitoring since the mid-1990s. Absolute gravity is still too cumbersome and expensive to use regularly at volcanoes.

### A. Microgravity at Calderas: Campi Flegrei (1969–1984)

The typical compositions of eruptive products at a volcano provide a basis for classification of the nature of precursory microgravity changes. Large silicic

calderas, where long-term unrest is common and devastating eruptions occur infrequently, are characterized by periods of inflation and deflation with residual gravity changes indicating subsurface mass increases (Figure 9). Gravity changes differing from those predicted from the elevation changes have been interpreted in terms of magma movements and hydrothermal fluid migration. Observed elevation changes have been large at these calderas (ca. 1 m) and the gravity data fall close to, but not always on, the free-air gradient.

In the center of Campi Flegrei caldera, the ruins of an ancient Roman market (Serapeo; see Figure 10) bear witness to long-term caldera unrest. Mollusk borings in the stone columns indicate earlier periods below sea level and recent measurements indicate that during two crisis periods (1969–1972 and 1982–1984), uplift of some 3.3 m occurred. During uplift, gravity at Serapeo decreased less than predicted by the free-air gradient, suggesting a subsurface mass increase. Inflation and gravity increases were seen over a large area and were thought to be caused by a magmatic intrusion of around  $2 \times 10^{11} \text{ kg}$  at some 3 km of depth. Slower deflation continued until 1990. Similar observations (though with a mass increase of only  $10^{10} \text{ kg}$ ) at Rabaul caldera in Papua New Guinea preceded an explosive eruption by about 10 years.

### B. Microgravity at Andesitic Volcanoes: Poas Volcano (1985–1989)

The explosive nature of many andesitic eruptions and the possibility of risk mitigation make this category of volcanoes the most important to monitor effectively in the short to medium term. These volcanoes are intermittently active and tend to have rather complex edifice structures with several craters. The intrusion of magma into poorly consolidated material and even the buildup of magmatic gas pressure are sometimes detectable because these processes can occur close to the surface and the density contrasts are large.

A characteristic of andesitic volcanoes is that the gravity–height change data tend to plot close to the  $\Delta g$  axis of Figure 9 (the height changes are usually rather small). One of the longest time series of microgravity data for a volcano is from Poas in Costa Rica. A network of stations in and around the active crater revealed increases and decreases in gravity associated with phreatic eruptions and the gradual disappearance and final re-establishment of the crater lake (Figure 11). Increases at

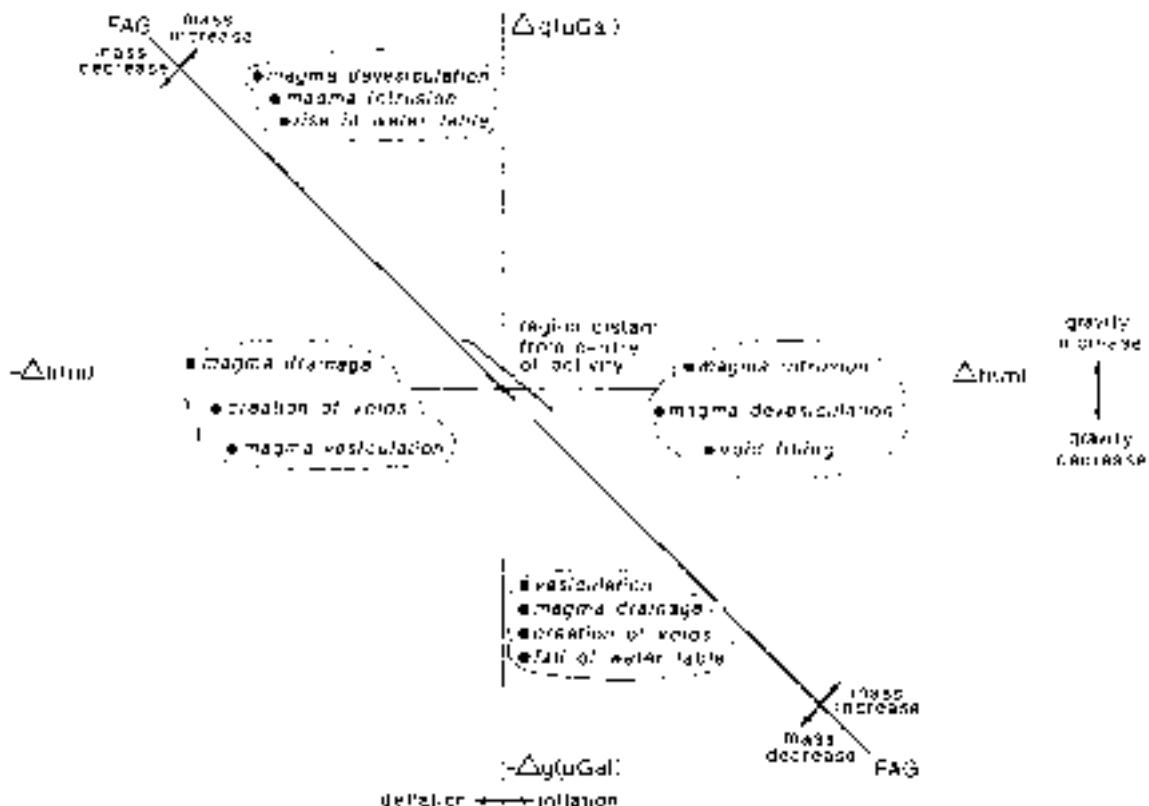

FIGURE 9 Graph of height changes (horizontal axis) against gravity changes (vertical axis). Measured gravity and elevation changes may be plotted on this graph and the interpretations read off. The diagonal line is the free-air gradient (FAG) at  $-308 \mu\text{Gal m}^{-1}$ . Data plotted above this line on the right-hand side (positive  $\Delta h$ , i.e., inflation) represent net gravity increases and therefore subsurface mass increases which, on volcanoes, are most likely caused by magma intrusion, magma devesiculation, and void filling. Data falling in other regions of the graph have correspondingly different interpretations as marked.

FIGURE 10 The ruins of the market of Serapeo at the center of Campi Flegrei caldera (Naples, Italy) provide a classic example of long-term caldera unrest. When built in ancient Roman times, the market must have been above sea level, yet by 1834 (left) it had sunk below sea level, and the mollusk borings more than a meter up the columns indicate lengthy periods even further below sea level prior to this. However, recent surveying measurements show that the region rose by 3.3 m between 1969 and 1984, raising the whole market well above sea level again by 1991 (right).

**FIGURE 11** Summit crater of Poas volcano, Costa Rica, in 1994. The photo shows the crater rim with the crater bottom some 200 m below. Behind the ridge in the center is the hot, acidic lake that disappeared between 1989 and 1997. By 1998 it had overfilled to such an extent that it was beginning to flood the main crater floor.

stations in the southern part of the crater bottom began in 1985, preceding the phreatic activity and loss of the lake by 4 years (Figure 12). By integrating the magnitude of the residual gravity changes over the area of their extent, the subsurface mass increase can be deduced:  $10^8$  kg of new mass appeared beneath the crater between 1985 and 1989. This new mass may have been a magmatic intrusion, deposition of sulfur, the redistribution of the hydrothermal system, or some combination of these.

### C. Microgravity at Basaltic Volcanoes: Mount Etna (1990–1993)

The hazard to human life and property at these volcanoes is smaller, but comprehensive surveillance program have been carried out at the more active ones such as Kilauea on the island of Hawaii and Etna on Sicily. An important characteristic of these volcanoes that influences the observed microgravity changes is their ten-

dency to develop flanking rift systems. Magma may be intruded passively into dikes and can feed flank eruptions exploiting these rifts. Thus very large mass changes can occur without elevation changes (data plot near the  $\Delta h$  axis on Figure 9), but large elevation changes can also occur (during rifting events, for example) and then gravity data fall close to the free-air gradient. Separate deflation events on Kilauea had gradients between  $-171$  and  $-607 \mu\text{Gal m}^{-1}$ , thought to indicate magma migration away from the rift zone leaving voids, and then later passive intrusion into these void spaces.

Microgravity increases as large as  $400 \mu\text{Gal}$  were found between June 1990 and June 1991 at a network of stations near the summit of Etna volcano, Sicily (Figure 13). There was no eruptive activity at this time, and the ground deformation was less than a few centimeters, the microgravity increases were therefore caused by subsurface mass changes. A model for the gravity increases (Figure 14) shows the change in the shallow plumbing system at this time. The level of magma within the summit feeder pipe (modeled with a radius of 25 m)

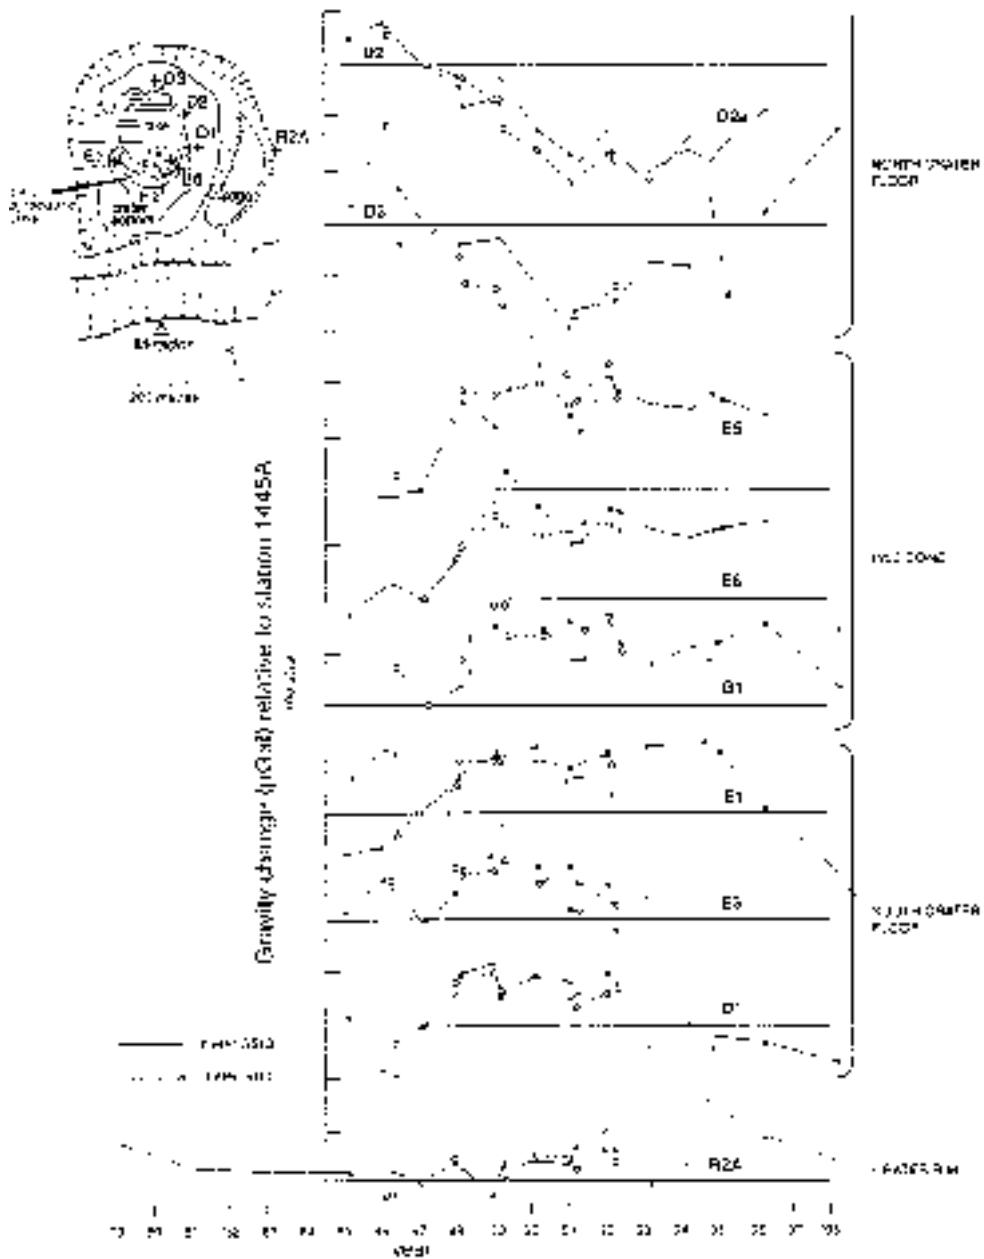

FIGURE 12. Microgravity changes at stations in and around the active crater at Poas between 1979 and 1998. Geyser activity began at the lake in 1987–1978 and the lake disappeared in 1989. It was reestablished in 1997.

rose at some time between the two sets of observations and a dike was apparently intruded in a south-southeastly direction trending away from the summit. The point at which this modeled dike intersects the topography is the site of the vent for the December 1991–April 1993 eruption. In this case it would appear that the gravity increases indicated rising magma which later fed a large eruption.

## VII. PRINCIPLES OF MAGNETIC MONITORING

A total magnetic field map can be drawn using data from a network of stations either near the ground surface or from an airplane or helicopter. Variations through time

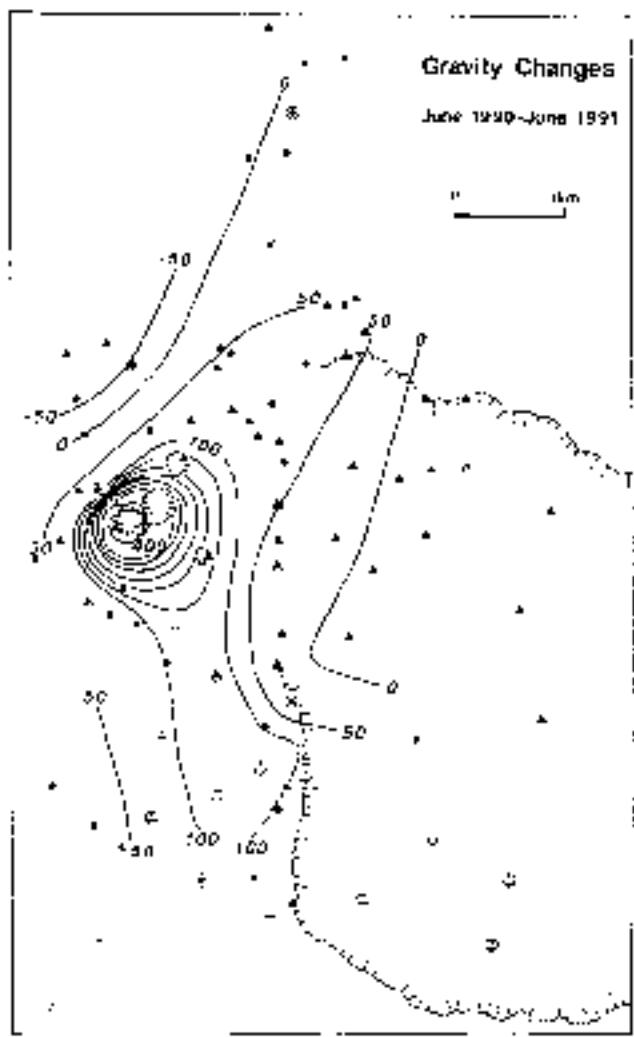

FIGURE 13 Map of microgravity increases at Etna volcano measured between June 1990 and June 1991. The largest increases are close to the summit craters and reflect an increase in magma level within the feeder system. Gravity increases were also seen in an elongated south-southeasterly trending region close to fractures which opened up at the end of an eruption in 1989. This was probably caused by the intrusion of a dike.

may also be monitored using a stationary continuously recording magnetometer or by repeating measurements at a network of stations, if stations can be precisely relocated.

Magnetic monitoring of volcanoes is relatively underdeveloped compared with ground deformation and microgravity monitoring. Magnetic changes associated with volcanic activity have been successfully observed, some of which were precursory to eruption and hence identify the potential of magnetic monitoring methods.

However, magnetic effects are generally more complex and difficult to interpret than gravity or deformation data.

The magnetic field at the surface of the Earth ranges in intensity from approximately 25,000–70,000 nT, depending mainly on latitude. About 99% of this field is generated by circulation in the Earth's partially molten outer core, with minor contributions from the magnetic effect of near-surface rocks themselves and external sources such as the ionosphere.

There are two main types of rock magnetism; remanent magnetism and induced magnetism, both of which depend on the occurrence of magnetic or magnetizable minerals in the rock. Remanent magnetization, the essentially permanent magnetization in rocks, is acquired at the time of either rock formation or a subsequent crystallization event. Induced magnetization is a temporary magnetization generated in rocks by the present-day ambient magnetic field of the Earth. Rock magnetism only occurs at temperatures below the Curie point (ca. 550°C).

The intensity of magnetization in a rock depends largely on the abundance of magnetite in the rock. Since most volcanic rocks commonly contain magnetite they are often strongly magnetized, enough to divert a compass needle in some cases, and hence the unreliability of the compass as a navigational tool in volcanic areas. The intensity of magnetization in more basic rocks (e.g., basalt) is in general stronger than that in less basic rocks (e.g., andesite). Surveys of the spatial distribution of magnetic effects of volcanic rocks can be used to generate models of structures within volcanoes or to determine the depth and volume of lava flows. In magnetic monitoring of active volcanoes, measurements of the magnetic field are repeated, either continuously or intermittently, at the same location over a period of time in order to detect changes in the magnetization of the subsurface rocks.

"Volcano-magnetic" effects are caused by a number of mechanisms, the most important being thermal demagnetization or remagnetization, and piezomagnetic effects. Thermal demagnetization occurs as the rock heats through its Curie temperature. The effect is reversible, and remagnetization occurs when the rock cools again. Piezomagnetic effects are magnetic changes due to changes in stress regime such as magma intrusion or depressurization, which are generally irreversible. Other possible mechanisms for volcano-magnetic effects include (1) chemical changes to magnetic minerals, for example, alteration by hydrothermal activity, (2) mass redistribution such as intrusion or major landslides, or (3) electrokinetic effects due to fluid flow in the rocks.

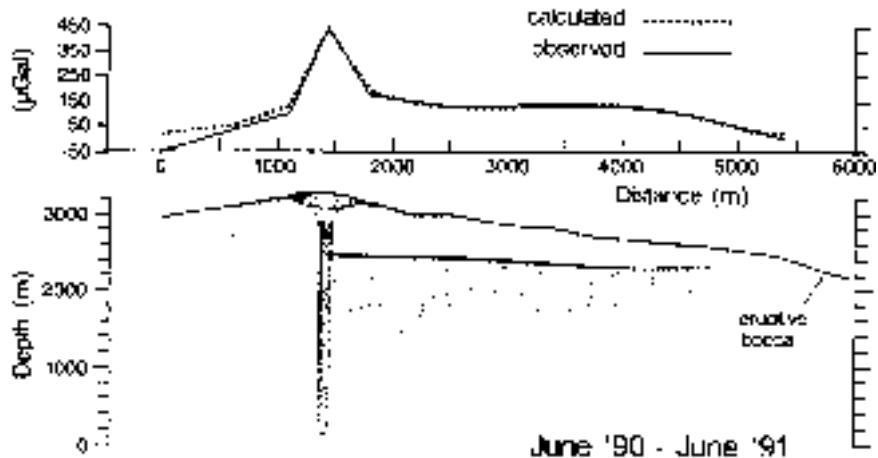

FIGURE 14 Model of the subsurface magma movements thought to have caused the microgravity changes seen in Figure 13. The south-southeasterly trending dike is only 4 m wide, but the summit feeder pipe is 25 m in radius, which accounts for its larger gravitational effect.

#### VIII. TECHNIQUES USED IN THE FIELD

The intensity of the total magnetic field only is generally measured, though it is possible to measure its constituent parts (e.g., horizontal and vertical components); however, this requires precisely leveled instruments which can be difficult to maintain in areas undergoing significant ground deformation. Instruments used are either proton precession magnetometers (accurate to 0.1 nT) or cesium/rubidium vapor magnetometers (accurate to 0.01 nT). Measurements must be corrected for secular variations (i.e., changes with time) in the Earth's magnetic field itself, which is achieved by monitoring magnetic field changes at a base station outside the region influenced by the volcano. Each site on the volcano may respond differently to these ambient field changes but this can be calculated mathematically and subtracted from the observed data.

#### IX. CASE HISTORIES OF MAGNETIC OBSERVATIONS

Most commonly, magnetometers are set up at a site on a volcano and left to record "continuously" (i.e., measurements are recorded every 1–10 minutes). If these data are telemetered to an observatory and the system is powered by solar cells, the site need only be

visited for maintenance. Other continuously measuring devices may be battery powered or the data may be recorded on site, in which case they need to be serviced more often, which can be logistically demanding in difficult terrain. Alternatively, measurements may be repeated intermittently (e.g., every few days or weeks) at monumented sites using a portable magnetometer (Figure 15). In this case it is essential that the magnetometer be relocated in precisely the same position (horizontally and vertically) for each measurement. In some studies, combinations of both continuous and intermittent sites have been used.

FIGURE 15 Portable proton precession magnetometer in use on the south flank of Mount Etna, Sicily. Precise centering over a permanent marker is essential where repeat measurements of a network are to be made.

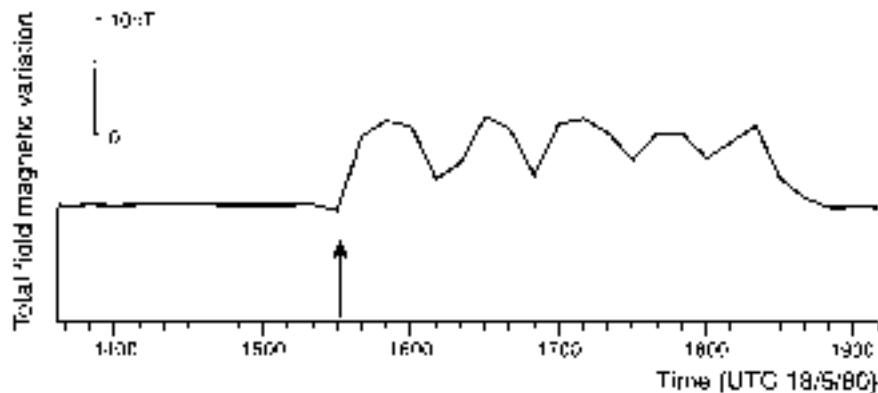

FIGURE 16 Variations in total magnetic field recorded at a site on the west of Mount St. Helens volcano before and after the catastrophic eruption of 1980 May 18 at 0832 PDT (1532 UTC). Time of eruption denoted by arrow.

#### A. Mount St. Helens Volcano (USA, 1980)

Magnetic changes were observed on the west side of the edifice of Mount St. Helens volcano at the times of the three major eruptions on May 18, May 25, and June 12, 1980. No magnetic changes were observed immediately before the catastrophic May 18 eruption (Figure 16); this is consistent with the triggering of the eruption by a sudden depressurization of the magma by a landslide. The increase of  $9 \pm 2$  nT occurring during the 12 hours following the May 18 eruption has been interpreted as a piezomagnetic effect resulting from the release of stress during the eruption. Since the net magnetic change is permanent, electrokinetic and thermal demagnetization mechanisms cannot have played a major role, and also the magnetic effects are in the opposite sense than could be attributed to the accompanying mass redistribution. This interpretation has been endorsed by mathematical models which show that a magnetic change with the same amplitude and sense would be generated by a pressure release of  $\sim 100$  MPa in a cylindrical or spherical magma chamber  $\sim 1$  km in diameter at a depth of  $\sim 5$  km. There was some indication of magnetic disturbances for several hours before the May 25 (Figure 17) and June 12 events, and even greater effects were recorded after these eruptions. These post-eruption changes are considered to reflect the effect of eruptive shockwave events on the ionosphere and were also recorded at least 1000 km away from the mountain.

#### B. White Island (New Zealand, 1974)

Magnetic measurements have been made at White Island in surveys repeated at approximately 4-month in-

ervals since 1968. Localized changes of up to 400 nT were measured within the crater between 1976 and 1982; both increases and decreases were observed during this time. Increases occur after eruption sequences and indicate cooling, while decreases are associated with eruptions and result from heating of the rocks at depths of 500–1000 m. For example, the magnetic changes observed between February and August 1974 (Figure 18) were interpreted as resulting from localized heating below Donald Mound. This was confirmed by the opening of a vigorous fumarole in that vicinity in September 1974. Modeling has shown that variations of 200–300°C

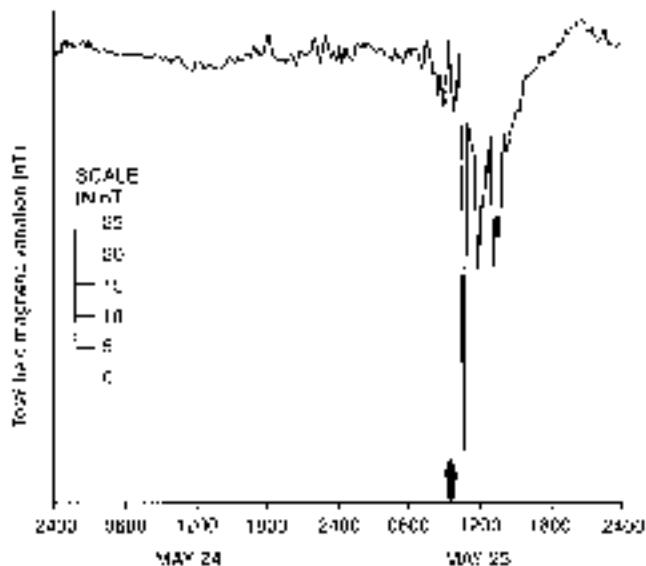

FIGURE 17 Variations in total magnetic field recorded at a site on the west side of Mount St. Helens before and after the eruption on May 25. Time of eruption denoted by arrow.

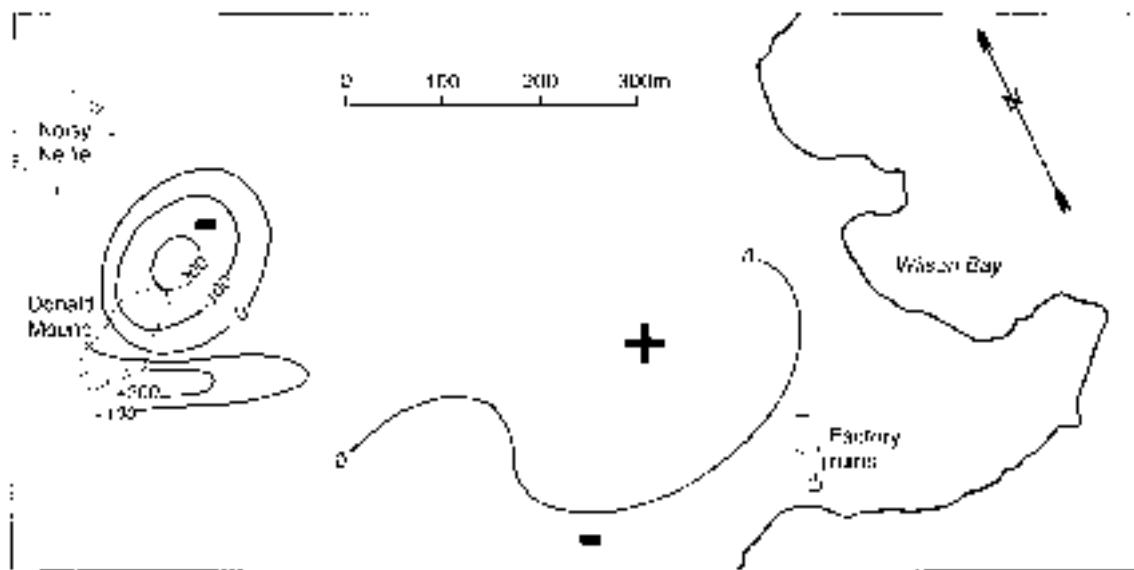

FIGURE 18 Map of the total field magnetic changes within the crater of White Island volcano between February and August 1974. Contour interval is 100 nT.

are required to account for the observed field changes. The rapid occurrence of these changes indicates convective (rather than conductive) transport mechanisms to be active in this case, such as the movement of hot gases or the ingress of cold rainwater.

### C. Aso Volcano (Japan, 1989–1990)

Increases and decreases in the magnetic field during an eruption sequence, recorded near the active crater in

1989–1990, occurred in five stages (Figure 19), each of a few months duration. These stages correlate with specific volcanic events and the occurrence of seismic tremor, and have been explained in terms of thermal magnetization (stages 1, 3, and 5) and demagnetization. Magnetic field decreases resulting from thermal demagnetization occurred when the system was heated because either the vent was plugged (stage 4) or the volcanic activity was enhanced (stage 2). Magnetic field increases followed either the opening of a vent (stage 1) or large explosions which made the vent more permeable (stage

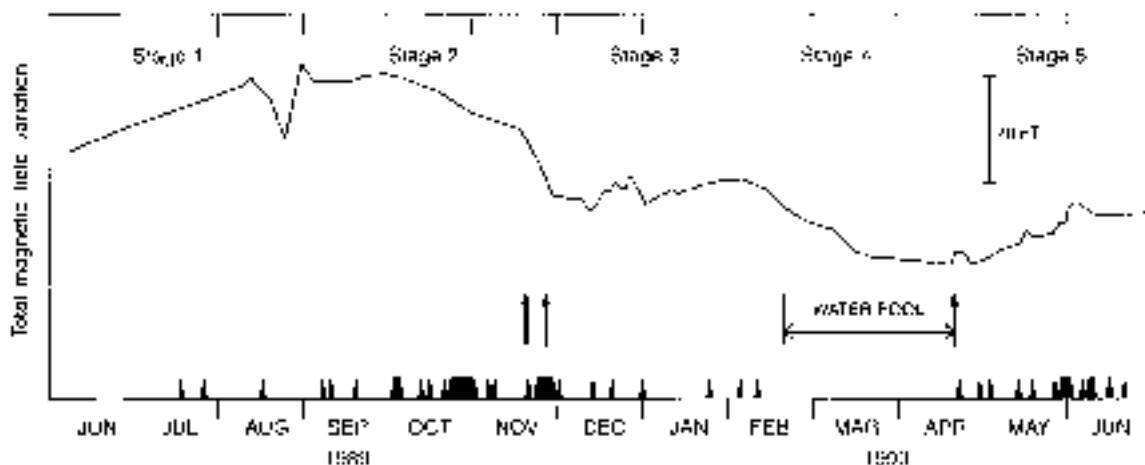

FIGURE 19 Variations in total magnetic field at Aso volcano together with details of eruptive activity. Vertical arrows indicate explosions, and black triangles show occurrence of eruptions. A pool of water formed within the crater in spring 1990.

5), thereby cooling the system. These magnetic changes have been modeled as originating in rocks at a 200-m depth at the vapor–fluid boundary. The vapor pressure is determined by the permeability of the vent cap and the heat supply from magma at depth. This vapor–fluid boundary therefore moves in response to vapor pressure, expanding or contracting the demagnetized zone and causing the magnetic changes observed at the surface.

---

#### X. CONCLUDING REMARKS

Ground deformation has long been used as a tool for monitoring and predicting volcanic activity. By combining the method with gravity and magnetic potential field techniques, it becomes a more powerful and rigorous indicator of subsurface processes. Each technique alone can produce results which are misleading or ambiguous, but by integrating data sets, many of the ambiguities are resolved. Not all volcanoes lend themselves equally well to each monitoring technique. Nevertheless, measurable changes in the physical properties of shallow subsurface structures beneath volcanoes ranging from young basaltic cones to andesitic stratocones to silicic calderas have been observed before, during, and after magma movement or eruption.

The cost of regular visits to a volcano to make routine measurements and the hazard to human life are such that there is an understandable drive to develop reliable, automated instrumentation with a telemetering capacity to send data in real time or at discrete intervals. SAR interferometry is clearly going to become a valuable ground deformation early warning tool once software for image processing is easily accessible to volcanologists. However, the fact that deformation can only be observed in the satellite vector means that this technique is unlikely to replace ground survey measurements. Of these, dual-frequency GPS is the most promising technique. With continuously recording GPS combined with remotely operating gravimeter and magnetometer stations, the temporal coverage of data is going to im-

prove dramatically, although the spatial coverage will never be as good using a few continuously recording instruments as it is with a large network of stations. However, by careful choice of station location (close enough to the activity to measure significant changes and far enough away to avoid direct damage and continuous disturbance) a compromise can be reached whereby virtual real-time data can be obtained at little or no risk to human life. Alternatively, if costs come down in the future it may be possible to deploy much larger numbers and denser arrays of continuously recording instruments, which, if data are telemetered to a remote operations center, would constitute an ideal surveillance system.

## GLOSSARY

- COSPEC** A ground-based, remote sensing, ultraviolet correlation spectrometer which measures the flux of sulfur dioxide gas from volcanoes.
- crystal fragments** Pieces of crystals which precipitated in magma prior to eruption.
- emissivity** The ratio of the radiant flux emitted by a body to that of a perfect emitter ("blackbody") at the same kinetic temperature.
- FTIR** Fourier transform infrared spectrometer, a ground-based, remote sensing infrared instrument which measures concentrations of various gases from volcanoes.
- fumarole** A crack or fissure through which volcanic gas is emitted.
- glass shards** Small fragments of quenched magma.
- lithic fragments** Pieces of the preexisting volcano which are incorporated and ejected during an eruption.
- magmatic-hydrothermal system** The plumbing system of a volcano within which a magma body is surrounded by an envelope of water derived from shallow levels.
- pumice** A low-density, bubble-rich material consisting

mainly of natural glass; it is a quenched sample of magma erupted explosively.

**remote sensing** The detection of a body's properties from a distance.

**spatial resolution** The ability of a remote sensor system to discriminate points or objects.

**thermal infrared** Part of the electromagnetic spectrum where a blackbody at room temperature (300 K) predominantly radiates. The thermal infrared region is usually defined between 3 and 1  $\mu\text{m}$ .

**TOMS** Total ozone mapping spectrometer, a space-based, remote sensing, ultraviolet spectrometer which measures sulfur dioxide erupted by volcanoes into the stratosphere.

**A**CTIVE VOLCANOES DURING an eruption or between eruptions exhibit various signs reflecting their current activity, including degassing and thermal anomalies. Because of the high temporal and spatial variability of volcanic phenomena volcanoes need to be regularly monitored to better understand the dynamics of each volcano. Thirty years ago, volcanologists focused their efforts on qualitative field observations of volcanic phenomena. In the past 25 years, there has been an explosion of research on volcano dynamics. This includes the development of modeling, laboratory experiments, advances in technology, and a better understanding of theoretical principles concerning physical and chemical volcanology.

Gas measurements and thermal monitoring are research fields which have developed rapidly during this time, with data acquired at the ground, from the air, and from space with various instruments. This article describes the available measurement methods, data, and scientific objectives presently being pursued. It concludes with a view of the next scientific steps needed to advance the knowledge of eruption dynamics and to make accurate forecasts of volcanic activity.

As datasets grow in size and complexity, it becomes a formidable challenge to better integrate and quantitatively interpret the information so that new technologies will have their full impact on providing clues for volcanic modeling. Some new approaches concerning the dependence of the data on their scale or resolution of observation and acquisition are also discussed.

---

## I. GAS MEASUREMENTS AND MONITORING

### A. Principles

Volcanologists have long recognized that volatiles are an essential component in volcanic systems. Since volatiles play an important role, their behavior can be examined to provide a better understanding of volcanic activity. Volatiles escape from magma bodies through fumaroles and hot springs, which are often located on a volcano's flanks. Thus, studies of volcanic gas can furnish important insights on the sources of magmas, how magmas move upward to the surface, the influence of hydrothermal systems, and the types of eruptions—for example, explosive vs. effusive—that are observed. The amount of gas dissolved in a magma determines, in large part, whether an eruption will be violent or not. Armed with this information, our ability to forecast future activity is improved. Studies of volcanic gases provide important information not only for the behavior of magma before an eruption, but also when and why a volcano erupts.

Despite the utility of gas information, such studies traditionally have been neglected in favor of geophysical investigations such as seismic and deformation monitoring. There are several reasons. The access to high-temperature fumarolic discharges in an active crater is often difficult and hazardous, and the sampling and subsequent analysis of the gases require considerable skill. Compared to seismic information which is collected on a continual basis at a site which is remote from the active crater, direct sampling of gas normally is done on a

sporadic basis, with intervals of weeks, months, or even years between samples. Until recently, we have had a poor theoretical understanding of how multicomponent gases behave in high-temperature environments such as volcanoes. Compared to experimental studies which examine only one or two individual gas species, the study of volcanic gas is complicated because it is a mix of many different major, minor, and trace gases.

Since the last 30 years, these limitations are being overcome for four principal reasons. First, volcanologists have begun to apply remote sensing techniques to measuring gas. These measurements have facilitated the sampling of the gas, since a scientist can make measurements at a distance from the crater on a semicontinual basis. Furthermore, a number of different gas species are now being studied by remote sensing. Second, advances in technology are beginning to permit semipermanent installation of gas sensors in craters, allowing around-the-clock monitoring. Third, the use of stable isotopes has helped define the origin and transport of gases. Fourth, our understanding of volcanic gas thermodynamics has been greatly improved in the last 15 years. Much of this progress can be ascribed to the work of Werner Giggenbach of the Institute of Geological and Nuclear Sciences in New Zealand.

Equipped with direct sampling of crater gas, remote sensing measurements, and theoretical understanding, we can begin to understand the behavior of volcanic systems through the study of gases. As importantly, we can start to see the local effects of volcanic gas upon the surrounding terrestrial and aquatic environments, namely health effects upon people, livestock, agriculture, soils, and forests. Lastly, the information is essential for understanding regional and global effects of volcanic gas upon our atmosphere and climate.

### B. Direct Measurements of Volcanic Gases

#### 1. *High-Temperature Fumarolic Discharges from Active Craters*

The spectacular emanations of gas that are seen in the craters of active volcanoes are visible manifestations of the presence of magma at depth beneath the crater. However, gas observed escaping at the surface is not derived solely from the magma. Rather, the gas is a mixture from different sources that have interacted during the lifetime of the volcano. A certain percentage of the gas is derived from magma, which will be initially rich in components such as sulfur and carbon dioxide ( $\text{CO}_2$ ). Since these gases have comparatively low solubil-

ties in magma, they are progressively lost during degassing, while more soluble gases such as water ( $H_2O$ ) and hydrochloric acid (HCl) are retained. Indeed, water is the most abundant volatile component in magmas and therefore will constitute most of the gas that escapes at the fumaroles. This magmatic water, as well as the other gas components, is mixed with surface waters that infiltrate the volcano's permeable structure and contribute to the gas discharge at the surface. As these surface waters are added, the magmatic gas is diluted, increasing the water content to an even greater extent. Certain types of hydrothermal systems are created by the interaction of acidic magmatic gases (e.g.,  $SO_2$ , HCl) with surface waters and with rock. These hydrothermal reactions can provide a source of gases such as  $CO_2$  and hydrogen sulfide ( $H_2S$ ). A component of the gas mixture may be added at deeper levels (e.g., chloride, boron) as a result of the subduction of tectonic plates, which transports and/or liberates volatiles. In a marine setting, there may be a direct or indirect addition of seawater, which enriches the chloride concentration of the gas.

To sample high-temperature gas, a volcanologist seeks out the hottest fumaroles which are most representative of magmatic gas compositions. These fumaroles are visited and sampled on a periodic basis over weeks, months, or years, depending on the activity of the volcano and the ease of access. If a volcano is erupting frequently, there will likely be a large gap in the data! Typically, the volcanologist first measures the tempera-

ture of a fumarole with a thermocouple, and then inserts a titanium or quartz glass tube into the fumarole. Once the gas is flowing through the tube, it is connected to an evacuated cylindrical bottle partly filled with concentrated sodium hydroxide (NaOH) solution (Figure 1). The NaOH solution absorbs acid gases such as  $CO_2$ ,  $SO_2$ , and HCl by neutralization reactions, for example,  $NaOH + HCl = H_2O + NaCl$ . Other gases which do not react with NaOH (e.g., hydrogen, helium, carbon monoxide) are collected in the evacuated headspace of the bottle. These bottles are informally called "Giggenbach bottles" by volcanologists after Werner Giggenbach, who first developed the technique in the 1970s. In addition to this gas sample, the hot gas is rapidly cooled in a condenser placed in an ice bath. This "condensate" provides a quenched liquid sample of the gas which is analyzed for various elements and isotopes.

Gas data which are collected over a period of time can provide important information concerning the activity of a volcano. First, it is possible to follow the declining magmatic influence as activity wanes. Second, changes in permeability and pressure within a volcano can be interpreted using gas data. Below we present several examples of these two types of activity.

Certain volcanoes go through long periods of quiescence and comparatively short periods of activity (e.g., Mount St. Helens, Washington State, USA; Mount Pinatubo, Philippines). Normally the activity is the result of magma being emplaced at shallow levels in the

FIGURE 1 Sampling of volcanic gases from a fumarole at Galeras volcano, Colombia. A titanium tube has been inserted into the fumarole. The tube is connected to an evacuated gas sampling bottle by using heat resistant plastic tubing. The gas flows through this system to the bottle, where it is trapped by the alkaline solution or in the headspace. (Photo courtesy of Eric Fontaine.)

crust. When this occurs, the volcano reactivates, accompanied by vigorous degassing. At this stage of activity, the magma is comparatively gas-rich. If the magma continues to degas without new injections from below, gases such as  $\text{CO}_2$  and  $\text{SO}_2$  decline in concentration. At the same time, surface waters infiltrate progressively into the system. Figures 2a and 2b show changes in  $\text{H}_2\text{O}$  and  $\text{CO}_2$  for crater fumaroles at Mount St. Helens during 1980–1981. In its initial stages during 1980, the levels of

$\text{CO}_2$  in the gas were comparatively high. With continued degassing,  $\text{CO}_2$  was lost and the gas was enriched in water. Similar trends are observed for the Showa-Shinzan lava dome at Usu volcano, Japan. The dome was emplaced during the 1940s and degassed thereafter. This can be seen from Figures 2c and 2d, which show significant declines in carbon and sulfur in the 1950s and 1960s as the system became water-dominated. During this time, the carbon/sulfur ratio declined (Figure

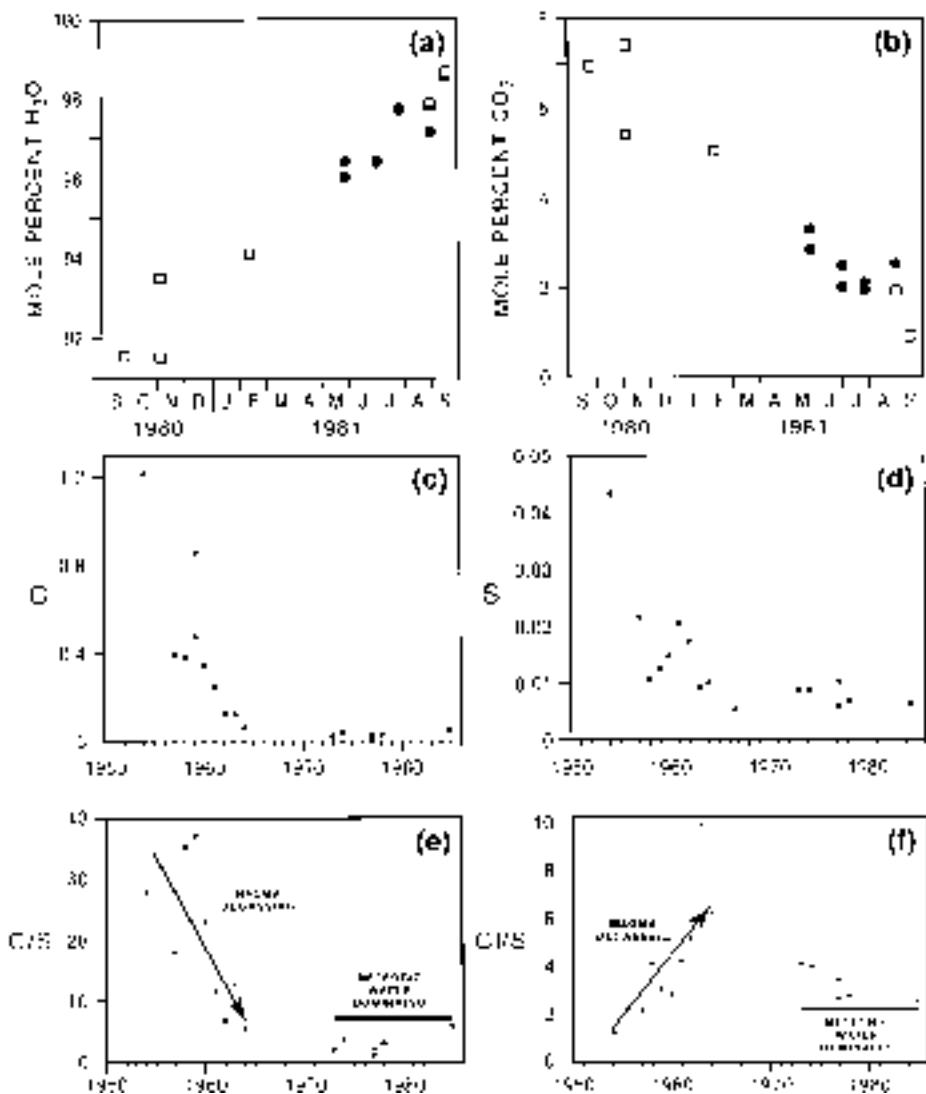

FIGURE 2 (a)  $\text{H}_2\text{O}$  concentrations and (b)  $\text{CO}_2$  concentrations in gas from crater fumaroles, Mt. St. Helens, 1980–1981. Res.* **73**, 177–211. Copyright 1996, with permission from Elsevier Science.)

2e), since CO<sub>2</sub> is less soluble than SO<sub>2</sub> in magma. Conversely, the chlorine/sulfur ratio increased (Figure 2f), since HCl is more soluble than SO<sub>2</sub>. These examples show how volcanic activity can be traced using gas analyses. If fresh new magma were to be added to the volcano's shallow magma reservoir, the gas should exhibit corresponding increases of CO<sub>2</sub>, SO<sub>2</sub>, and C/S, and a decline of Cl/S.

The plumbing system of a volcano also can change during its activity. For example, fractures may develop as a result of earthquakes or eruptions, thereby facilitating the liberation of gas from the magma. By contrast, the system also may close at times from filling and plugging of fractures and cracks. High-temperature gases and fluids transport significant quantities of elements in solution. With cooling, these dissolved materials may precipitate and help fill open spaces such as fractures. The simple rise of a plug of magma within a volcanic conduit also can be sufficient means to partially close a volcanic system. There is thus an interesting interplay between processes which serve to keep a magmatic-hydrothermal system relatively open and other processes which can partially or completely seal the system. As a result, the plumbing systems of active volcanoes have permeabilities which vary both spatially and temporally during the course of activity. If permeabilities change, so can the internal pressures within the volcano. If pressures reach a certain critical threshold, an eruption may be imminent. One way to monitor these changes in permeability and internal pressure is by using gas analyses. When a system is permeable and "open," the flow of magmatic gas is high, and concentrations of magmatic gas components such as SO<sub>2</sub> and HCl are elevated. When the system is partially sealed and "closed," magmatic gas flux declines; instead, a hydrothermal gas component becomes more important, with proportionately larger amounts of CO<sub>2</sub> and H<sub>2</sub>S released.

As discussed above, the relative amounts of reactive and abundant gas species (e.g., CO<sub>2</sub>, SO<sub>2</sub>, H<sub>2</sub>S, and HCl) can be interpreted to better understand the activity of a volcano and to determine whether the chances for an eruption may be increasing. Many other components in gases are present in small quantities; among these are nonreactive gases such as helium (He), argon (Ar), and nitrogen (N<sub>2</sub>), and trace amounts of metals such as lead, zinc, and gold. The trace metals are important for ore deposit formation but are generally not used to interpret volcanic activity. The concentrations and isotopic composition of nonreactive gases, however, may vary significantly in time and space on a volcano, and they can provide the volcanologist with valuable information on the sources of the gases. For example, the concentration

and isotopic composition of helium in a gas provide insight into new inputs of magma into a chamber beneath the volcano. This type of information is essential for monitoring purposes.

## 2. Soil Gas

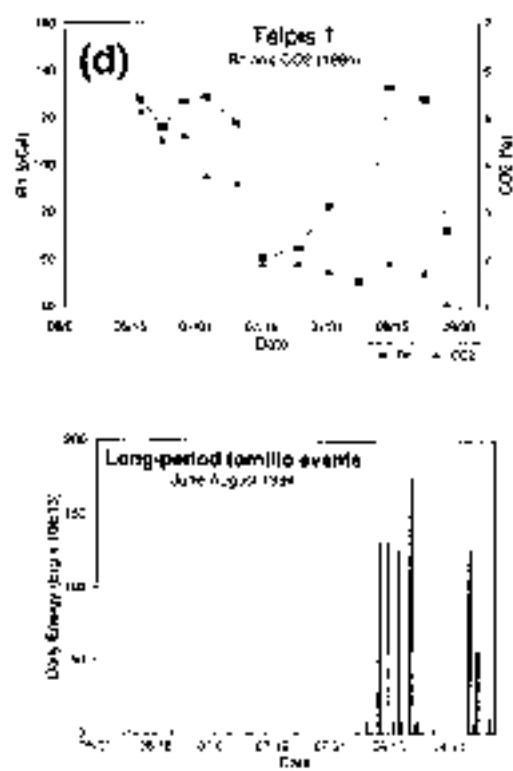

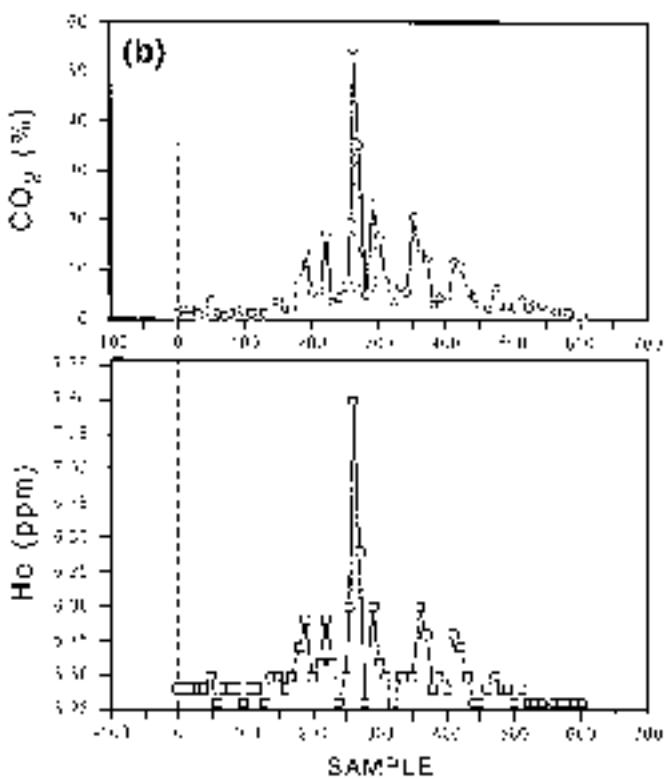

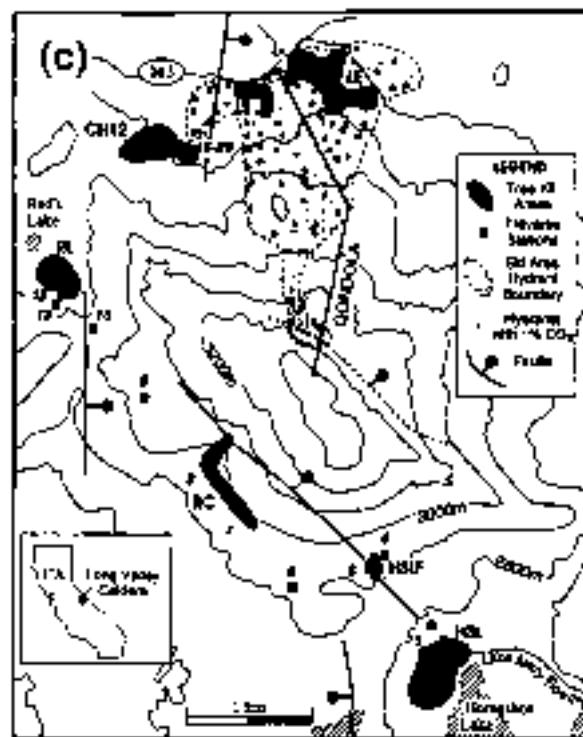

Volcanoes release gas not only from the central crater through openings such as fumaroles, but also on their flanks by diffuse degassing of species such as CO<sub>2</sub>, helium, and radon (Rn). Whereas the high-temperature gases in craters tend to be highly acidic and reactive (e.g., SO<sub>2</sub>, HCl), species such as CO<sub>2</sub>, He, and Rn do not react with country rocks. These gases can be emitted at lower temperatures through subsurface fractures and faults. The distributions and quantities of these gases provide information on the overall permeability of a volcanic edifice, the potential for lateral degassing from areas other than the active crater, and the ability of a volcano to diffusely release large quantities of CO<sub>2</sub> and other gases.

Diffuse degassing is typically monitored by measuring gas concentrations in soil gas or dissolved gas from springs. For soil gas analyses, a probe is inserted into the soil to approximately a meter in depth, a gas sample is pumped into an infrared gas detector or into a syringe and the gas is then transferred to an evacuated container (Figure 3a). Alternatively, gas detectors are installed in the soil for a period of time. At springs, water samples are taken at the source and placed in bottles which are sealed to prevent gas loss.

Before interpreting spatial or temporal trends of diffuse gases on a volcano in terms of volcanic, seismic, or tectonic activity, it is important to identify other mechanisms which may influence the gas distributions. For example, climatic effects such as rain, humidity, and barometric pressure can significantly influence the amounts of diffuse degassing.

Volcanoes can exhibit diffuse degassing anomalies at various scales. Volcanologists have recognized that elevated soil gas concentrations are associated with faults and fractures. Figure 3b shows a soil gas traverse across a faulted zone on the flanks of Vulcano, an active cone on the island of the same name in the Aeolian Islands of Italy. CO<sub>2</sub> and He concentrations are both high and variable across the faulted zone, which appears to be 300–400 m wide. Maximum CO<sub>2</sub> concentrations exceed 50%, compared to background levels close to zero. Helium reaches a maximum of 7.5 parts per million (ppm), compared to an atmospheric background of approximately 5.0–5.5 ppm.

Mammoth Mountain is located on the southwestern

margin of Long Valley caldera in eastern California, east of Yosemite National Park. In 1990, a broad region of tree kill began to develop on Mammoth Mountain after elevated seismicity was observed in 1989 (Figure 3c). The tree kill resulted from the diffusive release of CO<sub>2</sub>; the source of the CO<sub>2</sub> appears to be magmatic, at least in part. Figure 3c suggests that the areas of tree kill and elevated CO<sub>2</sub> concentrations in the soil gas are associated with faults. Thus, the CO<sub>2</sub> released since 1990 may have been the result of fault reactivation associated with the 1989 seismicity and/or intrusion of magma beneath Mammoth Mountain.

In certain instances, soil gases can be correlated with volcanic or seismic activity. Figure 3d shows variations of CO<sub>2</sub> and Rn at Galeras volcano, Colombia, during the period June–September 1994. The occurrences of constant- and low-frequency seismic events (“tornillos”), which are related to the internal pressure of the volcano, also are shown for this period. Both Rn and CO<sub>2</sub> show general declines with time; however, Rn concentrations increase abruptly when tornillos first appear. By contrast, CO<sub>2</sub> continues to decline. The overall declines appear to be climatically controlled, specifically a drying out of the ground. However, Rn also exhibits an anomalous response to seismic activity within the volcano, while CO<sub>2</sub> does not.

### C. Remote Sensing Measurements of Volcanic Gases

As we have discussed above, direct measurements of gas from volcanoes are not simple, due to logistical difficulties, limited access to active craters, and the danger and risk that are sometimes involved. Since the late 1960s volcanologists have been increasingly experimenting with methods to measure volcanic gas using remote sensing. This approach is attractive, since the measure-

ments are made at a distance from the volcano, and the instrument and observer are not actually in the gas plume. Thus, the approach is inherently safer and logically easier. Furthermore, remote sensing offers a means to make a greater number of measurements than can generally be done when sampling volcanic gas directly. Lastly, remote sensing measurements of a gas plume are more representative than direct measurements of individual fumaroles, although the number of gas species determined remotely is less than that for a gas sample collected at a fumarole. In this section we examine remote sensing techniques, both ground-based and from satellite platforms, which are being used by volcanologists. These include ground- and aircraft-based COSPEC correlation spectroscopy to measure SO<sub>2</sub> emissions and total ozone mapper spectrometer (TOMS) satellite measurements of SO<sub>2</sub>. We also discuss some of the promising new methods that are currently being developed to remotely sense volcanic gas. At the millennium we appear to be in a period of transition between first-generation remote sensing and a second generation which will offer us new insights into how volcanoes degas and their effects on the Earth's atmosphere.

#### *1. Sulfur Dioxide Emissions Measured by COSPEC*

The COSPEC is an instrument developed in the 1960s by Barringer Research, a company in Toronto, Canada, to measure emissions of SO<sub>2</sub> from industrial stacks for pollution monitoring, as public and government consciousness was raised. Volcanologists quickly realized the potential of the COSPEC, since volcanoes are essentially natural smokestacks. The COSPEC was first used at volcanoes in Japan, but most of the credit for developing and championing use of the COSPEC at active volcanoes goes to Richard Stoiber of Dartmouth College, who demonstrated the power and versatility of the

---

**FIGURE 3** (a) Measuring CO<sub>2</sub> in soil gas by infrared absorption, Masaya volcano, Nicaragua. The soil gas is pumped through a probe inserted into the ground. The volcanologists are wearing gas masks to protect against acid gases from the active crater several kilometers distant. (b) High levels of CO<sub>2</sub> and helium in soil gases observed across a faulted zone at the base of Vulcano, Vulcano Island, Italy. The gray areas are considered anomalies. The spacing between points is 10 m. (From Baubron, J.-C., Allard, P., Sabroux, J.-C., Tedesco, D., and Toutain, J.-P., 1991. Soil gas emanations as precursory indicators of volcanic eruptions. *J. Geol. Soc. London* **148**, 571–576. Reprinted by permission of the Geological Society Publishing House.) (c) Map of tree kills from CO<sub>2</sub> in soil gas on Mammoth Mountain, Long Valley caldera, California. Note the association between areas of tree kill and mapped faults. (From Rahn, T. A., Fessenden, J. E., and Wahlen, M., 1996. Flux chamber measurements of anomalous CO<sub>2</sub> emission from the flanks of Mammoth Mountain, California. *Geophys. Res. Lett.* **23**, 1861–1864.) (d) Relationship between radon and CO<sub>2</sub> in soil gases and seismic energy, Galeras volcano, Colombia. Radon increases with seismicity, while CO<sub>2</sub> does not show a response. (Reprinted from Heiligmann, M., Stix, J., Williams-Jones, G., Sherwood Lollar, B., and Garzón V., G., 1997. Distal degassing of radon and carbon dioxide on Galeras volcano, Colombia. *J. Volcanol. Geotherm. Res.* **77**, 267–283. Copyright 1997, with permission from Elsevier Science.)

instrument at volcanoes worldwide. He and his students not only showed how the COSPEC could provide important information on volcano degassing, they also made a fundamental contribution to climate studies by estimating the amount of  $\text{SO}_2$  that is released by volcanoes on a global basis. These calculations were based largely on their COSPEC results at many individual volcanoes.

The COSPEC functions in the ultraviolet part of the electromagnetic spectrum, with the sky used as the source of ultraviolet energy. Light enters the instrument and travels through a series of mirrors, lenses, and slits to reach a detector and photomultiplier, where the light is converted into electric pulses and amplified. If gas is present in the path of the instrument, the COSPEC detects the amount of ultraviolet radiation that is absorbed by the  $\text{SO}_2$ . Since the COSPEC is measuring the concentration of gas through a thin cylindric slice of the atmosphere, the concentration of  $\text{SO}_2$  in this slice is expressed as parts per million-meters (ppm-m), rather than simply as ppm for an instrument which directly measures gas within a plume.

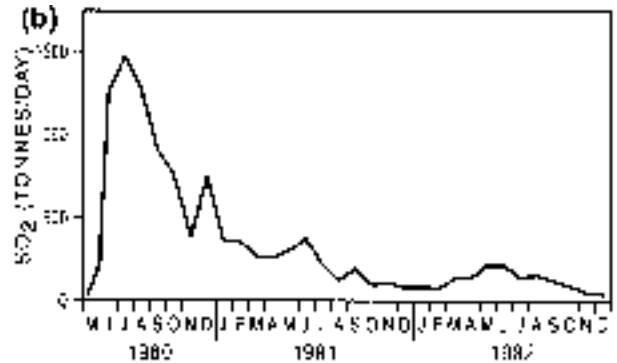

Typically, the COSPEC is mounted in a vehicle, with the telescope, mirror, and lens assembly oriented vertically upward (Figure 4a). The vehicle then makes traverses beneath the gas plume, with the traverses oriented perpendicularly to the direction of the plume. If there is no road access, the COSPEC can be placed in an aircraft which is flown under the plume. The COSPEC also can measure from a stationary position. Since the volcanologist's goal is to measure the amount of  $\text{SO}_2$  released from the volcano over a period of time, it is essential to measure the width and speed of the plume as it is dispersed downwind from the actively degassing crater or craters. Unfortunately, the speed of the plume frequently is difficult to estimate, and scientists often rely upon the wind speed as a proxy.

As use of the COSPEC became more widespread through Stoiber's influence, volcanologists recognized that explosively erupting volcanoes emit large quantities of  $\text{SO}_2$ . Nevertheless, it was frequently difficult to make such measurements, since volcanic ash from the eruption could interfere with the COSPEC measurements. Despite these problems, COSPEC measurements have shown that erupting volcanoes are capable of emitting thousands to millions of metric tons (tonnes) of  $\text{SO}_2$  each day. During its cataclysmic eruption on 18 May 1980, Mount St. Helens injected between 480,000 and 2,200,000 tonnes of  $\text{SO}_2$  into the atmosphere. Afterward, COSPEC measurements revealed that the  $\text{SO}_2$  emissions declined progressively during 1980 and 1981 (Figure 4b). The decline in  $\text{SO}_2$  from the volcano was

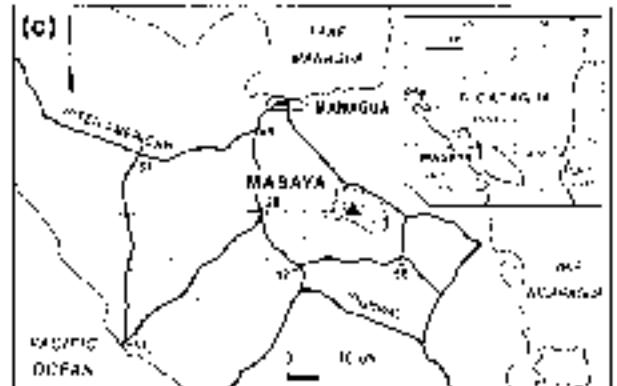

(a)

(b)

(c)

coincident with increasing H<sub>2</sub>O and decreasing CO<sub>2</sub> fumarolic gas concentrations during this time (see Figures 2a and 2b above). The two datasets indicate that the magma beneath the volcano was becoming increasingly depleted in gas during this period.

In addition to erupting volcanoes, there are others which are active but do not erupt, or they erupt infrequently. Instead, their activity is manifested by nearly continuous degassing, and the COSPEC is used to monitor this style of degassing. Masaya volcano in Nicaragua is a good example. Its recent activity has been characterized by periods of degassing lasting years, with little or no ash or lava erupted. The acid gas is blown westward by tradewinds, and a large region is adversely affected (Figure 4c). Much of the vegetation and crops such as coffee plants are killed, and people and livestock living in the affected zone suffer respiratory problems.

At first, scientists did not appreciate the levels of gas emitted from passively degassing volcanoes such as Masaya. As COSPEC measurements became more routine, it was realized that certain volcanoes emit very large quantities of SO<sub>2</sub> indeed, sometimes rivaling the amounts from erupting volcanoes. In addition to Masaya, which releases up to several thousand tonnes of SO<sub>2</sub> each day, Mount Etna in Italy and Popocatépetl in Mexico are significant producers. Etna emits between 5000 and 20,000 tonnes/day depending on its activity. Popocatépetl was observed to passively release close to 50,000–60,000 tonnes SO<sub>2</sub>/day on occasion in 1997! These are staggeringly large quantities, and scientists do not fully understand how volcanoes can release such large amounts without eruptive activity. This problem is a challenge for future volcanologists.

Since SO<sub>2</sub> is but one component of the overall gas budget emitted by both erupting and passively degassing volcanoes, it is clear that significant quantities of H<sub>2</sub>O,

CO<sub>2</sub>, HCl, and other gases also are injected into the atmosphere by these volcanoes. Once we independently know gas ratios (e.g., the sulfur/chlorine ratio determined from fumarole gas analyses or other remote sensing techniques) and the SO<sub>2</sub> flux measured by COSPEC, we can calculate volcanic emissions of other gases to the atmosphere.

By extrapolating their COSPEC measurements at different types of volcanoes worldwide, Stoiber and his colleagues were able to estimate that volcanoes emit an average of 19 million tonnes of SO<sub>2</sub> annually. By comparison, industrial sources emit about 70–80 million tonnes each year. Although industrial emissions are larger than volcanic emissions, volcanoes clearly inject important quantities of SO<sub>2</sub> into our atmosphere. In fact, volcanoes are the only natural source of SO<sub>2</sub>. This is a good example of Earth's degassing. Without the COSPEC, we would be unable to make such calculations and estimates.

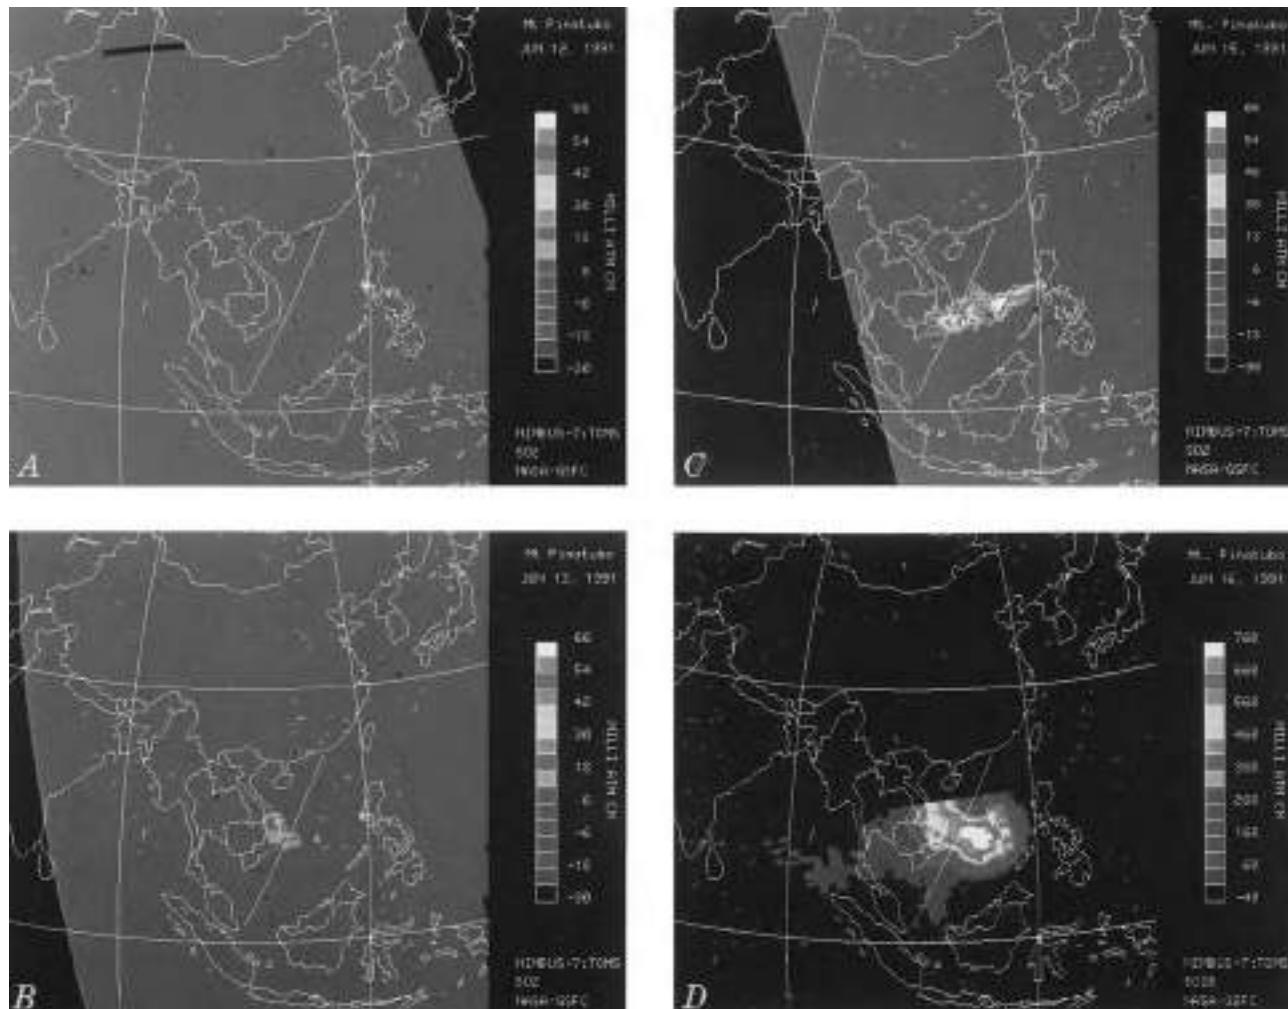

## 2. *Sulfur Dioxide Emissions Measured by TOMS*

The first total ozone mapping spectrometer was launched aboard the Nimbus 7 satellite spacecraft in 1978. Since that time, it and other similar instruments have been making measurements of stratospheric ozone, using the near-ultraviolet region of the spectrum. During the El Chichón eruption, Mexico, in 1982, it was observed that ozone levels were anomalously high, until it was realized by Arlin Krueger and his colleagues at NASA that TOMS was detecting volcanic SO<sub>2</sub>, in addition to ozone. In effect, SO<sub>2</sub> produces strong absorption at the shortest TOMS wavelengths (300–320 nm, similar to COSPEC). Thus, TOMS immediately became an invaluable means to measure large injections of SO<sub>2</sub> into the stratosphere by volcanic eruptions. Since 1979, TOMS has measured SO<sub>2</sub> from over 50 eruptions worldwide. The largest emissions so far observed were about 20 million tonnes of SO<sub>2</sub> from the 1991 eruption of Mount Pinatubo, 7 million tonnes from El Chichón in 1982, 4 million tons from Nyamuragira, Zaire, in 1981, 1.5 million tonnes from Cerro Hudson, Chile, in 1991, and 1.2 million tonnes from Sierra Negra, Galápagos, Ecuador, in 1979.

Figure 5 shows SO<sub>2</sub> measured by TOMS during the June 1991 Mount Pinatubo eruptions. The 12–13 June 1991 SO<sub>2</sub> outputs were relatively small compared to the climactic eruptions on 15 June. Figure 6 shows SO<sub>2</sub> emissions measured by both TOMS and COSPEC during the August–September 1982 eruptions of Galunggung. Frequently, the two sets of measurements do not

---

**FIGURE 4** (a) Two COSPEC instruments installed in a vehicle to measure SO<sub>2</sub> fluxes from Popocatépetl volcano, Mexico. The vehicle is driven underneath the plume with the COSPEC telescope oriented vertically upward. (Photograph courtesy of Glyn Williams-Jones.) (b) Average SO<sub>2</sub> fluxes in metric tons per day from Mount St. Helens, 1980–1982. Note the progressive decline with time. (Reprinted with permission from Casadevall et al., 1983. Copyright 1983 American Association for the Advancement of Science.) (c) Dispersion of gas westward from Masaya volcano in Nicaragua, as determined by repeated COSPEC measurements. (From Stoiber, R. E., Williams, S. N., and Huebert, B. J., 1986. Sulfur and halogen gases as Masaya caldera complex, Nicaragua: Total flux and variations with time. *J. Geophys. Res.* **91**, 12215–12231.)

**FIGURE 5** (a)–(d) Emissions of SO<sub>2</sub> during the climactic eruptions of Mount Pinatubo volcano, Philippines, 12–16 June 1991, as measured by TOMS. The highest SO<sub>2</sub> concentrations are shown in white, and the lowest in black. In (b) two masses of SO<sub>2</sub> can be seen, one located near the volcano from the 13 June eruption, and the other 1300 km to the west from the 12 June eruption. The figure in (d) shows the very high SO<sub>2</sub> concentrations produced by the largest eruption on 15 June. For (d) note the change in concentration scale for the right-hand column of SO<sub>2</sub> concentrations. The spatial scale is defined by the two curved latitude lines (0° and 30°N), which are separated by approximately 3300 km. (From Krueger et al., 1994. Figure kindly provided by the U.S. Geological Survey.)

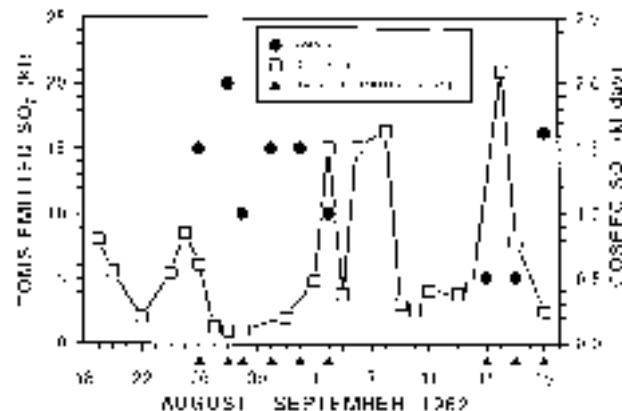

correspond, probably because TOMS recorded high SO<sub>2</sub> values from explosive eruptions, while COSPEC measured lower SO<sub>2</sub> levels between the eruptions.

The TOMS does have some disadvantages. Its 50 × 50-km spatial resolution is relatively coarse, and it cannot easily make measurements at night, at low sun angles, or at high latitudes. It is designed to make measurements of stratospheric SO<sub>2</sub> injected by relatively large eruptions; therefore, it cannot measure low levels of SO<sub>2</sub> in the troposphere. If ash and sulfate aerosols are present in the eruption column, SO<sub>2</sub> can be overestimated.

A second generation of TOMS instruments was launched on the Earth Probe and ADEOS satellites in 1996. These instruments were designed to better measure volcanic SO<sub>2</sub> by increasing the spatial resolution and selecting wavelengths optimum for SO<sub>2</sub>. Unfortunately, the ADEOS satellite failed in 1997.

### 3. Other Remote Sensing Measurements

While COSPEC and TOMS have provided us with valuable information on SO<sub>2</sub> emissions from volcanoes, we know comparatively little about emissions of other

**FIGURE 6** SO<sub>2</sub> fluxes from Galunggung volcano, Indonesia, during the months of August and September 1982, as measured by TOMS and COSPEC instruments. The SO<sub>2</sub> scale for TOMS is an order of magnitude higher than that for COSPEC. The triangles indicate the occurrence of vulcanian eruptions, which generally coincide with the TOMS measurements. (Reprinted from Bluth, G. J. S., Casadevall, T. J., Schnetzler, C. C., Doiron, S. D., Walter, L. S., Krueger, A. J., and Badruddin, M., 1994. Evaluation of sulfur dioxide emissions from explosive volcanism: The 1982–1983 eruptions of Galunggung, Java, Indonesia. *J. Volcanol. Geotherm. Res.* **63**, 243–256. Copyright 1994, with permission from Elsevier Science.)

gas species such as CO<sub>2</sub>, H<sub>2</sub>S, HCl, and HF. We know even less concerning gas species which are present in volcanic gas in trace amounts. Unfortunately, the ultraviolet part of the spectrum is not particularly useful when trying to measure these gases. Instead, the infrared region holds much more potential, and this is where current efforts are being directed to measure gases other than SO<sub>2</sub>. As we have discussed earlier in this chapter, the use of gas ratios may hold very useful information in terms of volcano behavior, particularly when the gas solubilities in magma are different. Thus, remote sensing measurements of gas ratios are an important line of inquiry. If two gases are ratioed, the variability of the plume speed (which is needed for flux measurements) is eliminated, and thus gas ratio measurements are inherently more precise and accurate than flux measurements of individual gas species.

Infrared measurements of gas must contend with potential interferences from nonvolcanic gases which are present in the atmosphere. Chief among these is water vapor, and CO<sub>2</sub> and methane (CH<sub>4</sub>) are also potential interferants. Three principal lines of research currently are being pursued: Fourier transform infrared spectroscopy (FTIR); gas correlation radiometry; and thermal infrared multispectral mapping.

An FTIR instrument is typically deployed in a stationary position on the ground and pointed at a hot source,

for example, an infrared lamp, the crater, or the Sun. Volcanic gas which is present between the instrument and the source is then measured (Figure 7a). The FTIR method is powerful because it enables a volcanologist to rapidly measure different gases at various wavelengths simultaneously. By knowing the absorption wavelength of a particular gas and correcting for interferences, it is possible to calculate gas concentrations in ppm-m. From these data, gas ratios can be calculated. Figure 7b shows a plot of SO<sub>2</sub> vs. HCl concentrations as measured by FTIR. It can be seen that the SO<sub>2</sub>/HCl ratio of the gas is higher at Mount Etna than at Vulcano.

Another infrared technique being explored is that of gas correlation radiometry. The basic principle is similar to that of FTIR, except that the radiometer is set to look at specific spectral regions, rather than a broad spectrum of absorbances, each with their own characteristic wavelength. During measurements, a gas cell and a clear cell, which are mounted on a rapidly spinning disk called a chopper, are compared for their relative signals. This approach is being used to measure volcanic CO<sub>2</sub>, which is difficult because the atmosphere contains about 365 ppm CO<sub>2</sub>. Thus there is an important background interference which is present. Gas correlation also is being used to measure trace gases such as carbon monoxide (CO) and carbonyl sulfide (COS).

In the past several years, the thermal infrared multispectral scanner (TIMS) has been employed to map SO<sub>2</sub> plumes from aircraft. This work has been conducted at Mount Etna and Kilauea volcanoes. Essentially, the TIMS is a small-scale version of TOMS but operates in the infrared region rather than the ultraviolet. TIMS has the important ability to make two-dimensional maps of SO<sub>2</sub> distributions within volcanic plumes. This is difficult or impossible to do by COSPEC, FTIR, or gas correlation. Thus, TIMS can map spatial and temporal variability of SO<sub>2</sub> within a volcanic plume, and such maps will help us better understand the heterogeneous distribution of gas within the plume. A satellite-based version of TIMS, called ASTER, is planned for launch in 1999. ASTER has the potential to map volcanic plumes from space on a worldwide basis.

## II. ASH MEASUREMENTS AND MONITORING

### A. Principles

Volcanic ash is released by explosive eruptions. While causing much misery for people downwind from a vol-

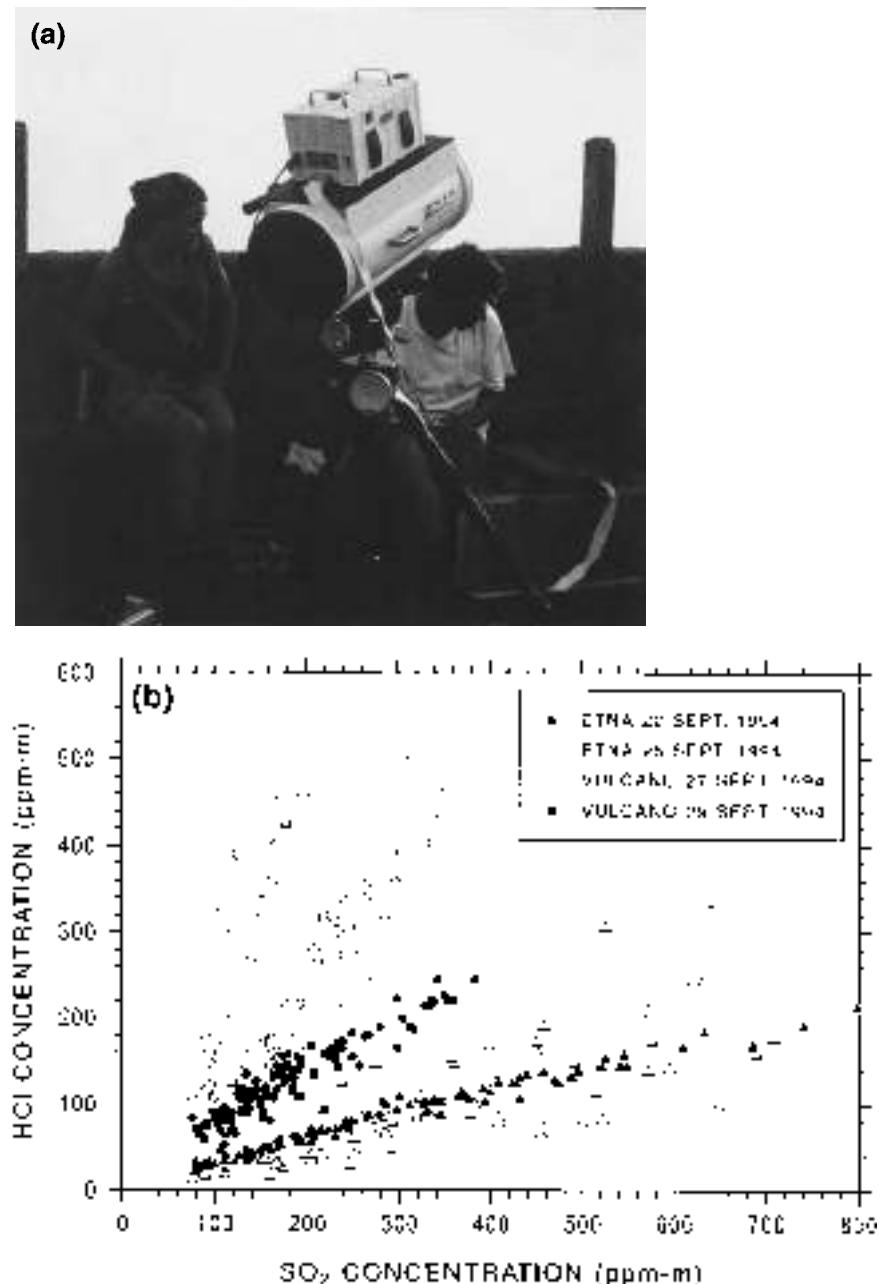

FIGURE 7 (a) Deployment of a Fourier transform infrared spectrometer at Masaya volcano, Nicaragua. The spectrometer is using the Sun as a source of infrared energy. (b) Plot of SO<sub>2</sub> vs. HCl concentrations at Vulcano and Mount Etna volcanoes, Italy, as measured by FTIR. The SO<sub>2</sub>/HCl ratios are higher at Mount Etna. (From Francis *et al.*, 1995.)

cano, the ash can be studied in a number of ways that provide important insights into the nature of the eruption. Indeed, the ash provides a record of the magmatic and plume conditions during the eruption. If one is able to sample the ash at different points in time during

the eruption, it is possible to examine changes that are occurring within the volcano and in the eruption column. Essentially, the ash layers provide a way to reconstruct different events at the volcano during the eruption.

With these points in mind, a volcanologist takes careful note of the stratigraphic position of an ash layer at a particular geographical locality. For example, an observer stationed at one site carefully records the accumulation rate of the ash by noting the cumulative thickness at given time intervals. Changes in texture and grain size of the ash also are recorded. The observer will take periodic samples of the ash, noting the time and the sample's stratigraphic position.

After the ashfall has ended, the observer will visit many different sites around the volcano, making detailed measurements of the ash accumulation by recording information such as thickness, changes in textures and grain sizes, and maximum fragment sizes. With this information, it is possible not only to reconstruct the dispersal pattern of the ash but also to estimate volumes of erupted material and eruption dynamics.

## B. Composition of Volcanic Ash

Volcanic ash consists of three main components: (1) fragments of minerals, (2) glass shards and pumice grains, and (3) accidental lithic fragments (Figures 8a–8c). Mineral fragments are crystals which originally precipitated from the magmatic liquid before the eruption. The variety of crystals provides information on the composition of the magma. In addition, the chemistry of the minerals can be used to determine the temperature, pressure, and depth conditions of the magma prior to the eruption. In this way, ash samples at different stratigraphic positions from a deposit can tell us if the composition, temperature, or depth of the magma changed during the course of an eruption. Mineral grains also can contain small inclusions of trapped magma, typically 0.05–0.2 mm in diameter, which have solidified to glass (Figure 8d). This glass can be analyzed by specialized microanalytical techniques to estimate the amount of gas that was dissolved in the magma before the eruption.

Glass shards and pumice grains are solidified samples of the magma. Essentially, the liquid magma froze during the eruption due to rapid cooling. Since an explosive eruption is violent, the frozen magma is broken into small pieces of bubbly pumice and even smaller glass shards. The density and percentage of bubbles in the pumice can be measured to estimate indirectly the amount of gas originally present. For example, a bubble-rich, low-density pumice implies high gas contents. The chemical composition of the pumice and glass fragments also is determined to see if the chemistry of the magma changed during the course of an eruption, or if mixing of different

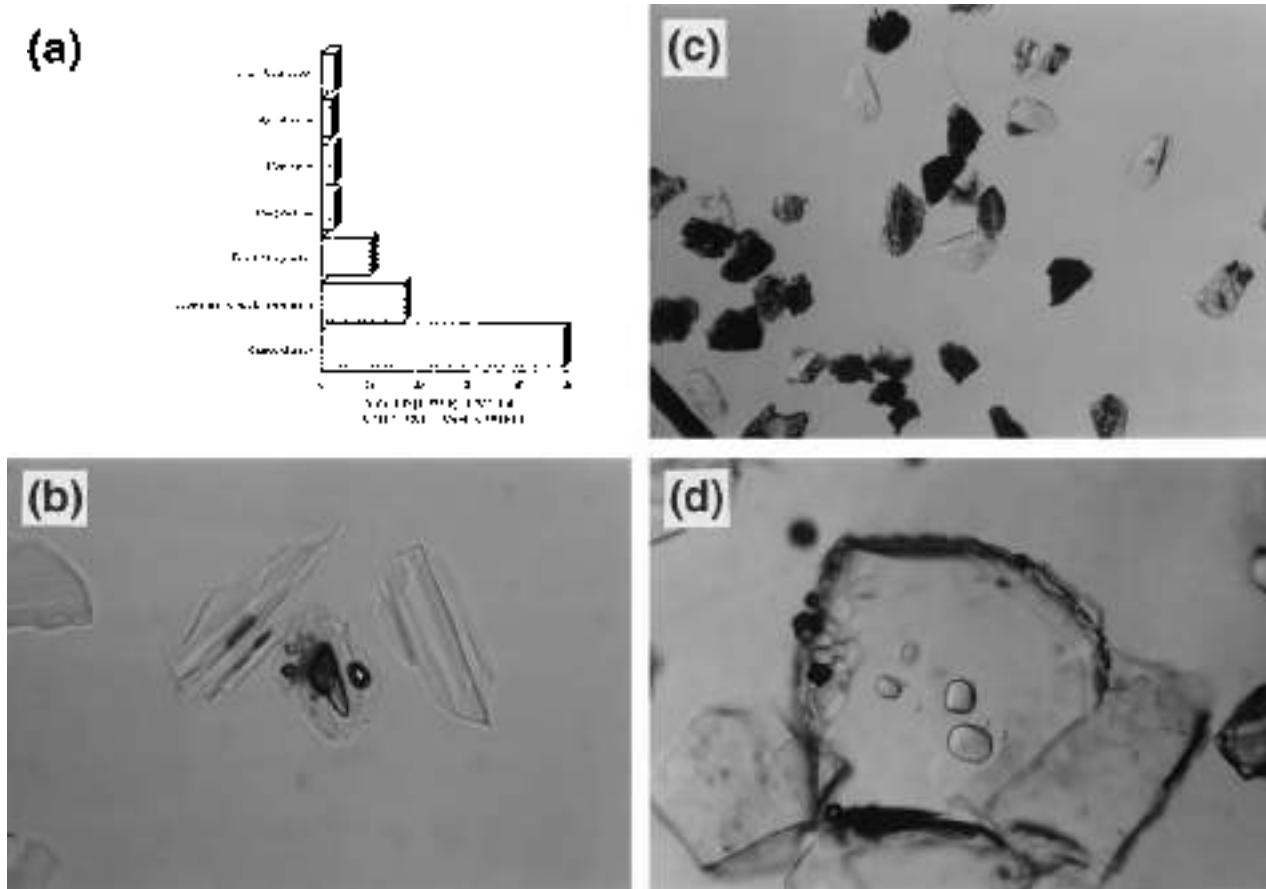

magmas occurred. For example, the chemistry of ashes from the 1992 eruptions of Mount Spurr, Alaska, represented three different magma compositions.

Lastly, the composition of accidental lithic fragments helps us understand the types of rocks surrounding the volcanic conduit and plumbing system. If the geology of the region has been studied previously, then it may be possible to estimate if an eruption deepens with time, based on the nature of the lithic fragments at different stratigraphic levels of the ash bed.

## C. Morphology of Juvenile Glass Shards

The presence of juvenile material such as pumice grains or glass shards in ash is an indication that fresh magma is present beneath a volcano (Figure 8b). This is a very important determination, because explosive magmatic eruptions can be very large and destructive events. If glass shards are detected in ash from a volcano that has suddenly reactivated, this observation has significant implications for hazard assessments. Specifically, the glass indicates the presence of magma beneath the volcano, and the potential for larger, more explosive and destructive eruptions clearly exists. By contrast, some volcanoes that reactivate contain little or no glassy material, the ash being dominantly accidental lithic material that has been scraped from the conduit walls (Figure 8c). The lack of glassy juvenile material does not necessarily imply that fresh magma is not present, but it does suggest that the possibility of a magmatic eruption is somewhat lessened. For the volcanologist who is trying to use the content of the ash as a guide to future activity, perhaps the most difficult situation is when there are only traces of glassy material present. Do the very small amounts of glass indicate fresh magma, or is the glass a remnant of a previous eruption involving magma? Fresh glass has a comparatively low refractive index, while older glass shards can have higher or variable refractive indexes, resulting from water that has been incorporated into the glass structure at low temperatures.

The morphology of glass shards can help identify the nature of the eruption. Shards that are bubble-rich with cuspatate shapes are indicative of a gas-rich magmatic eruption. Other shards can be platy and planar, lacking bubble walls. These shards are suggestive of either a gas-poor eruption or one where magma has interacted with groundwaters, fragmenting the magma before significant bubble growth could occur. These eruptions are termed phreatomagmatic. During an eruption, the shard morphologies in ash samples may vary, and these

**FIGURE 8** Different types of volcanic ash. (a) Composition of volcanic ash from the March 1986 eruption of Augustine volcano, Alaska, showing glass shards, rock fragments, and pieces of minerals. (From Heiken, G., 1994. Volcanic ash: What it is and how it forms. *U.S. Geol. Surv. Bull.* **2047**, 39–45. Figure kindly provided by the U.S. Geological Survey.) (b) Shards of magmatic glass produced by the eruption of the Lower Bandelier Tuff, New Mexico. Length of longest shard is 0.3 mm. Width of photo is 0.8 mm. (c) Photomicrograph of ash from the 14 January 1993 eruption of Galeras volcano, Colombia, showing presence of mineral fragments (transparent colors) and rock fragments (dark colors). Width of photo is 2 mm. (d) Photomicrograph of inclusions of glass trapped in a quartz crystal from the Bandelier Tuff, New Mexico. Largest inclusion is about 0.12 mm in diameter. Width of photo is 2 mm.

variations can be correlated to other changes that are observed.

#### D. Soluble Components on Volcanic Ash

When volcanic ash is suspended in an eruption column, a certain proportion of the gas phase is condensed onto the surfaces of the ash particles. When these particles fall to the ground, they remove a component of the gas phase. This component can indirectly provide valuable information on the magmatic gas. By collecting and then leaching freshly fallen ash that has not been rained

on, a volcanologist can measure the amount of gas ( $\text{SO}_2$ ,  $\text{HCl}$ ,  $\text{HF}$ ) removed by the ash. When the ash is leached, the gases are in the form of anionic complexes such as sulfate ( $\text{SO}_4^{2-}$ ), chloride ( $\text{Cl}^-$ ), and fluoride ( $\text{F}^-$ ) in the solution. From this information, ratios such as  $\text{S}/\text{Cl}$  can be calculated to obtain an indirect estimate of the magmatic component which is present in the gas. For example,  $\text{S}/\text{Cl}$  leachate ratios greater than 0.5 indicate that the ash has an important magmatic component, while lower ratios imply a smaller magmatic influence. While these values are only rough guidelines which are somewhat arbitrary, experience has shown the information can be useful, particularly if integrated with other indicators such as the percentage of glass shards. Before the

cataclysmic 18 May 1980 eruption of Mount St. Helens, S/Cl ratios of ash leachates were less than 1, indicating a variable magmatic component in the gas phase. During the 18 May eruption, the ratios were as high as 1.3, showing that the magmatic component had increased significantly.

### E. Tracking Volcanic Ash Clouds by Satellite Remote Sensing

Volcanic eruption plumes may be transported significant distances. The largest eruptions form stratospheric plumes which circle the Earth many times. In regions surrounding a volcano, ash is frequently deposited over a wide area. Further afield, the plume continues to move, containing gas, aerosols, and very fine-grained ash particles. The dispersion of volcanic plumes thus can be a global phenomenon, and remote sensing techniques such as Earth-orbiting satellites can be used to track the evolution of plumes as they are transported in the atmosphere. Practically speaking, the monitoring of eruption plumes is very important for people on the ground who may be affected, and for aircraft flying overhead, since volcanic ash can foul jet engines.

Near the volcano, a type of radar called C-band radar (also referred to as Doppler or NEXRAD radar systems) can be used to map eruption columns and to detect ash which is between 1 mm and several centimeters in size. Unlike radar in aircraft which is unable to detect the presence of ash, C-band radar can sense the presence of ash up to 100–200 km from the volcano. It also can be used in all types of weather, and clouds do not pose a problem. The radar can detect the height of an eruption column; with this information, eruption rates can be estimated as

$$H = 236.6Q^{1/4},$$

where  $H$  is the height of the column in meters and  $Q$  is the eruption rate in kilograms per second. Sometimes the top of the column may be underestimated, since the radar does not detect ash particles much smaller than 1 mm. C-band radar also can be used to study the fallout of ash particles, particularly the loss of large particles, and size distributions of ash can be obtained from different patterns of radar reflectivity. The radar is useful in environments close to the volcano where ash particles are comparatively big. It is less effective at greater distances after the large particles have fallen out of the column.

Further from a volcano where C-band radar is no

longer effective, weather satellites can track the movement and velocity of eruption plumes. For example, the geostationary GOES-7 satellite is able to observe a significant part of the western hemisphere on a nearly continual basis. However, discriminating between eruption plumes and meteorologic clouds can be difficult. The advanced very high-resolution radiometer (AVHRR), aboard the polar-orbiting NOAA-11 and NOAA-12 satellites, has proven very useful not only for tracking eruption plumes, but also for distinguishing between volcanic plumes and clouds. The AVHRR contains two thermal infrared bands at 10.3–11.3 microns ( $\mu\text{m}$ ) (Band 4) and 11.5–12.5  $\mu\text{m}$  (Band 5). For the individual bands, volcanic plumes and meteorologic clouds frequently appear similar on the satellite images. When Band 5 is subtracted from Band 4 during image processing, the volcanic plumes can be more easily resolved from clouds. Transparent volcanic plumes are most easily distinguished, while opaque plumes laden with large ash particles, water droplets, or ice are more difficult to tell apart from clouds. An example of Band 4 and Band 4–5 data is shown in Figures 9a and 9b for the eruption plume generated by the 18 August 1992 eruption of Mount Spurr, Alaska.

Using the AVHRR data, eruption plumes can be viewed every few hours. In addition to tracking the plume, it is potentially feasible to measure the top of a cloud, its temperature, and the amount of thermal energy released. Figure 9c shows an AVHRR image of plume dispersal across North America on successive days after the 16–17 September 1992 eruption of Mount Spurr.

---

## III. THERMAL MEASUREMENTS AND MONITORING

### A. Principles

The thermal aspect of surface and subsurface volcanic activity is crucial in monitoring and interpreting the dynamics of intereruptive cooling and degassing, as well as surface heating due to magmatic activity. The thermal measurements characterize the volcanic heat output of these active regions. While the measurements give direct information on the subsurface state via various types of thermal anomalies (e.g., small spatial anomalies with high intensity, and large thermal anomalies with low intensity), they also provide direct or indirect information on the internal volcanic dynamics: injection of

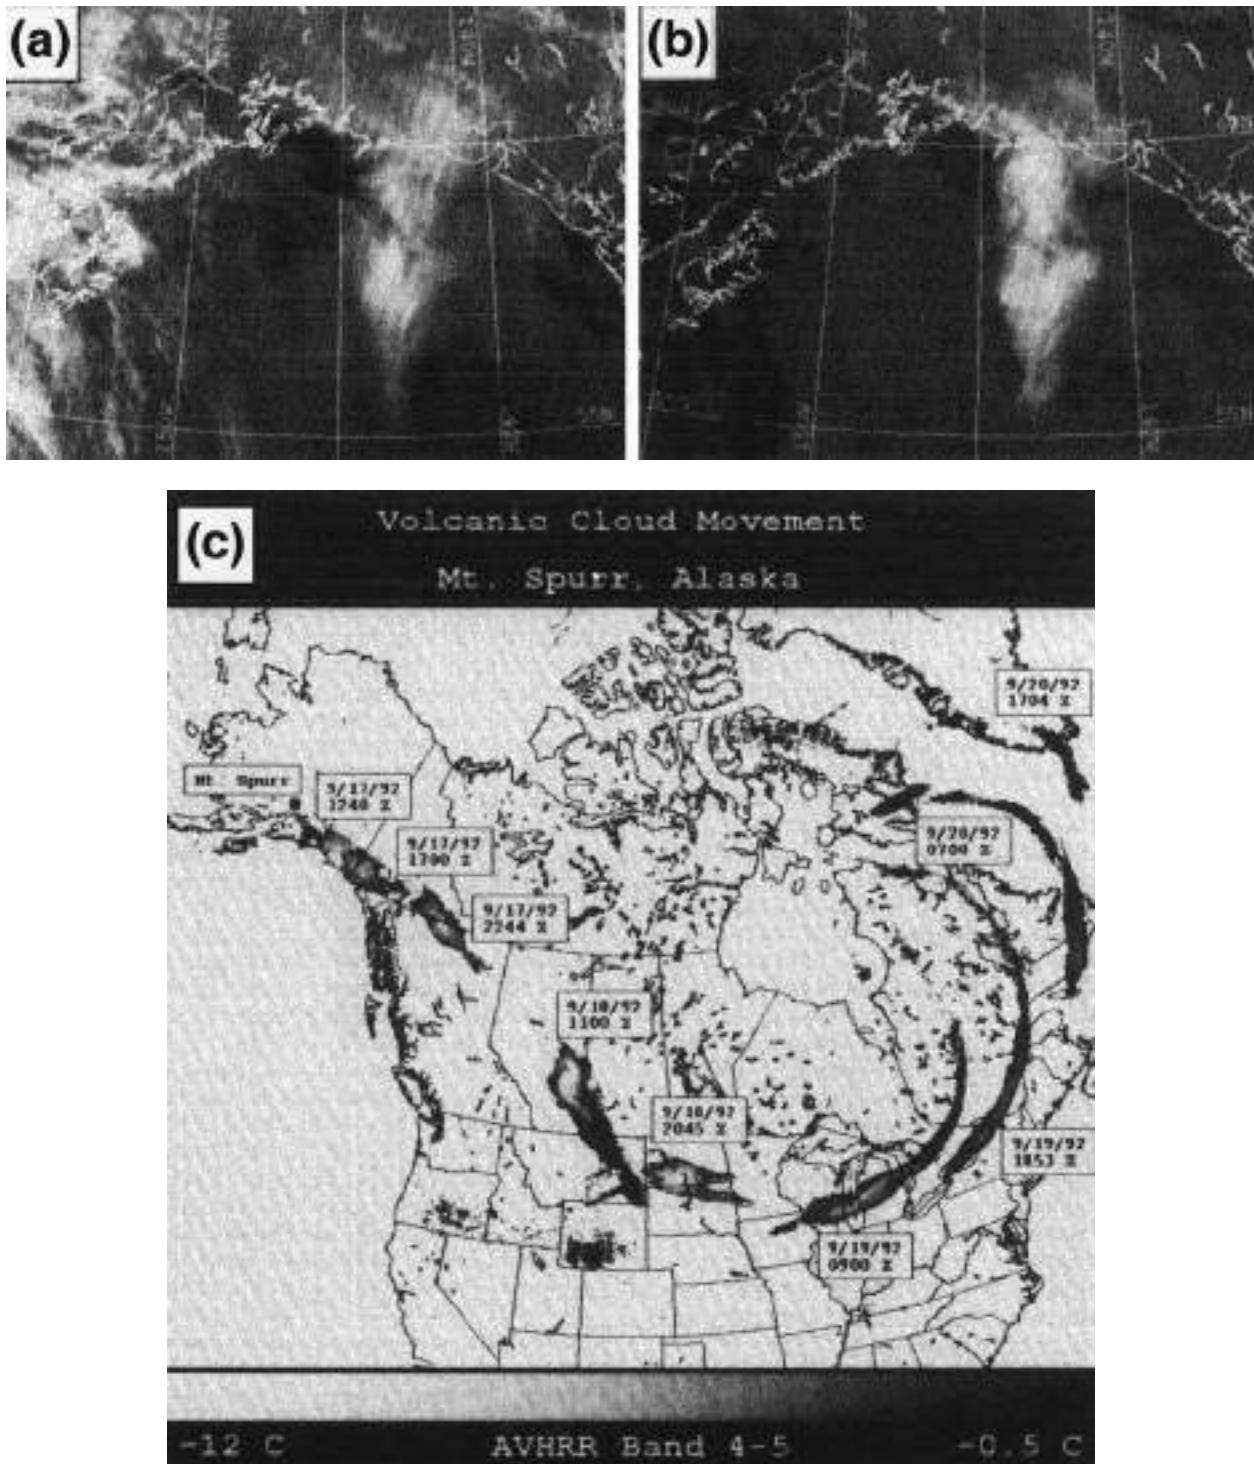

FIGURE 9 (a) AVHRR Band 4 image and (b) Band 4 minus Band 5 image from the 18 August 1992 eruption of Crater Peak, Mount Spurr, Alaska. The volcanic plume is better defined in (b) due to the subtraction procedure. (c) Composite Band 4 minus Band 5 AVHRR image showing long-distance transport of the volcanic plume from the 16–17 September 1992 eruption of Crater Peak. (From Schneider *et al.*, 1995. Figure kindly provided by the U.S. Geological Survey.)

magma from depth via lava coming to the surface, gas escaping through fractures, and active lava flow emplacement. Such information is important for the interpretation and modeling of volcano dynamics. The thermal monitoring of the surface can give precursory warning of future eruptions. Finally, the monitoring of eruption plumes has become another important challenge in recent years for improved safety of air travel in many regions of the world.

For these reasons, volcanologists are interested in surveying thermal fields outlined by unusual temperature distributions at the surface of a volcano. This can be done by thermal or radiant flux measurements from the ground and from space. Thermal measurements directly in the ground give absolute temperatures at a single point but cannot cover large regions. However, the growing access to remotely sensed data during the last 30 years has been a powerful means to monitor volcanic activity globally.

## B. The Origin of Thermal Anomalies

The internal geothermal heat produced by the ascent of magma toward the surface of a volcano will dissipate predominantly via underground convection, surface transfer, and/or radiative transfer into the atmosphere. Indeed, the transfer of volcanic heat by conduction (e.g., of the magma through adjacent rock walls) is itself very inefficient. Such an input of volcanic heat at the surface will increase the geothermal flux ( $80 \text{ mW m}^{-2}$  on average). The heat budget at the surface of the volcano can be expressed as

$$\phi_{\text{sol}} + \phi_{\text{geo}} = -W_s - W_{\text{cr}},$$

where  $\phi_{\text{geo}}$  represents the geothermal flux at the surface, and  $\phi_{\text{sol}}$  represents diurnal and annual solar heating variations.  $W_s$  is the radiative heat output and  $W_{\text{cr}}$  the convective heat transfer from the ground to the air. Positive and negative signs indicate a gain and a loss, respectively, from the surface.  $\phi_{\text{sol}}$  is usually the most significant component which will increase the temperature of a surface.

However, volcanic areas exhibit a large increase of the geothermal flux, thus we may observe thermal anomalies which have a localized increase in the surface temperature. Since it is important to compare warm and cold thermal values in the same region which have similar atmospheric, meteorological, and emissivity conditions, fluxes are better described by their relative intensities between areas of volcanic activity compared to neighboring inactive regions. The heat loss by wind convec-

tion may be estimated with the knowledge of meteorological variables including local wind speed and air temperature. The relative radiative heat loss, in  $\text{W m}^{-2} \text{ sr}^{-1}$ , may be measured from various remotely sensed platforms, the choice of spectral bands of the electromagnetic spectrum being made in accordance with the temperatures of interest and the Planck law. In general, the higher the surface temperature, the lower the wavelength of its maximum radiative energy (Figure 10). For example, surfaces with temperatures of  $100^\circ\text{C}$  or less will only be observed from Landsat satellites in thermal infrared (TIR,  $8\text{--}14 \mu\text{m}$ ) bands, while surfaces with temperatures of  $600^\circ\text{C}$  and greater can be detected in the short wavelength infrared (SWIR,  $1\text{--}3 \mu\text{m}$ ) and near infrared (NIR,  $0.7\text{--}1 \mu\text{m}$ ), and even sometimes in the visible (VIS,  $0.4\text{--}0.7 \mu\text{m}$ ).

The physics of radiation between the ground and the sensor is in fact more complicated, because part of the emitted radiation is absorbed, scattered, or emitted by the atmosphere. Furthermore, when data are acquired during the day, reflected solar radiation is also captured by the detector. However, data acquired at night may be corrected with the help of standard atmospheric models to deduce a quantitative thermal image of the observed surface. The emissivity of the surface, which is a property of the surface or an object, also controls the radiant energy fluxes. Emissivity for a blackbody is unity and for most natural materials is less than 1 (a function of its texture, composition, age, erosion state, etc.). As a consequence, if a natural surface and blackbody surface have identical temperature, then the blackbody surface

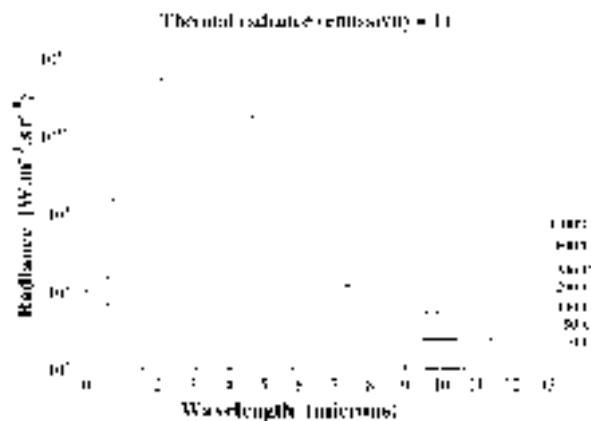

FIGURE 10 Graph showing thermal radiance and temperature sensitivities versus the wavelength. The TIR band ( $8\text{--}14 \mu\text{m}$ ) is sensitive to emitted thermal radiance from surfaces with temperatures in the range of those characteristic of sea and land ( $300 \text{ K}$ ). With an increase in the surface temperature, the peak of maximum radiations is displaced to shorter wavelengths.

will emit more than the natural body. Hence, depending on the scientific objectives, images can be processed to provide maps of the emissivities of an area or maps of the temperature distributions.

Spatial, temporal, and spectral clues provide additional information to discriminate between different thermal volcanic features. For example, circular anomalies are generally associated with crater lakes and domes, while elongated anomalies may suggest lava tubes or lava flows. Knowledge of the topography of a volcano also gives valuable information to better interpret the thermal anomalies, since both fields are intimately related; for example, flows will erupt either from craters or flank fractures. The temporal evolution of a volcanic event provides additional constraints on the interpretation of thermal anomalies; a series of images showing the evolution of an active lava flow and its cooling stages will be easier to interpret than a single image taken as a snapshot. Of course, such a series also will be very valuable for the modeling of the dynamics of lava flows.

Fluids such as gases and water escape through the volcano via open conduits such as fumaroles, lava lakes, or fractures. The temperature of these volcanic pathways will depend partly on the origin of the gases. A magmatic origin will be associated with high-temperature gases ( $>300^{\circ}\text{C}$ ), while water vapor of atmospheric origin (water from rain penetrating into the ground) will give lower temperature volcanic surface areas. Hence, to take a convenient example, the measurement of the temperature of a fumarole will be indicative of the origin of the gas. In many cases, however, an increase in the intensity of a thermal anomaly will not be a straightforward precursor of an eruption. In some circumstances, the pre-eruptive period is instead distinguished by decreased thermal anomalies due to the sealing of fracture networks as was observed on Lascar volcano (Chile) in 1992 where the dome activity was inversely related to its surface temperature. Hence, whenever possible, thermal measurements and observations need to be interpreted with caution in conjunction with other types of measurements. In particular, it is important to be able to discriminate between eruptive (e.g., active lava flow) and non-eruptive volcanic phenomena (e.g., high-temperature fumaroles).

### C. Acquisition of the Thermal or Radiance Data

#### 1. Ground-Based Measurements

Direct measurements of thermal activity require the use of a thermocouple or of thermometers in a network to

estimate the ground temperature at various depths by local contact measurements (Figure 11). Other ground-based methods consist of making the measurements from a remote point of observation using a radiometer, giving an integrated temperature over a narrow target typically of one arc degree or less in one or more wavelength bands. Caution must be taken when interpreting the thermal data since they represent isolated measurements over an entire active volcano. In the case of remote instruments, they may give nonrepresentative temperature estimates due to resolution problems and solar reflection.

New technologies allow the use of handheld thermal infrared video-imaging instruments. Figure 12 shows an example of such a video camera which provided thermal anomalies on Masaya and Telica volcanoes (Nicaragua) in 1997. Imaging digital radiometers have not yet been extensively used on the ground despite their great potential in monitoring the entire spatial distribution of the observed area, instead of a single averaged thermal value. The principal reason is the heavy weight of the instrument, making it difficult to use in the field. However, with new focal plane array technology, digital video cameras will soon become very portable to use in both the SWIR and the TIR spectral windows.

#### 2. Airborne Sensors

Airborne missions provide regional synoptic viewing of a temperature distribution of a volcanic region at large scales from tens of kilometers down to a few meters. They have been equipped with thermal sensors since at least the late 1960s. For example, activity on Hawaii has been monitored at several different periods in the 1980s and 1990s with thermal infrared sensors on a NASA aircraft flying at various altitudes between 1 and 10 km above the ground. The sensors provide images acquired simultaneously in different spectral bands from the visible to the thermal infrared regions. Daytime and nighttime flights are performed, with the nighttime thermal images giving the best thermal contrast between active volcanic regions and their neighboring inactive areas. Other volcanic regions have been surveyed by aircraft campaigns in remote areas such as Kamchatka. Infrared video cameras can be used from helicopters to survey the temporal evolution of volcanic activity.

#### 3. Spaceborne Sensors

Satellite images provide global viewing of the planet (e.g.,  $185 \times 185$  km for a Landsat satellite image) on a continuous basis with a periodicity depending on the type of satellite. This offers great potential for monitor-

**FIGURE 11** Temperature measurements in an active lava flow on Mount Etna obtained with a thermocouple during the 1991–1993 eruption. Temperatures varying between 800 and 1080°C were found locally.

ing active volcanoes. However, depending on the type of study, we usually have to choose between images acquired with high spatial resolution and low temporal resolution (e.g., panchromatic SPOT images with a spatial resolution of 10 m and a temporal coverage of 16 days) or images with low spatial resolution and high-frequency temporal coverage. For example, the AVHRR sensor on the NOAA satellite series gives images with a maximum spatial resolution of 1 km and a temporal frequency of 12 hours. Moreover, in many volcanic regions, acquisition of data will be reduced by meteorological or volcanic conditions which may prevent analysis and interpretation of these images. Examples include clouds and volcanic plumes obscuring the clarity of the region of interest.

variable in space and time; the temperature of an active region (e.g., a lava flow or a fumarolic vent) may vary significantly within a few centimeters of the ground, as well as over the course of a few hours or minutes. To precisely interpret and analyze such variability surveyed from various distances, the dependence of the remotely sensed data on the spatial and temporal resolution has to be known. Attempts have been made to divide the estimated temperature obtained at a satellite into subscale temperatures. Another approach is to consider the observed thermal field as highly variable and to estimate its dependence on the scale of observation. This is the basis for a new statistical approach of multifractals and multiscaling being developed to analyze and model highly variable geophysical fields such as thermal regions of volcanoes.

#### D. Space–Time Resolution of the Data

A crucial question when analyzing and interpreting remotely sensed data is that of the spatial resolution. The best qualitative and quantitative interpretation is obtained when combining data from different sources, in different spectral ranges, and at various spatial resolutions. A related question is how to account for the subscale thermal components associated with subscale volcanic structures (e.g., a lava dome 300 m wide compared with the AVHRR 1-km resolution). These questions are important since volcanic phenomena are highly

#### E. High-Amplitude Anomalies

Thermal anomalies are considered to be of high intensity when they include temperatures above 300°C at the centimeter scale. Lava flows, lava lakes, lava domes, and some fumarole fields fall into this category. Examples of active lava flows which have been studied include Hawaii, Mount Etna (Italy), and Lonquimay (Chile), in some cases during an eruption when the flows were advancing down the flanks of the volcano. In the case of Lonquimay, the interpretation of Landsat TM (The-

FIGURE 12 (a) Insight Vision portable video camera used to take thermal images on Telica volcano (Nicaragua) during March 1997. (b) Thermal image of the crater wall of Telica acquired with the camera. Escape of gases through fissures in the wall can be observed in this thermal image using the distribution of temperatures. The maximum temperature is about 140°C.

matic Mapper) satellite data suggested that the temperature of the crust forming the outer part of the flowing lava was in the range of 170–250°C for the top of the flow, with a very small fraction of incandescent lava at higher temperatures around 1100°C. Characterizing the

surface temperature distribution across active lava flows helps validate thermal models. For example, the viscosity of the lava depends strongly on its temperature, and a small decline in the temperature may therefore lead to a large increase in the viscosity. A thermal anomaly observed on Vulcano with the Landsat TM thermal infrared band in 1986 showed a maximum temperature of the fumarolic field of 10°C above the surrounding background temperature, while temperatures of 319°C were measured on the ground during the same period. This is not surprising, since these thermal measurements have been acquired at a different resolution: 120 × 120 m for the Landsat sensor and on the order of centimeters for the ground temperature. Various approaches recently have been used, such as the dual-band method or the multiscaling framework (see above), to account for such discrepancies in the thermal intensities versus the resolution.

Although lava lakes are uncommon, their thermal signatures also have been measured. For example, the Mount Erebus (Antarctica) and Erta 'Ale (Ethiopia) lava lakes have been observed using various satellites. Satellite thermal images of crater lakes are particularly useful in regions where field measurements are difficult or impossible to obtain on a regular basis. In the second case, complementary satellite and field data have provided an opportunity to follow the evolution of the two Erta 'Ale crater lakes since 1960.

The volcanic history of Lascar volcano (Chile), which has been well studied, is a good case study of a lava dome. While the general activity of the dome is easily monitored remotely, exhibiting a circular thermal anomaly of high intensity, the more detailed intracrater activity is more difficult to follow because of the low resolution of the images. However, it is interesting to note that the thermal intensity of the dome anomaly is observed to decrease prior to small eruptions, in relation to a pressure buildup associated with subsidence of the dome.

Another high-amplitude anomaly which has been successfully studied remotely is fumaroles. In high-temperature fumaroles, gases are generated from magmatic activity with varying concentrations of SO<sub>2</sub>, HCl, CO<sub>2</sub>, and H<sub>2</sub>O, whereas low-temperature fumaroles are dominated by water vapor. High-temperature fumarole fields have been identified at Poás (Costa Rica), Colima (Mexico), Lascar, Vulcano, and Momotombo (Nicaragua), to name a few. On Lascar, the high-intensity fumaroles along the margin of the lava dome were identified as very small spots of irregular shapes. However, because of the large abundance of volcanic gases and aerosols present above the fumarole vents, thermal measure-

ments from remote platforms have been less useful. Hence, the emitted or reflected radiations are highly absorbed or scattered by the gases and vapors which are present above a fumarolic field, and most of this radiative signal will not be received by the detector.

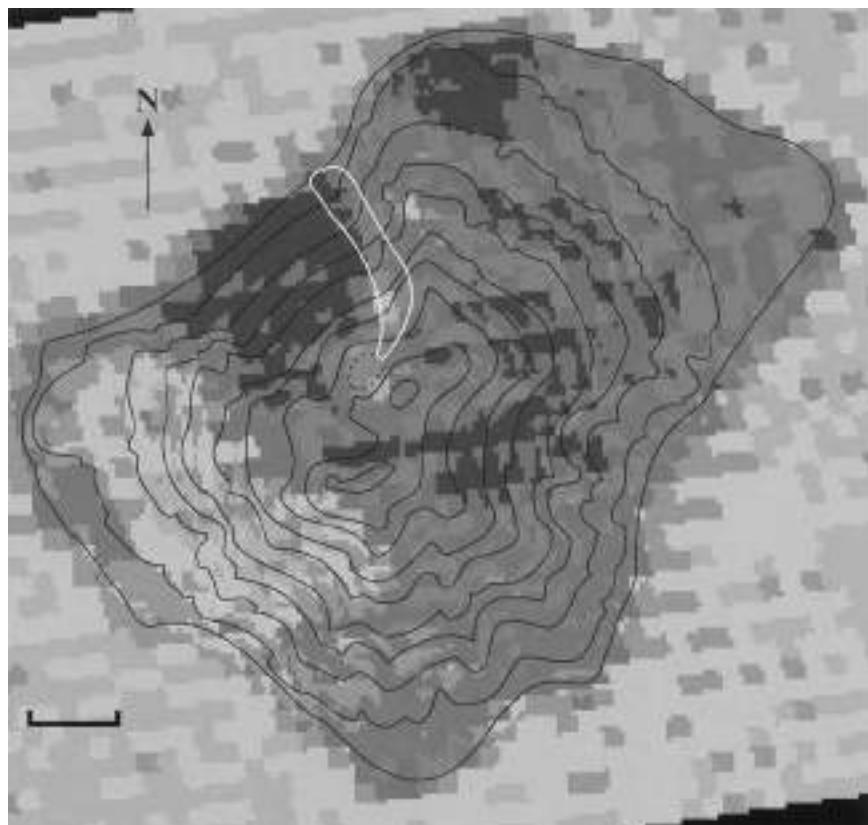

#### F. Low-Amplitude Anomalies

Weak thermal anomalies may be observed when a magma body is approaching the surface (e.g., lava tubes, magmatic intrusions), leading to low-intensity anomalies. Cooling lava flows, as well as escape of gases through fumaroles or crater lakes, also may form thermal anomalies of low intensity. In such cases, the only useful wavelength band is the TIR region. Examples of small thermal anomalies are the lava flows observed on Mount Etna 1 month after the 1986 eruption, or 11 months after the emplacement of the 1986 lava flow on Stromboli Island (Italy) (Figure 13). In this case,

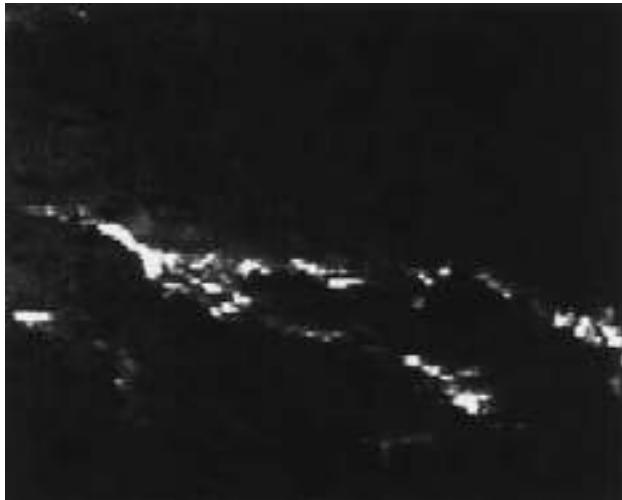

a Landsat TIR image exhibited an elongated anomaly corresponding to a 10-m-thick lava flow that had flowed down the volcano 11 months previously. This thermal anomaly was estimated from space to be 150 m wide with a relative amplitude of  $6^{\circ}\text{C}$  compared to inactive areas on the island. Two other thermal anomalies were discovered on the same image, one associated with strombolian activity present in two crater vents at the summit of the volcano and the other due to topography. This last anomaly shows the importance of knowing the relation between the thermal radiance field and the topographic field.

Most impressive is the monitoring of active lava tubes, such as at Kilauea, where the active lava is flowing in underground tubes from the crater to the coast. While the lava tubes are not noticeable in the visible part of the spectrum (e.g., with our eyes), they can be surveyed using thermal images from aircraft, helicopters, or satellites (Figure 14).

More often the low-temperature anomalies are due

**FIGURE 13** Nighttime Landsat TM Band 6 image of Stromboli with 100-m contours from 1986. An anomaly is outlined in white, representing a lava flow emplaced 11 months before the acquisition of the data. The highest temperatures are shown in light tones ( $\approx 30^{\circ}\text{C}$  at  $120 \times 120\text{-m}$  resolution), while the lowest intensities are shown in dark tones ( $\approx 18^{\circ}\text{C}$ ). The scale bar is 530 m, and the spatial resolution is  $120 \times 120\text{ m}$ . (Adapted from Gaonac'h *et al.*, 1994.)

**FIGURE 14** Digital thermal image of active lava flowing in tubes within a lava flow field at Kilauea volcano during December 1995. This image was acquired with an Inframetrics 760 video camera in the 8- to 12- $\mu\text{m}$  region from a helicopter.

to fumarolic areas which may represent a larger area than lava flows or lava tubes. Well-known examples are the fumarolic areas on Vulcano or Pozzuoli (Italy), which have been monitored for several decades. Figure 12b shows an example of a low-amplitude fumarolic field present at the bottom of the crater of Telica volcano in 1997. This image, taken with a portable video camera, provides an instantaneous distribution of the thermal anomalies observed in the field. However, temperature measurements made from the ground may be very different from estimates made from space. This is especially obvious for fumarolic fields which may exhibit a temperature variation of 200°C over several centimeters. Interpretation of the temperatures should be made with caution, especially when interpreting local variations.

The last case of low-temperature anomalies are crater lakes where the acidic water may have a variable surface temperature related to injection of magmatic gases. Examples include the crater lakes of Taal volcano (Philippines) and Poás (Costa Rica).

#### IV. FUTURE DIRECTIONS

Where will we be in 5, 10, or even 50 years' time regarding these approaches to monitoring volcanoes? We see three main avenues of development. First, technology will surely improve in terms of detection capabilities,

size, and cost effectiveness. Probably it will be possible to place *in situ* gas monitoring devices in craters for extended periods of time, allowing us to have a continuous record of gas emissions. For this to happen, the devices will need to (1) withstand the incredibly harsh environments of active craters, and (2) selectively analyze individual gases without significant interferences from other gas species. These are the main problems that confront us today. Given these problems, infrared remote sensing devices will improve to become smaller, more portable, and capable of detecting a multitude of gases. We can envision the day when infrared instruments are installed permanently on certain volcanoes to record gas data continuously. Such *in situ* and remote sensing techniques will permit volcanologists to record gas data in much the way real-time seismic data are recorded today.

Second, new generations of remote sensing instruments will be placed into orbit around the earth. These instruments will study volcanoes on a global basis. They will examine the detailed structure of volcanic plumes and track volcanic gases which are emitted. The measurements will provide three-dimensional maps of gas and thermal plumes and will allow scientists to study the interactions and effects of volcanic eruptions and emissions on the troposphere and stratosphere. Temperature measurements will continue to be made on active volcanoes, especially from remote sensing platforms. Yet, several problems will limit the interpretation of the data, such as the spatial resolution of the sensors, daytime instead of nighttime acquisition, and the distinction between different high-temperature anomalies. Other problems include the acquisition of temperatures from the ground, for example, isolated measurements, inaccessibility of the active volcanic area, and the practical impossibilities of high-resolution *in situ* mapping. Other questions arise when interpreting the thermal behavior of the surface of a volcano in relation to the activity of the volcano prior, during, and after an eruption. In the future, we expect thermal monitoring of active volcanoes to benefit from acquisition of data using sensors with higher spectral and spatial resolutions, and better models to interpret the evolution of the volcanic activity. The result will be temperature and thermal flux maps which will enhance our understanding of volcano dynamics. For example, sensors such as MODIS or ASTER, to be launched on the U.S. Earth Observation Satellite EOS-AM platform in 1999, will acquire data of the same volcanic region in various spectral bands, which may then be handled together to be either processed through the dual-band technique or through more elaborate methods of analyzing and interpreting

thermal anomalies such as the multifractal/multiscaling approach.

Lastly and perhaps most important, the new data which are provided will help scientists to better understand the overall behavior of an active volcanic system. As we develop our notions of gas solubilities, gas and heat transport in magma, and phenomena such as volcanic seismicity, we will be able to integrate this knowledge with the new data to comprehend the physical basis of how and why volcanoes reactivate and erupt. An important challenge is how to appropriately combine the various datasets in order to make significant advances in monitoring and developing robust models for volcanoes.

**T**HIS ARTICLE SYNTHESIZES the monitoring of active volcanoes using a wide range of techniques and instrumentation. It covers definitions, concepts of instrument design and use, and patterns and processes that occur before, during, and after eruptions. Ideas are illustrated using published case histories of Mount Etna, Italy, and Soufriere Hills, Montserrat. Both advantages and limitations of monitoring are discussed.

## I. INTRODUCTION

Volcano monitoring serves two key functions: it provides basic scientific data to develop our understanding

of the structure and dynamics of volcanoes, and it is crucial for hazard assessment, eruption forecasting, and risk mitigation at times of volcanic unrest. Monitoring provides the means to address questions of vital interest to communities affected by impending eruptions, such as, when and where will the volcano erupt? Which areas are safe or dangerous? When will eruptions cease? Optimal interpretation of data from monitoring, especially for the purpose of forecasting, depends critically on an adequate scientific understanding of volcano structure and processes, both in general and for each specific volcano. Thus, volcano monitoring at its most effective is a synergy between basic science and hazard assessment.

Historically, volcanic activity has been considered to be primarily of local interest because, with the exception of relatively infrequent large explosive events, most eruptions seriously affect small areas of only a few km<sup>2</sup>. As populations expand, however, more people are at risk from the direct or indirect impact of volcanic eruptions. In addition to the immediate hazards posed by eruptive products to life, property, and food production, volcanic activity of any kind may have a significant effect on the economy. During minor eruptions tourism may increase and boost the local economy. The loss, however, of agricultural farmland, farmhouses, communication and service infrastructure (roads, ports, water supplies, elec-

tric cables, etc.), and permanent changes in the local groundwater and drainage system can have severe economic consequences. A volcanic disaster on one side of the world can now have a significant economic impact on countries on the other. It is therefore of interest to all nations that volcanoes are monitored so that eruptions can be forecast and mitigating action taken. Successful mitigation of the local effects of an eruption (such as lava flow diversion and community evacuation) requires a detailed understanding of the eruption process, for which monitoring data are a vital component. More widespread effects can be mitigated to some degree with early warning, for example, allowing aircraft rerouting. Similarly, an appreciation of the climatic effects both locally and globally requires data from surveillance before, during, and after eruptive activity.

Volcano monitoring comprises the systematic checking of various types of geological, geochemical, and geophysical data at a volcano. Each type of data (such as measurements of temperature, gravity, or earthquakes) provides information about physical processes which may be related to movement of molten rock or other eruption precursory phenomena. All the available data should be synthesized in a coherent way so that interpretations may be arrived at that are consistent with all the observations. This interpretation then serves as a guide to anticipate what may happen next, and provides an opportunity to take appropriate mitigation measures.

Monitoring is complicated by the fact that data come in at different times and in different formats. Some data can be viewed "raw," but other data must be processed first, causing additional delays. For example, a seismic drum record may show that an earthquake has occurred, but additional processing is necessary to determine magnitude and location.

Monitoring results may be ambiguous. For example, thermal anomalies may occur if lava is erupted, but can also result from fires and from solar heating of the ground. Similarly, ground deformation may be caused by the injection of magma prior to eruption, but also by water table movements.

Until relatively recently, the only way to monitor a volcano was to watch it, and the amount of warning that could be given would depend on the communication between the lookout and the local population. For example, although Pliny the Elder was in a good position to assess the eruption of Vesuvius in 79 A.D., he was unable to provide any assistance to the fleeing people of Herculaneum and himself perished at Stabiae. Some people may have escaped by boat, but for most, there was insufficient time to evacuate. Modern techniques of volcano surveillance involve the use of a wide range of physical

and chemical measurements, some of which require lengthy laboratory work to analyze and some of which provide instant results. Each technique has advantages and drawbacks of some kind, but the more methods that can be used at one time, the better the chances of detecting precursory variations and therefore of being able to provide a warning. The most appropriate techniques to use depend on the type and scale of the hazard envisaged.

Thirty years ago volcanologists concentrated their efforts on field observations including seismic tremor, magnetic intensity, and thermal and gas output. About 20 years ago, advances in methods and technology allowed better modeling and lab experiments. In the last decade, completely new technologies involving satellites, GPS, SAR interferometry, and digital data, and the easy transmission of data from remote locations to computers in observatories and laboratories for automatic analyses and interpretation, have provided dramatically better data resolution at some volcanoes. Thus the potential exists to use better and more complete data to monitor volcanoes, but with higher initial costs and more equipment to maintain.

Monitoring a volcano has some similarities with monitoring the health of a patient. Some tests, such as checking a pulse, are simple and direct. Others, such as blood tests, take time to perform and to analyze, but provide fuller results. Like volcanoes, people can show similar symptoms that may be related to a wide variety of illnesses or conditions. For example, a simple skin rash may be caused by a minor and temporary allergic reaction, or it may herald a terminal disease. New fumaroles may open up at a volcano simply because the previous path for passive degassing has become blocked by precipitation of minerals, or because a new batch of gas-rich magma has been intruded to shallow depth. The first situation may not be too serious, but the second certainly is. Monitoring techniques were formerly based on the most easily measured phenomena; other effects were either not recorded or were treated as noise. Future progress will be enhanced by taking account of these more subtle or complex effects and by the more comprehensive acquisition and real-time analysis of continuous data sets over extended periods.

## II. INSTRUMENTS AND NETWORKS

The instruments used to monitor volcanoes vary widely in type, sophistication, cost, and effectiveness. Some

instruments are permanent; once installed they continue to collect data for long periods of time (e.g., a seismic network). Other instruments are usually deployed in temporary networks (e.g., gravimeters) whereas others are driven or flown in the vicinity of volcanoes to make measurements (e.g., COSPEC). It is important to realize that only a small number of the world's active and potentially active volcanoes are being monitored today. There is not a single volcano at which all these types of instruments are simultaneously in use over an extended period of time. However, several volcanoes have had at least some measurements of each type, and these are the ones about which the most is known.

### A. Seismic Monitoring

A century of seismological data testifies that seismic unrest in the form of earthquakes and tremor almost always precedes and/or accompanies volcanic unrest at all types of volcanoes. Seismic activity is considered to be the best indicator, and often a reliable short- to midterm (days to weeks) forecaster, of the level and evolution of volcanic activity. Seismic monitoring is one of the most common surveillance tools used by geophysicists and the equipment is fairly cheap and simple to install, although data collection and transmission become difficult in remote areas. Once the background seismicity has been characterized for a particular volcano, changes in the level or intensity, or appearance of different types of events, may herald the onset of activity. However, the resolution of the technique is not always very good, and sources (such as the movement of volcanic gases or cracking of rocks as fresh magma is intruded) are difficult to distinguish unless there are several seismic receivers spread out near the active crater. Successful forecasts of eruption have been made using seismology, and countless lives were recently saved after evacuation around Pinatubo and Mayon volcanoes (Philippines) following seismic precursors to renewed activity. However, although Galeras volcano (near Pasto, Columbia) was monitored for seismic precursors, none were observed for several hours prior to the fatal eruption in January 1993.

Seismic sources at volcanoes are highly complex and involve the interaction of gases, melts, and solids. The role of the melt and gas may be either (i) active, giving rise to pressurized intrusions of magma into preexisting or newly formed zones of weakness, or to sustained vibration of the melt and host rocks, or (ii) passive, where brittle failures and the consequent stress readjustments

modify the distribution of melts in the crust. Since volcanic media comprise dense systems of pores, fractures, and faults at all scales, sudden modification of the local stress field may induce seismic failure independent of melt propagation. These factors contribute to the substantial degree of ambiguity in volcano eruption forecasting on the basis of seismology alone.

### B. Ground Deformation

Ground deformation is another relatively cheap and common technique for volcano monitoring. Repeated measurements of relative vertical height and/or horizontal distance are made, and changes often precede a change in activity. Traditionally measurements have been made with levels and EDM (electronic distance measurement) theodolites, but GPS (global positioning system) measurements using a constellation of more than 20 satellites are being used increasingly. GPS monitoring provides a measure of changes in the distance to a satellite from any number of ground-based receivers by moving the receivers from place to place during a survey; thus, a large ground deformation network can be covered. The advantage of this method over the conventional ground deformation techniques is that it is quicker and less labor intensive, and is not dependent on clear weather. Another new satellite-based technique that has revolutionized ground deformation monitoring is synthetic aperture radar (SAR) interferometry, which involves taking radar "pictures" of large areas (such as a whole volcano) and comparing the image taken with images obtained on previous passes of the satellite (approximately monthly observations are currently possible). Differences between the images reflect ground deformation and the method is sensitive to movements of a few centimeters. However, these measurements cannot be made in areas with abundant vegetation, steep slopes, or snow cover.

It is usually assumed that a volcanic edifice behaves elastically, and that as pressure builds up within or beneath it, the volcano expands in a predictable way to accommodate the increased stress. However, brittle fracture rather than elastic deformation also occurs at volcanoes and the effect is that ground deformation is abrupt, often contemporaneous with eruption, rather than gradual and precursory. Thus, like seismic monitoring, this method is unreliable on its own for the forecasting of volcanic activity. Further, even though instruments are in place, some eruptions have no measurable deformation associated with them.

### C. Gas Monitoring

Volcanic gas analysis and temperature measurements are also commonly made. Precursory variations have been observed prior to some eruptions, but often the changes occur with the beginning of the eruption. The measurements are rather difficult to make within active volcanoes, as they necessitate someone climbing right down into the vent. Even modern high-sensitivity equipment must be located close to the source for accurate observations to be made. Satellite measurements of infrared radiation (temperature) can be made, although the source (a vent in a volcanic crater) is often too small for quantitative observations. Similarly remote measurements of SO<sub>2</sub> gas flux can be made, and while these methods are useful for monitoring the progress of an ongoing eruption, they are limited in application for eruption forecasting. Sharp increases or decreases in SO<sub>2</sub> may be precursors, but the measurements cannot be made continuously so information may be missed.

### D. Gravity and Magnetic Monitoring

The strength of a potential field varies with distance from the source, but never falls away to zero. Thus observation of gravity and magnetic fields can be made at relatively safe distances from the source, and provided they are made over a wide enough area, can reveal significant precursory variations. Magnetic precursors to eruption have yet to be observed, partly because the field is very complicated in volcanic regions. Gravity measurements are ambiguous without simultaneous elevation (ground deformation) observations, but the combination has been found to be an extremely powerful tool for volcano monitoring. The combined technique, which has become known as microgravity monitoring, has been found to be capable of detecting precursory changes within a volcano that other techniques have not resolved.

---

## III. MONITORING BEFORE ERUPTIONS

There is a period of time between the end of dormancy and the onset of eruptive activity, that may last days, weeks, years, or even decades, during which processes go on inside and beneath a volcano in "preparation" for eruption. These processes can be detected by making measurements at the surface and are termed "precursors."

Before magma or gases are erupted at the surface, they must either be transported from a deep storage region to a shallow region for temporary storage, or simply intruded into pipes and dikes feeding to the surface without storage (hence the difference in "preparation" time described above). Often the first observed signal is a change in deformation. If the magma movement is deep, the signal is small and spread out over a wide area. If it is shallow, then the deformation signal is stronger and is concentrated in a smaller area. The same processes that cause deformation also frequently cause small fractures to occur below ground level which are detectable as earthquakes. The earthquakes may occur in swarms at areas of stress concentrations—such as nearby faults—and in the immediate vicinity of magma where pressure changes are occurring (earthquakes do not occur in magma itself because magma is a liquid and has no shear strength). Magma movement may also disturb the local water table, and changes in flow and temperature of groundwater may be detected using a variety of electromagnetic techniques.

When magma is ascending the gases dissolved in it change their relative concentrations because different gases have different solubilities. Carbon dioxide (CO<sub>2</sub>) has very low solubility so it is the first to exsolve. Areas of CO<sub>2</sub> release have killed trees and other vegetation at several sites on Mammoth Mountain, California. Other gases such as chlorine (Cl) and sulphur (S) exsolve at shallower depths, and measurements of the Cl/S ratio can help determine whether fresh magma is present at shallow depths. The total amount of SO<sub>2</sub> also typically increases and may reach several hundred or even several thousand tons per day when magma reaches very shallow depths. Gases may begin to escape from newly opened vents at this time, and changes in the gravity and magnetic fields may also occur as the subsurface density and magnetic properties respond to the intrusion. Ground deformation may accompany all these phenomena.

Another common precursor is evidence of increased heat. Typically the temperature at fumaroles increases, and the average ground temperature may increase as well; this is especially easy to spot on snow-covered volcanoes because the snow melts.

The precursors to an eruption will depend on the type of volcano. Basaltic volcanoes tend to erupt freely flowing lavas, and the precursors might be a swelling of the volcano associated with the intrusion of magma into the edifice and the corresponding mass increase (observed as a gravity increase). Andesitic volcanoes erupt explosively and so the precursors might be a build up in volcanic gas pressure beneath the surface or the intrusion of magma within the edifice. These would be seen as net microgravity decreases and increases, respectively,

possibly associated with ground deformation. Calderas erupt large volumes explosively, and although a large caldera eruption has not been observed, it is thought that such an eruption may be triggered by the intrusion of hot basaltic magma into a reservoir of more silicic magma. The silicic magma would become superheated and the dissolved gases would rapidly expand and escape to the surface. The bubbles would entrain hot magma that itself would be degassing rapidly. Magma intrusion should be detectable as a gravity increase, while increased gas content would appear as a gravity decrease.

At a volcano that has not been historically active, or one where ground surveillance is not available, the first information that an eruption is imminent may come from "remotely sensed" or satellite thermal infrared data. The area near the vent may appear as a "hot spot," an area that is significantly warmer than its surroundings. Hot spots often grow larger with time as more heat affects the Earth's surface. The appearance of a new lava lake in a crater can be seen using these techniques, for example, although strictly speaking, an eruption has already begun by this stage. When magma is very close to the Earth's surface, incandescence may be seen in cracks, areas of steaming ground appear, lakes (of water) dry up, cracks and bulges may be evident, and volcanic tremor occurs on seismometers.

Many or all of the monitoring techniques available could, in theory, detect the processes that occur before an eruption. The problem is that monitoring networks are costly to install and maintain and it is very rare to operate a network "just in case." Therefore, unless a network has been previously installed and happens to be capable of providing data during the buildup phase prior to eruption, precursors are likely to be missed simply because the relevant observations are not made.

#### IV. MONITORING DURING ERUPTIONS

Interestingly, and perhaps surprisingly, the most important yet ambiguous monitoring data are those collected during an eruption. The processes that occur during an ongoing eruption involve the movement of magma and gases from a shallow storage or feeder region to the surface. During an eruption, the feeder system remains open and variations in geophysical phenomena that can be measured (seismicity, potential fields, temperatures, etc.) are limited as the process, albeit rather violent in some cases, is continuous and the changes in physical properties which are exploited by monitoring techniques are not occurring. However, there may be some changes

during an eruption, such as in the ratio of gases species, the gas flux, etc., that can be detected. These observations provide valuable information about the next stage in the eruption (whether it will be more or less explosive, involve a large volume of magma extrusion, etc.). Variations in the degree of magma vesiculation may occur during an eruption and these can be monitored using microgravity methods. Disturbances of the water table or hydrothermal system can be detected using seismic and electromagnetic methods.

We next approach what happens during eruptions by considering several different types of eruptions.

##### A. Explosions

An explosion is a very short-lived (a few seconds) but energetic event. When a strong explosion occurs at a volcano, seismic waves are generated in the ground, acoustic waves in the atmosphere, and a plume starts to rise. Seismic waves travel at several km/s so the seismic ground waves are often the first signal recorded on monitoring instruments. Air waves travel more slowly, about 330 m/s, so these take several tens of seconds to reach instruments on the flanks of a volcano, either microphones, barographs, or seismometers (the air wave couples back into the ground). Gas is suddenly expelled during the explosion. Plumes rise at rates of 50–100 m/s, so these may be observed locally and seen on satellites as they rise and spread laterally with the wind. Depending partly on atmospheric conditions, lightning may form within an ash plume, as early as tens of seconds for Surtsey volcano but more typically 5 to 20 minutes after charge separation has occurred. Deformation may include static strain steps as well as permanent changes in the shape of the vent, such as the excavation of a large crater. Gravity changes will accompany ground deformation (as the ground goes up, the value of gravity decreases). Any long-period seismicity associated with the explosion will be seen as noise on a gravity meter located within a few kilometers of the vent. There are not likely to be significant magnetic variations directly associated with explosive activity.

##### B. Sustained Explosive Eruptions

A sustained explosive eruption may occur on a timescale of a few minutes to a few hours. Such events are very energetic, and produce primarily ash and tephra. The onset of such an event produces seismic waves and acoustic waves as above, and a plume rises as well. However,

when sustained, the seismic disturbance is continuous and long lasting (volcanic tremor) and the strength of the signal is proportional to the intensity of the eruption. This typically changes as a function of time within the sustained eruption. Gravity changes are likely to be associated with ground deformation and seismicity but magnetic changes are not expected. Acoustic waves are continuous or episodic, and typically occur in bursts during strong pulses of explosions. In some cases acoustic waves can be heard 200 km or more away from the volcano. Lightning occurs in the eruption column a few minutes after eruption onset, and continues to occur for as long as the eruption lasts. Some lightning extends from the ash cloud to the ground, and some extends between charged regions within the ash cloud (intracloud lightning). If the plume is injected into the stratosphere, the amount of SO<sub>2</sub> can be estimated by TOMS satellite measurements. Plumes may travel hundreds of kilometers downwind, connected to the vent, and when the eruption stops, the plume continues to travel as a discrete mass carried by the winds. Some plumes have remained hazardous several days after the eruptions that produced them have ended. Large plumes that reach the stratosphere have been known to circle the Earth.

### C. Effusive Eruptions

Effusive eruptions produce lava flows instead of tephra. They are thus not explosive. The seismic signal produced by effusive eruptions is volcanic tremor, which may have a very gradual onset. The strength of the tremor varies with the rate of flow of lava. Since no explosions occur, no air waves are produced, although a hissing sound may be heard at close range. The ash plumes from effusive eruptions are typically small, rising to 1 or 2 km, so lightning is rare. (Ash plumes from effusive eruptions may account for less than 1% of the total erupted volume.) Deformation is of several types. New lava flows cover and change the shape of the land surface. Effusive eruptions often start at fissures, and the flow later localizes to one or more cylindrical vents. Each of these has a characteristic pattern of deformation which occurs before and during the eruption. Gravity is affected by the deformation, and the presence of new material on the surface will increase gravity. The filling and emptying of subsurface dikes and feeders also affects the gravity (causing increases and decreases respectively). Magnetic intensity will increase over a lava flow or dike as it cools, but decrease over a dike or feeder as it drains.

---

### V. MONITORING AFTER ERUPTIONS

#### A. General Cases

It is not easy to predict the beginning of an eruption, but it is even more difficult to predict the end of an eruption. Partly this is a problem of definition. A volcano never looks quite the same after an eruption as it did before and so it cannot return to exactly the state it was previously in. Therefore the definition of the end of an eruption may be rather subjective. It is clear when lava is no longer coming out of a vent, but there may be gases still being emitted, and lava flows take weeks or more to cool down to ambient temperatures. In some cases, the end of an eruption means simply the end of a particular phase of activity, or a type of activity. For example, a volcano may move from a continuous lava flow coming from a distinct vent to sporadic, strombolian activity from another vent. By some definitions, the volcano is still erupting; by others it is quiescent. It rather depends on the normal state of activity of the volcano and the experience or prejudices of the observer. Here we define an eruption as the flux (mass flow per unit time) of lava through a vent, including steam and gases. This is an operational definition to help put boundaries on the subject at hand; other definitions appear throughout this encyclopedia.

Most explosive eruptions, those that produce ash and tephra, generate volcanic tremor as the eruption is under way. In particular, the strength of the tremor is proportional to the intensity of the eruption as measured by ash column height or flux. Thus when an eruption wanes and approaches its end, the tremor decreases and reaches background values. Tremor generally accompanies each phase of eruption, and may occur between phases and after the last eruption as well. Earthquake swarms often occur throughout eruptive sequences, with some clusters of events associated with eruptive phases and some as indications of changing stresses in the vicinity. As eruptions near their ends, the swarms typically decay in rate with a power law, very similar to aftershock sequences following large earthquakes. Thus the two chief seismic indicators, earthquake swarms and tremor, both decay from high levels to background levels as eruptions are ending.

Lightning often occurs in ash columns of explosive eruptions, beginning a few minutes after the onset of the eruption. Lightning also ends as the eruption ends because the supply of new material cases; the new material is needed to produce charged particles and separate them. When this stops happening the lightning stops.

At the end of an eruptive period when intruded magma is cooling and solidifying *in situ*, the ground may begin to subside slightly due to thermal contraction. At the same time, as magma cools it will acquire a magnetic signature measurable at the surface and the density may increase, raising the values of the magnetic and gravity fields at the surface.

Degassing decreases also, although frequently it decays slowly and sporadically. Gas may continue to be released months or even years after an eruption.

Tephra eruptions deposit large amounts of unconsolidated material on steep slopes. If water is abundant, either rain or glacial, then lahars may be easily formed and may continue to occur for months or years after eruptions end. Low-magnification seismometers placed near flow channels may serve as effective lahar sensors. Several sensors are needed along channels at intervals of a few kilometers to be able to tell if a lahar is moving and to estimate its speed.

Although the eruption of lava and ash onto the ground may end, some of the finest ash, gases, and aerosols may remain suspended in the air for quite some time. If the suspended particles reach the stratosphere, they may be carried by strong winds all the way around the globe. One component of monitoring, satellite remote sensing, is concerned with precisely such ash clouds. In addition to climatic effects such as global cooling, the fine particles cause additional abrasion to airliner leading edges and produce "crazing" of windows, resulting in more frequent replacement. Thus the economic effects of eruptions—one component of the hazard—can last for years.

## B. Restless but No Eruption

A large-magnitude caldera-forming eruption has not taken place since volcano monitoring techniques have been developed. However, although a caldera eruption is less likely to occur than a smaller, explosive eruption such as occurred at Pinatubo, its effect would be so devastating that calderas in regions of dense population are monitored closely. There were crises during the 1980s at two such calderas, Rabaul (Papua New Guinea) and Campi Flegrei (Naples, Italy). In both cases, the ground rose up by over a meter and gravity decreased (as would be expected for an elevation increase), but not by as much as it should if the gravity change could be attributed solely to the height change. Thus in both cases, an overall increase in subsurface mass occurred (approximately  $10^{11}$  kg), but in neither case did an erup-

tion follow. Thousands of microearthquakes occurred beneath and adjacent to each caldera, but virtually no volcanic tremor was detected. Thus while it seems that magma was added to the reservoir of silicic magma beneath the calderas, there was apparently not enough to cause the catastrophic superheating expected to precede an explosive eruption. Although the amount of ground uplift was large enough to be alarming, the calculated increased volume of magma was small (a few percent), and so the risk in fact was small, although in both cases people were evacuated temporarily. Rabaul eventually erupted in 1994, but this was nearly 10 years after the seismic and deformation crisis. This implies that appreciable amounts of time may pass between the time when the magma reservoir is replenished and the time when the volcano finally erupts.

---

## VI. CASE HISTORIES

### A. Mount Etna

#### 1. Introduction

Mount Etna is important to the economy of Eastern Sicily, with agriculture and summer and winter tourism providing employment for thousands of people. Although there are no permanent homes within 10 km of the summit, year-round human activities on the upper slopes are proliferating and the risks from even a small eruption are consequently magnified. The earliest form of monitoring at Etna, as for other volcanoes, was direct observation. A huge array of monitoring techniques have been tested on Etna; methods that have proved successful in monitoring and sometimes in predicting eruptions include observations of seismicity, ground deformation, and microgravity. These, together with electromagnetic, magnetic, gas geochemistry, and various remote sensing techniques, have also provided key information on the volcanic plumbing system and the eruption process.

Techniques applied during the 1989 and 1991–1993 Etna eruptions are taken as examples of volcano monitoring today. The high level of activity at Etna and its easy accessibility have led to most available techniques for volcano monitoring, and some involving mitigation, being tested there. In 1989, 4 months of strombolian activity at the summit craters was followed in September by an effusive eruption from the southeast (SE) crater and the opening of two fractures. A noneruptive south-southeast (SSE) trending fracture extended more than

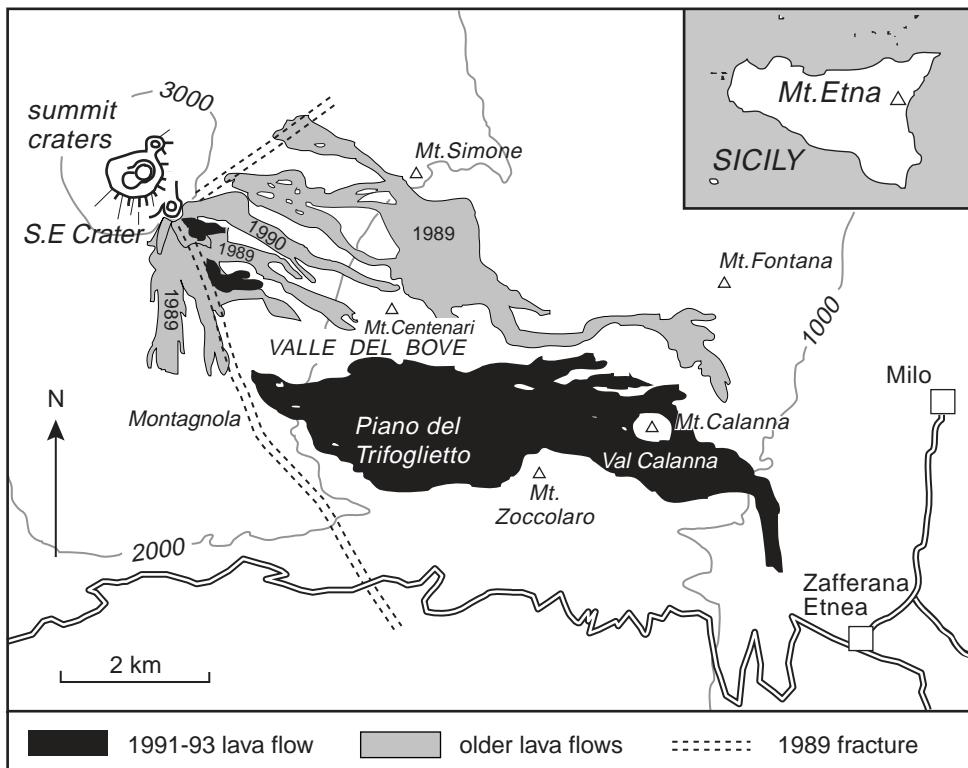

FIGURE 1 Index map of the summit region of Mount Etna, Italy. The 1991–1993 lava flow is shown in black and older lava flows in gray. Prominent fracture systems are indicated by pairs of dashed lines. Elevation contours are in meters.

7 km from the summit (Figure 1), passed close to the headwall of the Valle del Bove, and crossed the road between the Sapienza and Zafferana Etnea. The north-east (NE) trending fracture extended about 2 km from the summit crater area and lava was erupted along much of its length. No further activity occurred until a small explosive eruption from the SE crater in January 1990.

Activity on Etna was then unusually quiet until 14 December 1991 with the start of the most voluminous eruption since the end of the 1669 eruption. The activity was largely confined to a single bocca within the western wall of the Valle del Bove [2200 m ASL (above sea level)] erupting  $231 \times 10^6 \text{ m}^3$  of lava at an average rate of  $5.7 \text{ m}^3 \text{ s}^{-1}$ . The flow was more than 8 km long and threatened the town of Zafferana Etnea when it was successfully diverted. The eruption ended on March 31 1993, after 471 days.

## 2. Seismology

The first instruments set up to record earthquakes at Etna were deployed in the early 1900s; however, the first network of seismometers was not established on Etna until 1973. This network, comprising two to six

stations recording the short-period vertical component of seismic waves, was used to investigate eruption-related earthquakes and volcanic tremor. These studies showed that shallow (1–5 km) seismic activity usually preceded flank fissure eruptions by a few days. In contrast precursory seismic activity is not usually associated with summit eruptions, although they are often accompanied by tremor. Increased levels of tremor energy are consistent with an increased probability that an eruption may occur within weeks, days, or even hours. Modern seismometers detect ground vibration in three dimensions over a range typically of 0.1 to 10 Hz. “High-frequency” events (several hertz) are usually associated with deep (several kilometers) fracture events, while “low-frequency” events and tremor are thought to be caused by forced resonance of fluids in shallow (few kilometers) volcanic conduits.

A new seismic array was being developed and expanded on Etna by the Istituto Internazionale di Vulcanologia, Catania, prior to the 1989 activity, and data from up to 22 seismometers were available for analysis and comparison. Seismicity at Etna remained at background levels until July 1989 when a 10-km-deep (below

sea level, or BSL) magnitude 2.9 event beneath the southeastern Valle del Bove, and later a seismic swarm, heralded the onset of renewed activity. A second swarm in August 1989 originated only 5 km BSL. No noticeable seismicity occurred subsequently until the beginning of eruptive activity in the SE crater in September 1989 when a further swarm and large individual events, some of magnitude >3.0 to the northwest of the summit craters, occurred. These events may have been linked to the opening of the NE trending fracture that erupted a small amount of magma (Figure 1), while several hundred shallow seismic events over a 2-day period (1–2 October) accompanied the opening of the noneruptive SSE trending fracture (Figure 2). Although the causative mechanism of the seismicity is unclear, a temporal relationship exists between the occurrence of the swarm and the propagation of the fracture beyond the scarp of the Valle del Bove. No definitive evidence for shallow magma beneath this fracture was found (see below). Volcanic tremor throughout the 1989 eruption correlated strongly with eruptive activity; in particular a sharp increase in tremor amplitude always accompanied the change in activity from weak strombolian, to strong strombolian, to lava fountaining, to lava flows.

There was no further noteworthy seismic activity observed from the end of the 1989 eruption until 1 month prior to a small explosive eruption from the NE crater in January 1990. The brief explosive activity in 1990 was associated with a significantly higher amplitude tremor than the 1989 eruptions.

Seismic activity on Etna ceased until January 1991. Earthquake swarms were located along the NNW-SSE trending structure, along which magma later rose to

erupt in December 1991. Focal-plane solutions and the hypocentral pattern for these data have led to the suggestion that activation of the intrusion at depth occurred about 2 months before the eruption. The foci of the events became shallow (1–4 km BSL) only 1 week before the eruption began.

### 3. Ground Deformation

Like other flank events, this eruption appears to have been fed by a near-vertical dike, but in this case there were two dikes radiating from the SE crater. In the first, the magma traveled NE and intersected the surface, erupting lava. In the second, the magma traveled SSE but did not reach the surface though it did cause fracturing. There is evidence for dike intrusion up to 3 km from the summit along the SSE fracture, but the pattern of ground deformation at the distal end of the fracture was characteristic of an elastoplastic medium, and therefore was not linked with magma intrusion.

Precise leveling and triangulation measurements were made before, during, and after the 1991–1993 event. Data from over 300 stations in the summit region of Etna revealed a narrow trough of more than 1 m of subsidence running SSE from the summit, connecting the SE crater with the eruption site, flanked by two zones of inflation up to 37 cm to the east and 7 cm to the west (Figure 3a). This is consistent with a syneruptive dike intrusion at a depth of 450 m to its top and 1100 m to its base.

GPS is now widely used; by placing two or more GPS receivers either permanently or for the duration of a survey at locations of interest, the user can obtain  $x$ ,  $y$ ,

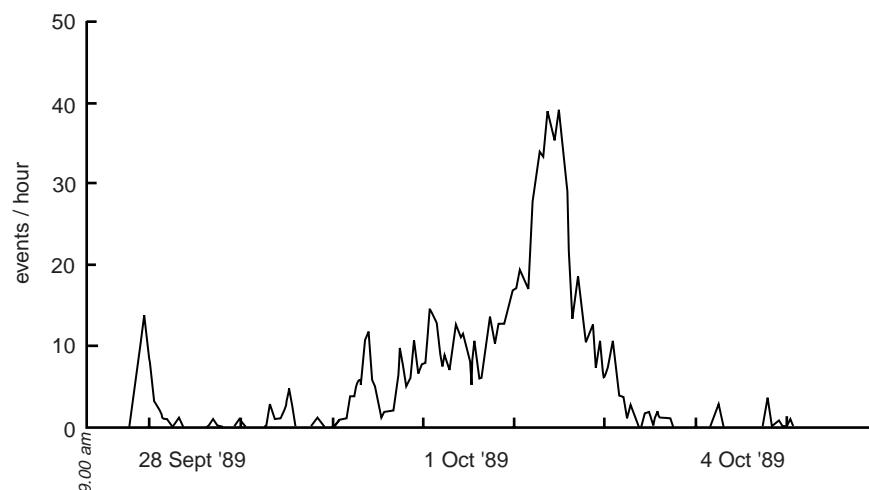

FIGURE 2 Number of seismic events per hour at Mount Etna for late September to early October 1989.

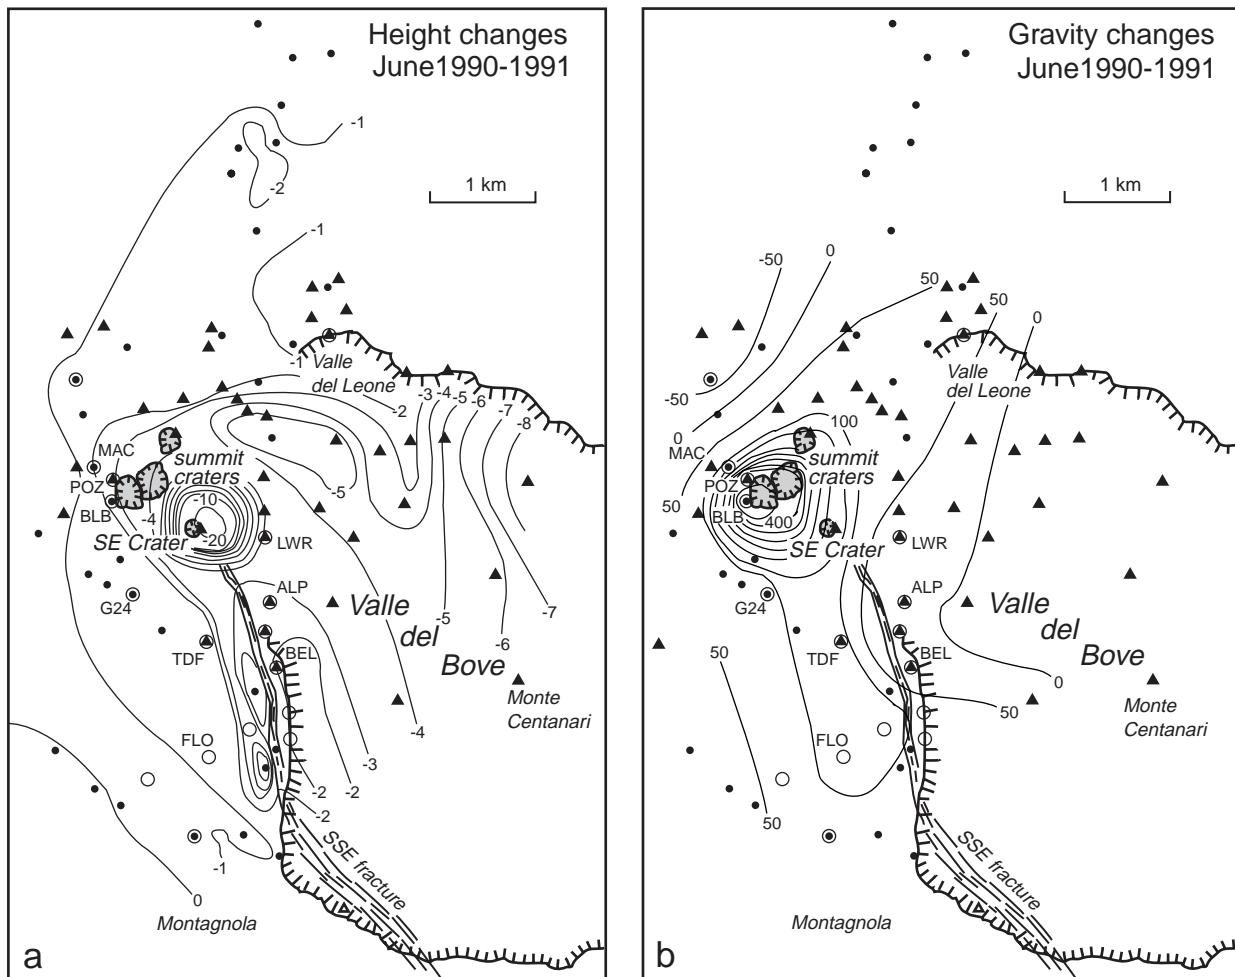

FIGURE 3 Height and gravity changes at Mount Etna from two surveys in June 1990 and June 1991. (a) height changes in cm; (b) gravity changes in milligals. For both, note the stronger gradient (closer contour lines) near the summit craters.

and  $z$  coordinates for each location with centimeter or even subcentimeter precision horizontally and vertically. Feasibility studies on the possibility of using permanently fixed receivers capable of automatically tracking satellites and recording and transmitting data for automatic processing and storage began on Etna in 1988. Data collected during the 1991–1993 eruption on a network of stations over the summit of the volcano extending down the flanks as far as Catania indicate that contraction of the whole edifice occurred during the first months of 1992. This has been modeled in terms of depressurization within a source (magma storage region) 1.5–3.5 km BSL. The volume of magma erupted during the same period exceeds the volume loss within the modeled region, suggesting this relatively superficial storage region may be linked to a deeper feeder system.

GPS technology has improved dramatically since 1993, and permanent stations have now been established at several key locations on and around the volcanic edifice. In addition, twice yearly campaigns now aim to occupy stations in the summit and flank areas; results have shown consistent radial expansion since 1992, consistent with relaxation of the edifice.

#### 4. Microgravity

Etna was one of the first volcanoes to be studied using microgravity; the technique typically involves repeated high-precision surveys in which the relative value of gravity at a number of stations is determined. Repeat microgravity surveys are used to investigate subsurface mass changes. Since their effect is sensitive to variations in the distance from mass anomalies, microgravity data

must be corrected for height changes and hence these surveys must always be accompanied by a ground deformation survey.

A microgravity increase (ca. 20  $\mu\text{Gal}$ ) attributed to a shallow (few hundred meters depth) source was observed across the southernmost end of the SSE trending non-eruptive fracture a few days after formation in October 1989. However, neither these data nor data from a network of microgravity stations around the volcano flank at an elevation of 1500–2000 m provided evidence in support of a magma intrusion associated with the fracture process.

The period June 1989–November 1989 was characterized by a gravity increase in the summit region (up to 100  $\mu\text{Gal}$ ) and was followed by a decrease of similar magnitude between November 1989 and June 1990. These data imply subsurface mass increases of  $10^9$ – $10^{10}$  kg followed by decreases, and are consistent with the eruption of  $10^9$  kg of pyroclastic material in January 1990. Between June 1990 and June 1991, although there was no surface eruptive activity, there were significant gravity changes (Figure 3b) in the summit area; the changes are too large by an order of magnitude to be caused by the minor deflation observed over the same period. The data have been interpreted in terms of a passive (aseismic) intrusion of magma into the pre-stressed region beneath the 1989 SSE trending fracture. The intrusion must have occurred some time between June 1990 and June 1991, several months after the formation of the surface fractures and several months before the onset of the 1991–1993 eruption. The intrusion

appeared to be in the location of the dike that fed the later eruption (Figure 4). Relative microgravity values remained constant in the vicinity of the fracture zone after the end of the 1991–1993 eruption, but decreased and subsequently increased again by 1994 in the summit crater region. This suggests that intruded magma solidified within the fracture zone, and the magma level within the summit feeder fell and then rose again, which is consistent with the increased summit activity observed since 1994.

### 5. Tidal Gravity

Microgravity data are corrected for the effects of Earth tides (up to ca. 200  $\mu\text{Gal}$  peak-to-peak, diurnal) before interpretation. A predicted Earth tide can be calculated for any location which represents the vertical component of gravitational acceleration on a solid, uniform Earth but does not account for variations due to topography, rheological heterogeneities, and ocean loading. Use of the predicted tide is satisfactory for many applications of microgravity (it is good to better than 8  $\mu\text{Gal}$ ). Currently there are continuously recording tidal gravimeters operating at Serra la Nave (for control) and at the Torre del Filosofo (TDF) near the summit. Clearly, although the spatial resolution of tidal gravity data is very limited compared with that provided by a microgravity survey, the temporal resolution is considerably improved (typically one observation per minute rather than several per year), which allows the rates of processes (such as dike intrusion, magma emplacement/drainage, etc.) to be determined.

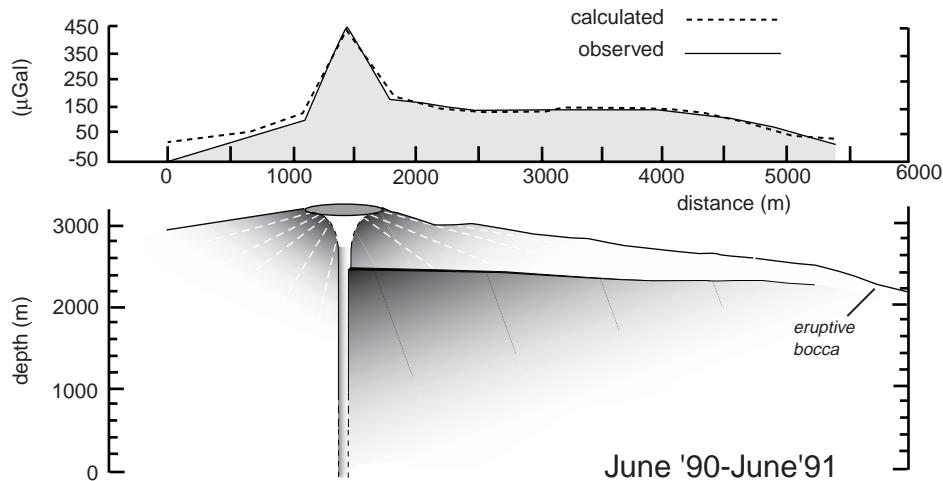

FIGURE 4 (top) Theoretical (dashed line) and observed (solid line) gravity profiles at Mount Etna. The theoretical curve is determined from a model of the distribution of light and dense rocks. (bottom) Model of a dike emplacement at Mount Etna. The dike is shown as the dark gray shaded structure extending to the right from the main conduit.

### **6. Self-potential (SP)**

Several electromagnetic techniques have been used to investigate variations in electrical conductivity due to subsurface volcanic structures. SP measurements, for example, made across the lower part of the SSE trending fracture after the end of the 1989 eruption, with an electrode separation of 110 m over a profile length of 1.32 km, showed two large positive anomalies up to about 100 mV in magnitude and several hundred meters in wavelength. These were interpreted in terms of shallow (near-surface) fluid movements in response to magma intrusion. These data therefore suggest that magma was intruded at depth beneath the SSE trending fracture during the 1989 active period although there was no eruption south of the summit. The SP anomaly was attributed to the heating of water in saturated rocks by volcanic gases from the intrusion. Regular SP observations (approximately monthly) between October 1989 and April 1993 showed that the anomaly gradually decreased, which was considered to be consistent with such a heating process.

### **7. Gas Geochemistry**

Magmatic intrusions can influence the concentration of soil gases. For a period of several days after the formation of the SSE trending fracture, H<sub>2</sub>, CO<sub>2</sub>, CO, and <sup>222</sup>Rn variations were monitored at the distal end of the fracture in an attempt to determine whether or not a magmatic intrusion was responsible. Continuous CO<sub>2</sub> flux monitoring revealed a dramatic increase from ~500 to 2000 ppm about 1 week after the appearance of the fracture, but the flux returned to normal values after 1 day. Although the <sup>222</sup>Rn activity was 5 times higher in the fractured region than in the adjacent unfractured areas, it was not possible to prove a link between the data and degassing of a magmatic body because observations were in the range previously measured in Etnan soil gases.

The 1991 eruption was preceded by a relative decrease in CO<sub>2</sub> flux across the distal part of the SSE trending 1989 fracture, suggesting that as magma rises, degassing preferentially occurs through the main conduits in the summit area. Some rapid fluctuations of soil gas fluxes across the SSE trending 1989 fracture also occurred during the 1991–1993 eruption. These results suggest that soil gas monitoring along the flanks of Etna can be useful for detecting early phases of volcanic unrest, while monitoring of degassing from the summit or fractures can provide early indications of near-surface magmatic intrusion.

### **8. SO<sub>2</sub> Flux**

The most widely used non-satellite-based instrument for remote sensing of volcanic plume compositions is the correlation spectrometer (COSPEC). The relative absorption of solar UV light by a volcanic plume is analyzed along with plume width and wind speed to give an estimate of the flux of SO<sub>2</sub> molecules. Relatively low SO<sub>2</sub> flux has been identified previously as a precursor to eruptions on Etna.

A slow increase in SO<sub>2</sub> flux was observed from August 1989, with a transition from a low, 1000 metric tons per day (T day<sup>-1</sup>) to medium values (7000 T day<sup>-1</sup>) by mid-September. During the second half of September and coinciding with the opening of the eruptive NE trending fissure in the Valle del Leone, SO<sub>2</sub> flux increased to an average of 15,000 T day<sup>-1</sup> and peaked at 23,000 T day<sup>-1</sup>. The flux decreased after this time and was at a low of 850 T day<sup>-1</sup> just 5 weeks before the 1991 eruption began. During the 1991–1993 Etna eruption, COSPEC measurements were taken regularly—sometimes as much as twice weekly. Comparison of data from the summit craters and the SSE trending 1989 fracture during the first few months of the eruption showed an anticorrelation which may indicate that while the magma is degassing significantly from the summit craters, the magma from the fissure is relatively volatile poor and vice versa (Figure 5). It was not often possible to compare the flux from the summit and fissure sites as the plumes were usually quickly mixed by the wind. The average SO<sub>2</sub> flux during the eruption was 5800 T day<sup>-1</sup>, but in April 1992 it dropped to 980 T day<sup>-1</sup>—this may have presaged the introduction of new magma to recharge the volcano feeder system.

### **9. Remote Sensing**

Fumarole and ground temperature increases have been found to precede volcanic eruptions. Changes in the radiant energy flux, or even the ground temperature of a volcano, can be measured remotely via satellite or airplane and can, in certain circumstances, provide eruption precursor information. Remote sensing is a fast growing field of volcano monitoring as more data and software become readily available. Data from the thematic mapper (TM) carried by the Landsat satellites and the advanced very-high-resolution radiometer (AVHRR) carried by NOAA satellites have been used to test the viability of the technique at Etna.

Airborne TIMS (thermal infrared multispectral scanner) data were collected in the summit and SE flank regions immediately after the cessation of eruptive activity in 1989. The temperature distribution in lava flows

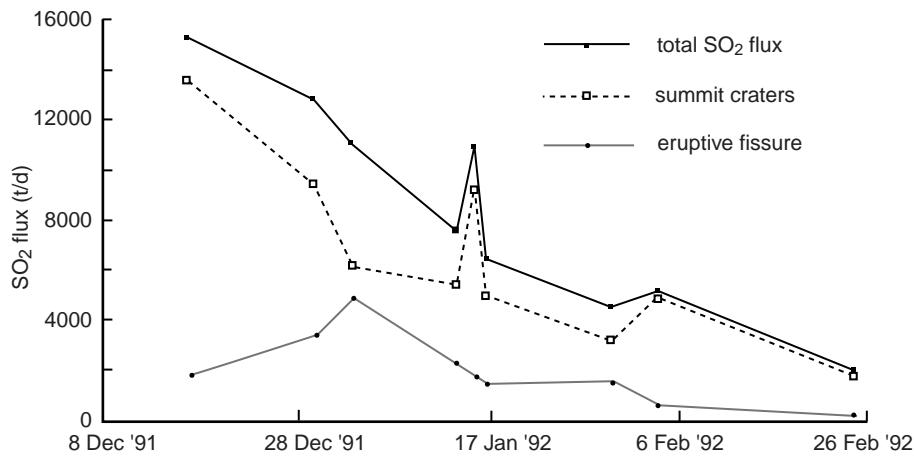

FIGURE 5 Sulfur dioxide ( $\text{SO}_2$ ) flux in tons per day at Mount Etna from 8 December 1991 to 26 February 1992. Measurements were made at the summit craters and near the eruptive fissure. The two were added together to give the total.

identified using this technique agreed well with “ground truth” observations made on the ground, but no thermal anomaly was detected along the SSE trending fracture. This supports the conclusion based on other data that the opening of at least the lower end of this fracture was not driven by the shallow intrusion of a dike. The possibility of real-time volcano monitoring using remote sensing came closer during analysis of the 1991–1993 lava flow field using AVHRR data. Ground truth data and lava flow maps were used to confirm remote sensing estimates of lava flow volume, active lava area, thermal flux, and effusion rates. Although this technique does not have an application for eruption prediction, it could provide frequent information on the progress of an inaccessible lava flow, the sites of secondary breakouts, and assessment of the associated hazards.

### 10. SAR Interferometry

Synthetic aperture radar satellites illuminate the Earth’s surface with microwave radiation and can be used for mapping topography to high precision. Provided that a reliable digital elevation model (DEM) is available, images obtained on ascending and descending orbits of the host satellite can be obtained. Interferograms are obtained by combining two such images and removing the effects of topography. Images for Etna during the waning stages of the 1991–1993 eruption indicated possible volcano-wide deflation. There are concerns, however, about the validity of this model as almost simultaneous ground surveys with GPS did not show the

deflation, and there seems to be a strong correlation between apparent elevation change and topography.

### B. Soufriere Hills Volcano, Montserrat

#### 1. Introduction

The reactivation of Soufriere Hills volcano, Montserrat, on 18 July 1995 took many people by surprise, including those who lived on the island. Yet there were signs beforehand that the volcano was preparing itself for eruption. Montserrat is part of the Lesser Antilles island arc, formed by the westward subduction of the North American tectonic plate beneath the Caribbean plate. Soufriere Hills is the active volcano on Montserrat, located on the southern part of the island. The volcano consists of a horseshoe-shaped crater which is open to the east. The crater was partly filled with remnants of a lava dome which probably had been emplaced around 1600 A.D. The youngest volcanic rocks are hornblende-bearing andesites.

Periods of seismic activity were recorded in 1933–1937 and 1966–1967; the seismicity was located underneath or near Soufriere Hills volcano. The seismic activity may have indicated shallow movements of magma beneath the volcano, and the activity could be regarded as “abortive eruptions.” Increased levels of seismicity were again recorded beginning in 1992, with a significant increase in deep earthquakes in November 1994. The three episodes demonstrate the cyclic nature of the

seismic swarms which appear to occur approximately every 30 years. The seismicity may represent intrusion of mafic magma into a holding reservoir at depths of 5–10 km.

No direct precursory activity was noted in the days immediately preceding the beginning of activity on 18 July 1995, although it should be noted that the monitoring equipment only comprised a seismic network. It is possible therefore that certain precursory signals were not recorded or observed.

## 2. Early Activity, July 1995 to January 1996

Initial activity consisted of phreatic explosions and cold base surges. No solid material such as glass shards was observed in the ash to indicate the presence of new magma. Yet SO<sub>2</sub> flux measurements by COSPEC correlation spectrometer showed values of 300 T day<sup>-1</sup> on average initially, with SO<sub>2</sub> increasing to 800 T day<sup>-1</sup> in early August 1995 immediately before a seismic swarm. The high levels of SO<sub>2</sub> are clearly indicative of magma residing at shallow levels beneath the volcano, with the seismic swarm implying magma intrusion or ascent. The early activity at Soufrière Hills nicely illustrates the problem of whether a reactivation of a volcano is "magmatic" or "nonmagmatic." The lack of fresh glassy ma-

terial in the ash does not indicate the presence of magma, while the high SO<sub>2</sub> levels clearly do.

This style of activity continued for approximately 4 months, accompanied by volcanotectonic earthquakes. In late September 1995 a small lava dome was extruded in the crater; the extrusion was immediately preceded by shallow hybrid seismicity. The hybrid seismic events are characterized by a high-frequency beginning and a long-period coda. A lava dome began to be extruded continuously in mid-November 1995, preceded by deformation in the crater area. During this time, the rate of dome extrusion was less than 2 m<sup>3</sup>/s, which was low compared to subsequent activity (Figure 6). This slow growth also was reflected by hornblende crystals which had reaction rims, indicative of slow magma ascent at shallow levels where hornblende was unstable and had time to react.

## 3. Accelerating Dome Growth, January to July 1996

The extrusion rate of the dome accelerated to about 2 m<sup>3</sup>/s in January 1996 (Figure 6). The first pyroclastic flows from collapse of the dome occurred in late March 1996 and were directed eastward due to the horseshoe-shaped nature of the crater.

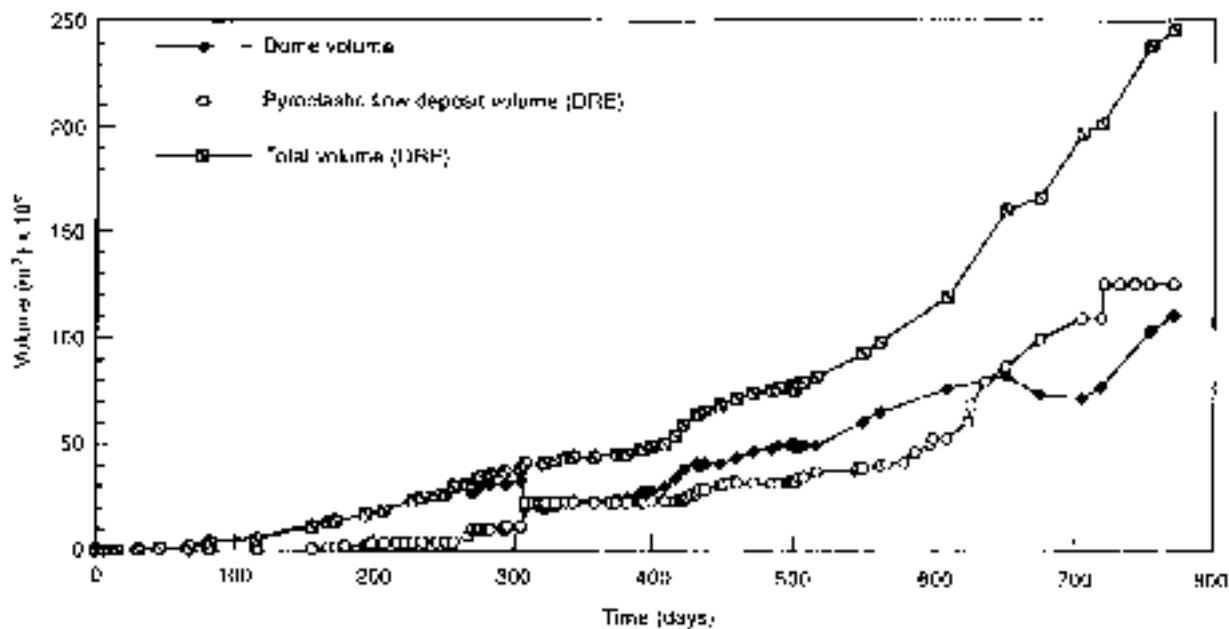

FIGURE 6. Diagram showing cumulative volumes of material erupted from Soufrière Hills volcano since 15 November 1995. Pyroclastic flow deposit and total volumes expressed as dense rock equivalents, dome volume is not. Note the generally accelerating rates with time. [From Sparks, R. S. J., Young, S. R., Barclay, J., Calder, E. S., Cole, P., Darroux, B., Davies, M. A., Druitt, T. H., Harford, C., Herd, R., James, M., Lejeune, A. M., Loughlin, S., Norton, G., Skerrit, G., Stasiuk, M. V., Stevens, N. S., Toothill, J., Wadge, G. and Watts, R. (1998). Magma production and growth of the lava dome of the Soufrière Hills volcano, Montserrat, West Indies: November 1995 to December 1997. *Geophys. Res. Lett.*, **25**, 3421–3424]

The extrusion rate accelerated further in July 1996 to greater than  $4 \text{ m}^3/\text{s}$  (Figure 6). This was a critically important time period for a number of reasons. First, as a result of the increased effusion rate, collapse of the dome occurred both more frequently and on a larger scale, generating larger pyroclastic flows in the process. Second, the magma appeared to rise at a faster rate, as shown by the lack of reaction rims on hornblendes. Third, the magma contained larger quantities of gas, as shown by higher  $\text{SO}_2$  fluxes (at times  $>500 \text{ T day}^{-1}$ ) and dome rocks with higher vesicularities than previously. The enhanced activity in late July 1996 was characterized by many hybrid seismic events, accompanied by increased levels of long-period seismicity. Cyclic tremor also appeared, termed "banded" by the visual observation of bands of tremor on seismic paper records. The banded tremor was sometimes accompanied by increased degassing or steaming from the dome.

Taken together, the monitoring data suggest that magma rose at an accelerated rate, thereby impeding degassing of the magma during its ascent. As a result, magma which emerged at the surface was more gas-rich. An alternative but related interpretation is that magma in the reservoir became richer in gas at this point. The higher gas contents propelled magma to the surface at an accelerated rate. This second hypothesis implies that the magma reservoir was open to replenishment by gas-rich magma from deeper levels. The two hypotheses may both have validity.

#### 4. High Dome Growth Rates, July 1996 through 1997

The first magmatic explosive eruption began on 17 September 1997, prompted by large collapses of the dome beforehand. The eruption was preceded by increased levels of hybrid and long-period seismicity, which reached their highest levels 5–6 days before the eruption. The seismic data suggest that the interior of the dome was pressurized and richer in gas. When the interior was exposed by the collapses, the explosive eruption ensued. A blast, surges, and pyroclastic flows containing pumice were generated by the explosion. The lack of rims on hornblendes in the pumice suggests that the magma rose quickly to higher levels, being able to retain a significant fraction of its original gas content. The presence of pumice in the pyroclastic flows is direct evidence for high gas contents in the magma prior to the eruption.

High levels of dome growth, magma production, seismicity, and  $\text{SO}_2$  flux continued through the end of 1996 and into 1997 (Figure 6). Magma was intruded near the southwest crater wall in late 1996, thereby deforming

and destabilizing it. By March 1997, material from the dome overtopped the weakened southwest wall, producing pyroclastic flows to the south for the first time. By June 1997 similar events occurred on the northern and eastern crater walls, also generating pyroclastic flows. The capitol of Plymouth was directly threatened by these events. On 25 June 1997 a large collapse occurred on the northeastern part of the dome, sending pyroclastic flows and accompanying surges in these directions which killed 19 people. Cycles of hybrid seismicity and deformation were observed to occur during this time (Figure 7). The cycles had periods on the order of tens of hours. During an individual cycle, it was observed that the highest level of hybrid seismicity corresponded with the peak of inflation. Immediately afterward, rockfalls and pyroclastic flows were generated, sometimes accompanied by minor vulcanian eruptions. The cyclic behavior was used to forecast likely times when pyroclastic flows would occur. The data suggest a model of repeated pressurization of the dome by rapidly ascending magma and gas release at shallow depths.

In August 1997 a series of vulcanian explosive eruptions occurred which produced pyroclastic flows on all flanks of the volcano. The eruptions were preceded by several days of elevated long-period seismicity. The eruptions were associated with cycles of seismicity and deformation similar to those observed in late June, and the individual hybrid seismic events sometimes merged into continuous tremor. The eruptions occurred immediately after the peaks in hybrid seismicity and inflation, lending credence to the overpressure hypothesis. Vulcanian eruptions also occurred in September 1997, but without hybrid seismic swarms. By 1998, the dome growth had slowed somewhat, although it continued to be active.

#### 5. Summary

Perhaps the two most notable aspects of the Montserrat eruption have been the accelerated dome growth in 1996–1997 and the episodic nature of this growth. The acceleration clearly implies a reservoir of magma which is open to inputs of magma from deeper levels. The episodic growth is interesting and enigmatic, perhaps partially a function of the very viscous andesite magma which may impede continuous magma ascent and dome growth. It is clear that in July 1996 the volcano underwent an important change and enhancement in its activity, possibly as a result of magma intrusion at deep levels. All major collapses of the dome have been preceded by enhanced levels of hybrid seismicity, implying increased internal pressures beforehand. The eruption of 17 September 1997 was preceded by a major collapse event

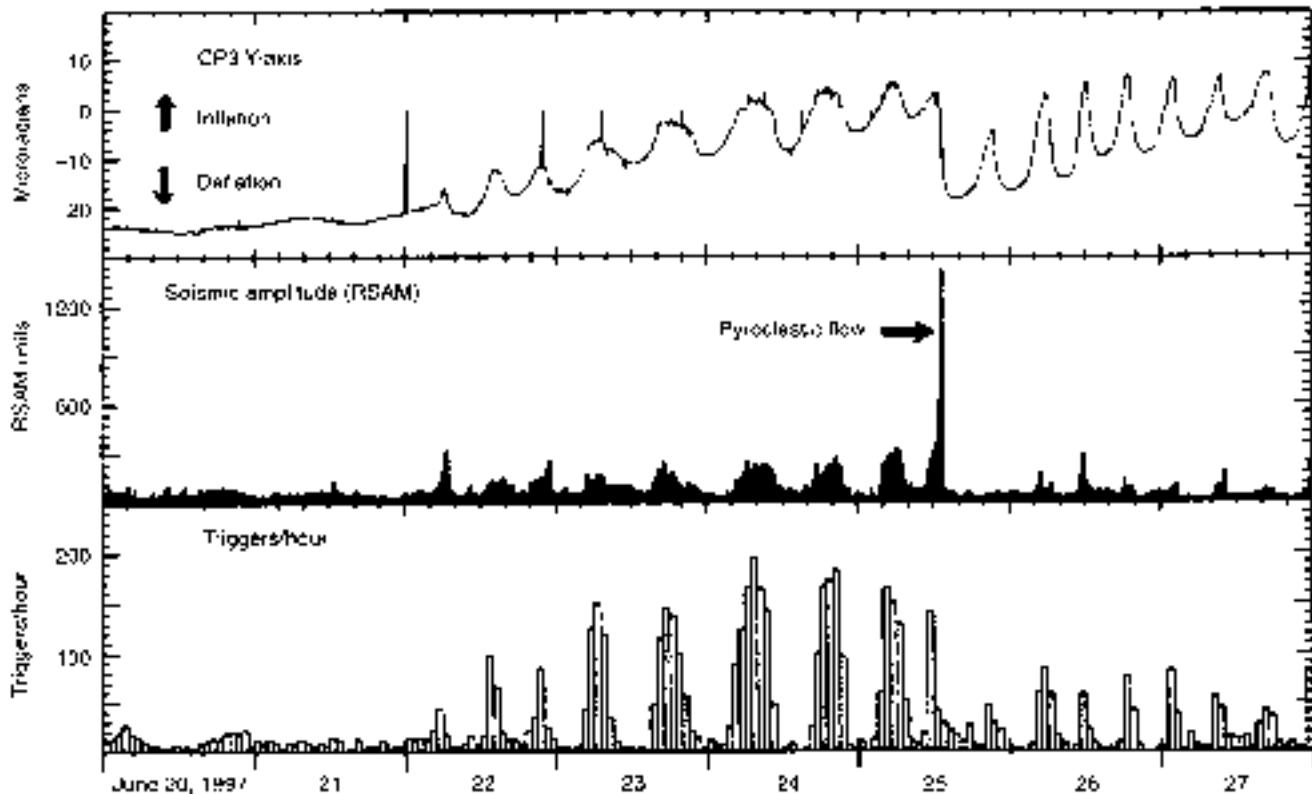

FIGURE 7 Diagram showing cyclic behavior of hybrid seismicity and deformation, 20–27 June 1997, at Soufrière Hills volcano. Note the overall increase in inflation and seismicity before 25 June. The lethal pyroclastic flow on 25 June occurred immediately after the peaks in seismicity and inflation. [From Voight, B., Hoblitt, R. P., Clarke, A. B., Lockhart, A. B., Miller, A. D., Lynch, L. and McMahon, J. (1998). Remarkable cyclic ground deformation monitored in real time on Montserrat and its use in eruption forecasting. *Geophys. Res. Lett.*, **35**, 3405–3408]

which exposed comparatively deep regions of the dome at the surface. Perhaps there is a depth threshold within the dome beyond which explosive eruptions are triggered. The model of internal dome pressure is also supported by the 1997 cycles of hybrid seismicity and deformation.

## VII. DISCUSSION

### A. Techniques Alone versus in Combination

Most of the monitoring techniques discussed in this article can give ambiguous data or, in worst cases, can give misleading data or even fail to give needed data. For example, earthquake swarms may happen during eruptions or when no eruption is occurring. If a large regional earthquake happens to occur, it will swamp the

seismometer for several minutes so that any volcanic signals cannot be seen. Further, instruments are subject to noise and physical damage. Radio and electronic interference can degrade many types of telemetered data, and eruptions themselves, or related phenomena like lightning, can damage or destroy instruments. Therefore it is generally best not to rely on only one instrument or one type of data, but rather to consider data from several different types of instruments simultaneously. This can increase the complexity of a volcano observatory but provides more complete information upon which to base decisions.

As an example, volcanic tremor is a common and fairly reliable precursor to many eruptions. However, there are many incidences of tremor without eruption. If satellite thermal data are available at the same time, then images may be checked for the presence of hot spots or plumes. Coincidence of tremor, hot spots, and plumes would be reasonably compelling evidence that an eruption was occurring, especially if the presence of ash in the plume could be determined. As another example,

gravity data alone may indicate that a change has occurred, but gravity data along with precise geodetic data permit the identification of whether water, air, or magma has been intruded (assuming a gravity increase).

The second or later data not only provide additional measurements, but they also provide confirmation that the activity is real or significant. A number of documents such as response plans for volcanic crises require more than one type of data to trigger various alert levels. Typical needed data include earthquakes or tremor, deformation of the ground such as bulges or cracks, and evidence of juvenile gases or heat. These have all occurred together during many well-documented eruptions, so the presence of all of them has a strong likelihood of being real precursors which must be taken seriously.

### B. Reliability, False Alarm Rate, and Safety Margin

Many types of data occur over various size ranges, and the small signals are “safe” whereas the larger ones indicate significant hazard. Thus a threshold must be determined which will serve as a guide to judge the appropriate level of concern. Examples would be earthquakes of a certain magnitude or deformation of a certain amount. Once a threshold is agreed upon, however, several issues arise. It is possible to make the threshold too sensitive: this means the dangerous signals will definitely be registered, but with a very high false alarm rate. Alternatively, the threshold may be set too high: this will keep the false alarm rate low, but may miss the onset of dangerous activity. A few minutes extra warning time may not seem like a lot, but could be significant for a commercial jetliner traveling at 8 miles per minute. The ideal threshold minimizes the false alarm rate while providing the earliest warning. Thus it gives the highest reliability and safety margin. Appropriate threshold estimates may be made in advance of eruptions, but then need to be fine tuned as the activity evolves, because physical changes may occur at the volcano.

### C. Intrusions versus Eruptions

One of the main large-scale problems of monitoring volcanoes is that many of the signals regarded as precursors, such as earthquakes and deformation, occur before both eruptions and intrusions. The reason the signals look the same is that the processes are the same at depth, differing only in whether or not the magma reaches the

Earth's surface. Thus not every geophysical event is regarded as a precursor; they often simply drive an additional inquiry or checking of other data.

Calderas are notorious for having high levels of unrest, so there are lots of potential precursors. For example, Long Valley caldera in eastern California has experienced more than 25 earthquakes of  $M = 5$  or larger, uplift of 60 cm, degassing of CO<sub>2</sub>, long-period earthquakes, local deformation, and increased heating, all in the last 19 years. No eruption has occurred, but it is thought that several intrusions of magma to depths of about 5 km have occurred. Thus, it is clear that intrusions do not always result in eruptions; the challenge is to decide if an intrusion will progress to an eruption or not.

---

### VIII. VOLCANO MONITORING IN THE FUTURE

While monitoring solely for the purpose of risk mitigation may reduce loss of life or property to a degree, its effectiveness can be greatly improved through the concurrent development of scientific methods and enhanced understanding of volcanic processes. Given the average interval between eruptions at many volcanoes, volcano monitoring tends not to be a high spending priority of governments, yet major volcanic eruptions can be national (and international) social and economic disasters.

Future developments in volcanic monitoring will depend on many factors including technological advances, improvements in analytical and interpretation methods, the ability to successfully integrate multiple data sets, and having detailed knowledge of volcanic structure and processes. The continued development of robust, inexpensive, and effective technologies for monitoring volcanoes is a vital and sometimes urgent requirement for volcano-affected countries. Advances in electronics in recent decades have helped progress toward cheap expendable sensors, thus reducing the inherent financial risk of losing expensive monitoring equipment and greatly benefiting the monitoring of volcanoes in developing countries. The World Wide Web has added a new standard for communication and it is now routine at some volcano observatories to run analyses tasks automatically and to post the results on web pages. These can then be checked on demand by anyone with a computer and modem. The web protocols have made it no longer necessary for each observatory to develop its own unique way of handling data.

The importance of a good knowledge of the geological and volcanic history and the nature of background activity at each particular volcano cannot be overemphasized; if what is "normal" is not known then the "abnormal" cannot readily be recognized. Again we appeal to a medical analogy: we know that a person's normal temperature is 98.6°F, so this provides the basis for identifying a fever. Most of the world's potentially active volcanoes, however, are not currently monitored. Furthermore, since no reliable laws of forecasting can be determined from the data collected by volcanologists to date, multiple integrated monitoring methods are needed at each volcano.

Monitoring techniques were, of course, originally based on the most easily measured phenomena; other phenomena were either not measured, or filtered from the signal as noise. The recording and analyses of these more subtle or complex effects using a variety of methods are the future of volcano monitoring. For example, it is now recognized that three-component and broadband seismometers provide vital information on shallow magmatic processes and should be incorporated into any volcano-seismological network. In the case of microgravity monitoring, the effects of the Earth tides are subtracted from the data before analysis and modeling. Advances in technology and analytical methods, however, will allow modeling of the response of both the volcanic edifice and the plumbing system to tidal effects, from which further insight could be gained into eruption precursors and processes at depth.

Traditionally, most types of data (e.g., for gravity or ground deformation) have been recorded periodically at a number of stations. Data collection in such cases is labor intensive, time consuming, and hence expensive and only provides "snapshots" of the real picture. Ideally, continuously recorded data at numerous stations should be telemetered to an observatory at which initial analysis could take place automatically, in real time, as has been achieved at some seismic networks. Recent advances in telemetry make such systems more viable, and once established would be less labor intensive and, in times of eruption, safer.

GPS and SAR have the potential to revolutionize ground deformation studies given the large areas that can be covered simultaneously. Since these methods give information of broad-scale changes they would be particularly effective in determining the significant edifice-wide inflation that might be expected to precede a dramatic change in eruptive style. COSPEC data are likely to become more reliable and consistent as more instrumentation becomes available and data collection becomes automated. Other promising techniques for

remotely investigating volcanic gases, for example, GASPEC, which measures CO<sub>2</sub> flux, and Fourier transform infrared (FTIR) spectroscopy, which measures the ratio of various gas species, are currently being developed. For example, variations in the SO<sub>2</sub>:HCl and HCl:SO<sub>2</sub>:SiF<sub>4</sub> ratios have been measured using FTIR. Multispectral infrared instruments to be carried by the first Earth Observing System satellite, due for launch in 1999, will greatly expand the capabilities and accessibility of spaceborne remote sensing for both thermal and gas studies.

Potential developments in analysis and interpretation include improvements to automatic detection and processing (ADP) of seismic data such that the large volume of data generated by an intense seismic swarm can be processed and that real events can be more reliably distinguished from noise. The effectiveness of ADP depends on the density and geometry of the array compared with the extent and depth of the active zones; data from the 1989 and 1991–1993 events on Etna suggest an array density of one seismometer per km<sup>2</sup> is required to resolve events associated with shallow magmatic intrusion. The Integrated Mobile Volcano Monitoring System developed by the USGS for use in volcanic crises was used to very good effect in the 1991 Pinatubo eruption; however, portable seismometers do not constitute an adequate alternative to permanent recording stations. While they provide satisfactory monitoring during volcanic events, they have no role in background surveillance or in recording the onset of seismic activity. Advances in interpretation will require more detailed knowledge of the structural complexities and heterogeneities typical of volcanoes in order to develop adequate models. Recent advances in nonlinear, high-resolution three-dimensional seismic tomography, for example, may allow the detailed interpretation of broadband seismic data. Such broadband data with a period greater than a few seconds are considered to be associated with mass transport and are currently the subject of much research into their causative mechanisms.

Although seismology will remain the most important monitoring tool for the foreseeable future, the integration of seismic data with results from other methods, for example, geodesy, gravity, electrical, and gas and temperature flux, will be far more powerful. "Smart" systems using artificial neural networks (ANNs) are now being developed to integrate the vast quantities of data resulting from technological developments to produce the simplest best-fitting models consistent with as much of the data as possible. Such systems, however, are only as good as the input data, and hence the need for detailed structural models and background information. Impor-

tant questions in contemporary volcanology include, what are the processes that trigger eruptions? Can the timing and location of an eruption be predicted? Is it possible to determine in advance the nature of an eruption and its likely duration? These issues present pressing problems both to basic science and to affected societies; they are being studied at several active volcanoes using a combination of geophysical and geochemical techniques.

The priority now in volcanic monitoring is the acquisition of more data and the development of rapid and reliable methods to collate, analyze, and interpret them. We do have some basic understanding of the mechanisms and processes operating within some volcanoes but we now need to expand this knowledge by integrating the experience gained from decades of independent researches. As well as technological and scientific advances, effective communication and interaction between volcanologists, civil authorities, and the affected populace are required to improve the mitigation of volcanic disasters.

## GLOSSARY

**acceptable risk** Risk that an individual or community is willing to accept, or that a public official is prepared to allow persons in his or her charge to accept. Acceptable risk is a function of the benefits of risk mitigation (safety and avoided losses) and its costs (losses of jobs and business, community disruption, the costs of transportation, housing, and food for evacuees, and costs of any structures to divert hazards). Tolerance for risk varies considerably, mainly because the benefits and costs of mitigating risks vary greatly from individual to individual and community to community.

**intermediate-range** Pertaining to the coming months and, occasionally, years. Intermediate-range forecasts are typically issued when a volcano is restless (or even erupting) but an eruption (or sharp change in an ongoing eruption) is not thought to be imminent.

**long-range** Pertaining to the coming years, decades, or longer. For most long-range hazard forecasts, also called

“hazard assessments,” the volcano in question is dormant and any seismic, ground deformation, or fumarolic activity is at background levels.

**short-range** Pertaining to coming hours, days, and weeks. Short-range or “immediate” forecasts or warnings are issued when unrest (or an eruption) is escalating sharply, or a hazardous eruption has just begun.

**volcanic hazards** Potentially damaging eruptive and post-eruptive phenomena such as pyroclastic flows, wind-borne ash, lava flows, volcanic gases, lahars, and large landslides. In probabilistic assessments, “hazards” are the probabilities of such phenomena.

**volcanic risks** The adverse effects of volcanic hazards, and the product of (*volcanic hazard*  $\times$  *vulnerability* to those hazards  $\times$  *value* of what is at risk). In probabilistic assessments, “risk” means the probability or likely magnitude of loss, calculated by the same formula.

MOST VOLCANIC ERUPTIONS leave deposits that allow reconstruction of eruptive histories and generalized projection of future activity. On shorter timescales, most eruptions develop over periods of hours to decades, announcing progress at every step. Most pre-eruption unrest and eruptions are driven by exsolution and expansion of a volatile phase, and associ-

ated failure of confining rock, both of which can be detected by geochemical and geophysical monitoring.

Officials and citizens can take precautionary actions on the same timescales. Thus, warnings of future eruptions or the further course of ongoing eruptions can avert many potential losses from volcanic hazards, including most loss of life and some economic and social losses.

To succeed, a warning must be:

1. *Accurate.* Accurate about the “what, when, and where” of volcanic hazards.
2. *Understandable.* In plain, nontechnical language, supplemented, if possible, by video or other images.
3. *Timely.* Early enough for recipients to take needed precautions.
4. *Widely disseminated.* Reaching all who need to hear it, for either individual or official decisions about mitigation.
5. *Credible.* From a trusted source or based on ample data and clear logic, and presented with enough certainty that it can be used for mitigation decisions.
6. *Catalytic.* With clear suggestions about what recipients can do to avoid the threat, and convincing reasons why these actions are preferable to inaction.

---

## I. THE BASIS AND CONTENT OF VOLCANO WARNINGS

### A. Pre-eruption Warnings

Three types of pre-eruption warnings are long-range forecasts and hazard maps; intermediate-range forecasts; and short-range forecasts. Each requires different data as input and different strategies for dissemination.

1. *Long-range forecasts and hazard maps.* For most volcanoes, the first warnings will be an assessment of the long-range likelihood of eruptions and a map of the areas that are subject to various eruptive impacts, for example, to lava flows, pyroclastic flows, eruption-induced mudflows, or ashfall >10 cm thick (Figure 1). Such assessments typically rely on the geologic or recorded history of eruptions at the volcano in question, estimation of the recurrence frequencies of various sizes and severity of eruptions, and the areas that have been affected by each type and scale of eruption. Some long-range forecasts are without memory of the previous eruption and assume a Poisson distribution of eruption years and magnitudes. Other forecasts “remember” the

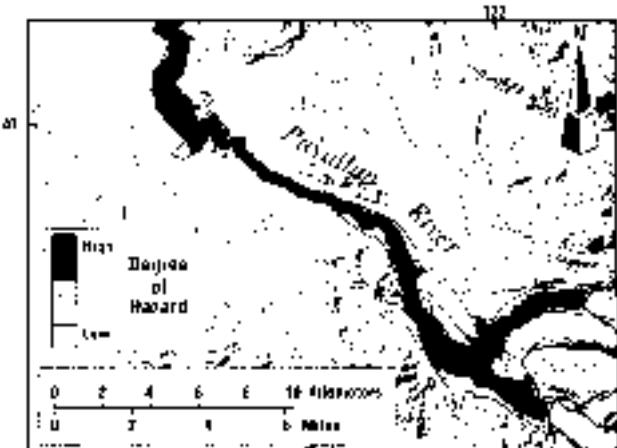

FIGURE 1 GIS-based hazard map, in this case for lahar hazard in the Puyallup River, northwest of Mount Rainier. Pre-existing lahar hazard boundaries (heavy lines along the valley walls) bracket deposits of prehistoric lahars. Grayscale “degree of hazard” is based on empirical equations that predict lahar inundation as a function of local topography (DEM) and lahar volume. The two match each other closely in this reach of the river. Gray area outboard of the white zone is not subject to lahar hazard. Modified from Iverson et al. (1998) by L. Faust.

year and magnitude of the previous eruption, especially if the volcano in question exhibits a pattern of regularly spaced (time-predictable) eruptions, or eruptions whose magnitudes are proportional to the length of the preceding repose (volume-predictable). Long-range forecasts also consider any tendency for eruptions to occur in clusters or to show cycles of eruptive behavior. Long-range forecasts and hazard maps are needed for land-use planning and for development of emergency plans.

2. *Intermediate-range forecasts.* Whenever unrest begins that might lead to an eruption within weeks to months, volcanologists may issue a warning such as, “The volcano is restless and might erupt within weeks to months, and needs to be watched closely.” At such an early stage of unrest, it is usually impossible to forecast the exact day or week of an eruption, or even whether an eruption will occur at all. Such forecasts help scientists and public officials to increase surveillance of the volcano, to review their emergency plans, and to renew public education about volcanic hazards.

3. *Short-range forecasts.* When a restless volcano gives a strong signal that it will erupt within hours to days, urgent short-range warnings are issued. Such warnings will be as specific as possible, including probable vent(s), areas subject to each hazard, and the estimated date, time, and likely ranges of type and magnitude of the impending eruption. A progression of increasingly spe-

cific and urgent warnings is sometimes issued as the signals and details of an impending eruption become clearer, and as uncertainties decrease. Short-range, “immediate” forecasts are often used to trigger evacuations, 24-hour watches, and other intensive mitigation measures.

## B. Syneruption Warnings

Though a forecast made during an eruption might seem too late, two important types of forecasts are needed after an eruption has begun: immediate forecasts of travel directions, arrival times, and intensity of various hazards, and intermediate-range forecasts of the further course and duration of an eruption.

1. *Forecasts of travel directions, arrival times, and intensity of various hazards.* All volcanic hazards require time to reach point(s) at risk. Real-time detection and tracking of slower-moving hazards allows messages to be sent to those at risk, while there is still time to flee, find shelter, or take other mitigation measures. For example, likely areas and times of volcanic ashfall from an explosive eruption can be forecast from wind data and from radar tracking of the ash cloud. The thickness and grain-size distribution of that fall can be projected from wind data and from the intensity and duration of the eruption. Eruption intensity, in turn, can be judged from the energy of volcanic tremor and from estimation of eruption column height.

2. *Intermediate-range forecasts of the further course and duration of an eruption.* Unlike earthquakes, hurricanes, and most other natural hazards, volcanic eruptions may continue for weeks, months, or even years. During this period, the eruptions may change in character or intensity. Some forecasts of the evolution of an eruption will rely on the course of past eruptions of this volcano; other forecasts may rely more on interpretation of current unrest (for example, of seismicity that is accompanying the eruption). Ideally, forecasts will combine both past history and interpretations of current unrest.

## C. Posteruption Warnings

All eruptions, and especially explosive ones, disturb watersheds around the volcano. Vegetation is killed or buried, and infiltration of rainfall into the soil is sharply reduced when fine ash covers the surface. Rainfall can trigger flash floods, lahars, and massive sedimenta-

tion in and around the rivers of surrounding lowlands. Short-, intermediate-, and long-range warnings can be issued.

1. *Short-range warnings of lahars.* Dangerous lahars can continue for years after a large explosive eruption. If the lahars are triggered by intense rainfall, warnings can state that rainfall has exceeded a threshold known to trigger lahars. Warnings can also state that a lahar of measured stage (“magnitude”) and velocity has been observed at an upstream point and will soon reach downstream points. Generally, these warnings will be specific for a particular river or set of rivers, and will complement a long-range lahar hazard map such as described in the next paragraph.

2. *Intermediate- and long-range estimates of sediment yield, channel shifts, and related flood hazard.* Annual rates of sediment yield and the number of years over which sediment is flushed from fresh pyroclastic deposits into the surrounding lowlands will vary with the nature and magnitude of watershed disturbance, climate, and topography. Although understanding of exactly how each of these factors controls the rates and locus of sedimentation is still evolving, some useful approximations can be made shortly after an eruption and refined as the sedimentation event and watershed recovery proceed. Because the volcanic sediment chokes existing channels, flooding occurs frequently and lahars can spread across alluvial fans. Lahar and flood hazard maps consider topography and expected sediment delivery to identify areas of likely inundation.

## D. Warnings of Risk (All Timeframes)

Warnings of hazards can be converted to warnings of risk by telling people what effects to expect on health, homes, other structures, crops, and the myriad of complex systems (for example, telecommunications, transportation, water, and power) of modern society. Some volcano warnings correctly anticipate the natural events but fail to explain how these events will affect people and their surroundings; as a result, official and citizens’ responses to warnings are delayed or inappropriate.

---

## II. THE FORM OF VOLCANO WARNINGS

In order to be useful, a warning of volcanic hazard must not only contain accurate information, but it must also

be in a form that gets the attention and is easily understood by those who must make mitigation decisions, either personal or official. Some forms for volcano warnings follow.

#### A. Factual Statements

Factual statements describe past and present activity of a volcano and make no extrapolation to the future. Factual statements are useful before any forecast can be made.

#### B. Forecasts of a Specified Outcome within a Specified Time Window

To provide the basic "what and when" of volcanic hazards, one of the most common types of warnings de-

scribes either a single event or a scenario and indicates a "window" of time within which that event or scenario is expected. A warning of this form might refer to the volcano as a whole, for example, stating that a moderate-size explosive eruption is expected within the next week. Alternatively, it might apply to a specific place, for example, stating that a lahar is expected to arrive at town X within Y hours. Sometimes, especially for eruption forecasts, a qualification like, "If current trends continue, then . . .," is added, because the behavior of a volcano can always change. The time windows for eruptive events may "open" at the time the forecast is issued, or at some later date; the length of the window will be proportional to uncertainty about when the events will begin. In principle, as an eruption approaches, successive forecasts can define shorter windows, such as "within a month," then "within a week," and finally "within a day" (Figure 2). In practice, opportunities to be precise

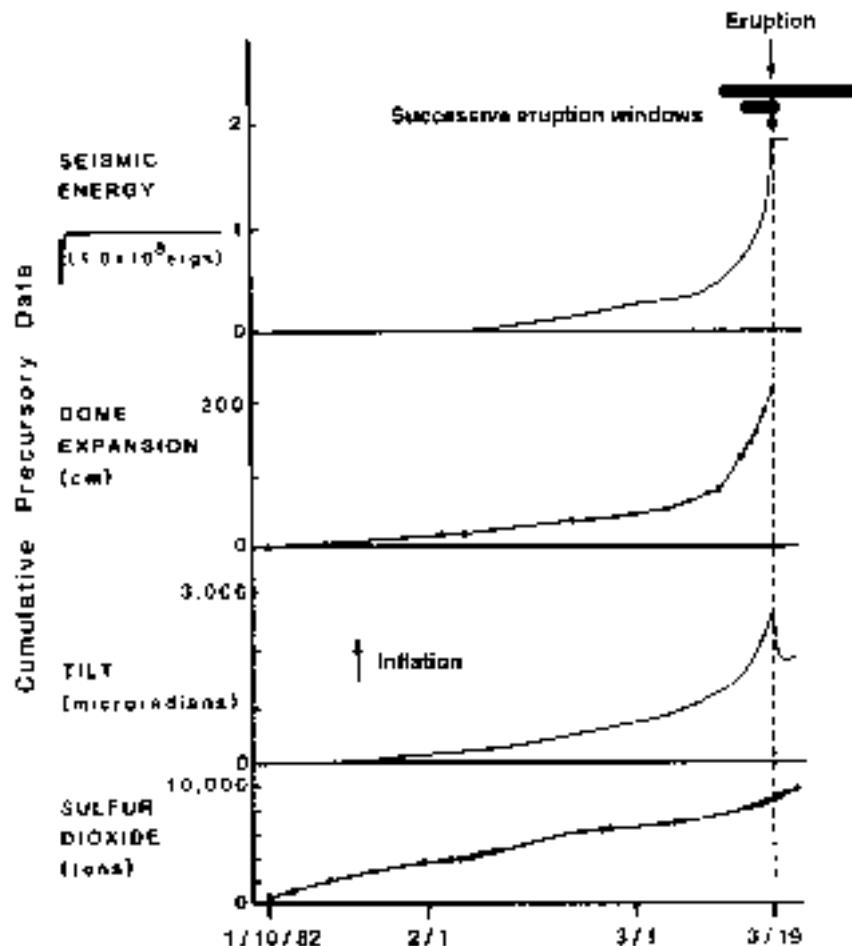

FIGURE 2 Escalating unrest and forecast windows for a small explosive eruption that occurred at Mount St. Helens on March 19, 1982. Solid bars show the "time windows" of three successive forecasts, each getting shorter as unrest escalated and the eruption drew nearer. [From Brantley and Topinka (1984).]

to the nearest day are still rare. When events such as downslope flow of a lahar or lava or downwind transport of volcanic ash are in progress, and current position and velocity are known, arrival times of such phenomena at specified locations can be projected.

### C. Probabilities of Several Possible Outcomes

A common situation of volcanic crises is that scientists know that an eruption is likely, but do not know what type or size of eruption will occur. The eruptive history of that volcano might include a wide range of possibilities, or monitoring data for the current unrest might be ambiguous. In such cases, an alternative to forecasts of specific phenomena within specific time windows is a probability tree of all possible outcomes, ranging from no eruption to the worst-case eruption. A time frame must be specified, perhaps days or perhaps decades, depending on immediacy of the threat. In the 1970s, probability trees were used to assess volcanic hazard near proposed nuclear power plant sites. More recently, probability trees have proven useful in volcanic crises because they (a) recognize natural variability and stochastic elements of volcanic phenomena, and uncertainties of interpretation; (b) educate those at risk about the full range of possible events, without oversimplification; and (c) show users the most likely scenarios, together with a semiquantitative basis for comparison with more familiar, nonvolcanic risks. Probabilities also help to avoid confusion between unquantified adjectives such as “low, medium, or high.” The latter can mean different things to different people. Unfortunately, probabilities can also be confusing to those who are unaccustomed to their use. An interesting and promising experiment is in progress on Montserrat, in which expert elicitation estimates the probabilities of various scenarios and associated uncertainties.

### D. Alert Levels

Often, it is useful for volcanologists to simplify their interpretations of unrest into a numerical, letter, or color code of alert levels. Regardless of whether numbers, letters, or colors are used, the basic concept is to define a small number of states of the volcano, from background rest to the highest level of unrest (usually, vigorous eruption). Most schemes have six or fewer categories. A scheme could be strictly factual—for example,

stating only the physical state of the volcano without an explicit forecast. Categories might be defined by rates of seismic energy release, ground deformation, and gas release, or by the nature of an eruption in progress. Looking forward, a scheme can indicate what is expected within a specified time window. One of the most useful aspects of alert levels, in addition to their simplicity, is that users understand that alert levels will be raised or lowered whenever the activity of the volcano warrants. To maintain their credibility, scientists must be equally willing to raise or lower alerts.

In some countries, civil defense plans are keyed directly to alert levels. For example, a plan might tell officials to evacuate a particular zone around a volcano if the alert level is raised to a specified level. This is a clear and appropriate use of alert levels, provided that (a) scientific decisions about alert levels are not dictated by political concerns about mitigation measures, and (b) the alert levels are simply a guide, not a rigid requirement, for mitigation decisions. Unfortunately, in the decade or so that alert levels have been in popular use, examples have arisen of public officials trying to influence scientists’ judgments about the activity of the volcano, and of unnecessarily rigid reactions to alert levels. Scientific and political judgments are better kept separated, and decisions about mitigation measures should remain political decisions that include factors such as community sentiment, economic risk, and acceptable risk.

### D. Hazard and Risk Maps

Maps are a convenient way to show the areal distribution of hazard and risk. One zone on a map might show areas subject to pyroclastic flows, another might show areas subject to lahars, and so on. Some maps also show areas that have statistically high likelihoods of tephra fall. However, examples of statistically unlikely falls at Mount St. Helens, Pinatubo, and several other volcanoes caution that the hazards of tephra fall are better shown by a sample plume and wind rose diagrams for each season. Increasing use of numerical models, digital elevation models, and geographic information systems (GIS) are enabling production of the next generation of hazard maps, in which various data layers can be compared to likely areas and travel distances of various hazards (Figure 1).

From maps, easy, visual comparisons can be made between hazards or risks in various sectors, or at various distances around a volcano, or at various elevations

above a valley floor. Some maps show different levels of hazard or risk expressed in adjectives such as low, medium, or high. If desired, the same hazards and risks can be expressed in terms of probabilities—with the advantages and disadvantages of probabilities noted above.

Although maps are everyday tools for volcanologists, they are too abstract and difficult for many users of volcano warnings. If users are embarrassed to admit map-reading difficulty, and if scientists are oblivious to it, information is not communicated and misunderstandings become likely. Three-dimensional perspective drawings are less abstract and easier to understand, and can be used to show virtually the same information. GIS technology allows 3D drawings to be made from any perspective.

Traditionally, hazard maps have been used to show long-range hazard assessments but, with improvements in computer technology, it has become technically easier to prepare updates for intermediate- and short-range warnings. One of the first uses of short-range warnings in map form is the projected trajectory of wind-borne ash from an explosive eruption. These maps can be transmitted to the cockpits of aircraft so that pilots can avoid the high risk from encounters with ash clouds. Another potential use is for short-range revisions of lahar hazard, if community responses could be fast enough to take advantage of such revisions.

Just as alert levels can be raised or lowered according to the unrest of the volcano, the boundaries of zones of hazard and risk can also be moved away from or closer to the volcano as the level of unrest or understanding of the hazard changes. Expandable or shrinkable zone boundaries make sense in principle, but require a substantial level of public education to avoid confusion.

If risks are quantified and used to define evacuation zones, public officials and their constituents should discuss acceptable risk. To seek zero risk is unrealistic because it automatically requires total evacuation of the entire region of a volcano. Sensible mitigation decisions will seek to minimize risk and, at the same time, to minimize unnecessary disruption of communities. Some trade-offs between the two are inescapable and public acknowledgment of this fact will make dialogue and decisions easier.

#### E. Video and Other Educational Materials

Tragic experience at Nevado del Ruiz (Colombia) in 1985 demanded that volcanologists find more effective

ways to teach about volcanic hazards. Video is one such way. The International Association of Volcanology and Chemistry of the Earth's Interior (IAVCEI), through the late Maurice Krafft and the USGS's Steve Brantley, prepared two videos for this purpose. "Understanding Volcanic Hazards" shows graphic footage of each major volcanic hazard, how fast and far it travels, and what it does to people and structures; a companion video, "Reducing Volcanic Risk," is a primer for public officials and citizens on how volcanic risks can be mitigated. As of this writing, a third IAVCEI video that would show engineering options for volcanic hazard mitigation is under discussion.

A variety of other educational materials have also been prepared in various countries—leaflets, colorful posters, comic books, and Web sites are all in use. No definitive study has yet been made of the effectiveness of these various materials, but we know anecdotally that all of them have been effective for different segments of populations at risk. The first IAVCEI video was especially effective before the eruption of Mount Pinatubo in 1991—a place where no eruption had occurred in people's memory. Web sites have been effective for "wired," computer-equipped segments of populations around Ruapehu (New Zealand, 1995), Popocatépetl (Mexico, ongoing), Soufrière Hills (Montserrat, ongoing), and Long Valley caldera (USA, ongoing).

Hazard and risk maps, and videos, will become increasingly available on the Internet, and opportunities will soon arise for public officials and citizens to pose interactive "what if" queries to Web- or compact-disk-based hazard estimation programs.

Volcano education needs to discuss the uncertainty of forecasts and the problem of false alarms. The difficulty has its roots in a more general problem of science education, in which students are often taught scientific facts but not taught about hypotheses and uncertainties. Scientists are therefore expected to know simple truths, such as whether or when a volcano will erupt, and many citizens do not understand that there are inevitable uncertainties in forecasts of complex systems. A corollary of uncertainties is that there will be false alarms. The frequency of false alarms will depend upon how well the volcanic system is understood, the specificity or vagueness of forecasts, and societal and scientists' own tolerance for risk. For obvious reasons, improved understanding of the volcano will result in fewer false alarms. So, too, will keeping forecasts relatively general, though there is no sense in making forecasts so general that they lose their utility. High tolerance for risk gives scientists some extra time to study the volcano and to be relatively sure about their forecasts, and thus to lower the

chances of false alarm; conversely, low tolerance for risk pushes scientists to issue forecasts before their data are conclusive, thereby raising the chance for false alarms.

---

### III. DISSEMINATION OF VOLCANO WARNINGS

Volcano warnings need adequate dissemination before they will be useful. Sometimes, scientists need only to convey their warning to a civil defense office and that office will pass the warning onward. More often, scientists need to remain involved in the process, partly to answer any questions that arise, and partly to learn what information and formats are most useful for users. In a few instances, scientists are left to handle dissemination entirely by themselves; this is far from ideal, because it erodes much needed time for field work and analysis, and because many scientists find it difficult to step outside their specialized technical world to communicate effectively with nonscientists. Some of the means for conveying volcano warnings follow.

#### A. Briefings, Community Meetings, and One-on-One Meetings

The best way for scientists to convey the general nature of volcanic hazards is in person at briefings of government and nongovernmental organization (NGO) officials, community meetings, and the like. It is important for scientists to build recognition and credibility among those who will receive warnings. Careful attention to developing credibility and personal rapport with officials and those at risk—before or early in a crisis—will make later dissemination of warnings easier and more effective. Personal contacts also tell scientists what the recipients of their warnings need to know. Meetings that are organized by a crisis center are also a good way of ensuring that all participants receive the same message and have a chance to hear each other's questions and answers. Information presented at such meetings becomes the background for subsequent, urgent warnings. Field and lab tours are also helpful, so that officials see the data gathering and analyses that form the basis of scientific warnings.

#### B. Concise, Formal Notification

Formal procedures generally use telephone “call-down” lists, faxes, specially tagged e-mail, and notices via dedicated warning networks such as those operated by civil defense, law enforcement, and aviation safety authorities. Messages over these channels are typically short, concisely worded, and serve as the legal documentation of warnings. Both providers and recipients of formal warnings commit to 24-hour-per-day, 7-day-per-week operation. Dissemination is generally completed within tens of minutes and prioritized so that the most urgent contacts are made within minutes of a warning being issued. Partial automation of warning dissemination speeds the process. Additional details can be offered by regular e-mail or on Web sites soon after an initial notification. Short, urgent messages sent by these channels presume that recipients already understand the general nature of the hazard, from prior education and briefings.

#### C. Public Information through News Media

The most effective way to reach a large population is through the news media—mainly through radio, television, and newspapers. Internet news services are a fledgling but growing source of volcano information. Effective warnings through news media require good communication between scientists and reporters and careful reporting. Most reporters and news organizations recognize their public responsibility for hazards warnings and try to discharge that responsibility faithfully, though short deadlines and space limits for reporters, competitive pressures for “scoops,” and scientists’ impatience with confused reporters can sometimes degrade the result. Many volcano observatories have found it useful to employ a person with both scientific and journalistic skills to be an effective bridge between the scientists and the news media. Larger media organizations have skilled science reporters; smaller news organizations without science reporters can greatly improve their coverage by assigning one or two people to report the volcano story throughout its duration.

#### D. New Channels for Warning Dissemination

A variety of new technologies have opened up new possibilities for volcano and other hazard warnings. One, the

World Wide Web, is a wonderful information tool, but requires the user to actively seek out the information. Other new communication technologies include distinctive telephone rings and recorded messages to all subscribers, and special signals that preempt radio and television broadcasts, and can even turn on radios or televisions automatically for warnings.

---

#### IV. CASE HISTORIES

Brief synopses of warnings at three volcanoes illustrate both successes and problems with volcano warnings.

##### A. Mount St. Helens, Washington, USA

Long-range warnings of Mount St. Helens' frequent, explosive eruptions were published by the U.S. Geological Survey (USGS) in a scientific journal in 1975 and issued officially in 1978 together with a booklet of details by D. R. Crandell and D. R. Mullineaux. These warnings outlined the types of future eruptions that might be expected, and noted that the volcano erupted once every few hundred years, and had last erupted from 1800 to 1857. On this basis, the 1978 report concluded that "the current quiet interval will not last as long as a thousand years; instead, an eruption is more likely to occur within the next hundred years, and perhaps even before the end of this century." Except for a brief flurry when an official misunderstood the long-range warning to indicate an imminent eruption, this warning attracted little attention and was soon forgotten by most recipients.

Just a few years later, the volcano awakened. Recipients of the booklet that accompanied the official warning discovered a valuable handbook. In late-March 1980, earthquakes beneath the volcano were reported as following "a classic pre-eruption pattern." Small phreatic eruptions began on March 27 and continued intermittently for the next 2 months. When rapid bulging of the north flank of the volcano was discovered in April, that, too, was reported. Initially, public statements said that any eruption was likely to be like those within St. Helens' past. As the earthquakes and bulging of the north flank continued, warnings were more explicit that an eruption was likely, and that a landslide was also likely and could trigger an eruption. Regrettably, it never became possible to forecast an exact date for the climactic eruption—even in retrospect. Scientists were

hoping to see diagnostic last-minute escalations of microseismicity and creep of the bulge, but neither occurred.

The main events of May 18, 1980, were a massive landslide and a laterally directed blast, followed by a plinian, vertically -directed eruption. No landslide of this scale had been positively identified in St. Helens' geologic history, although two were subsequently recognized. A laterally directed blast had been recognized before the 1978 long-range warning, though it was apparently of much smaller magnitude than that which occurred on May 18 and was not emphasized in 1980 warnings. Both the landslide and the blast that occurred on May 18 were substantially larger than anticipated.

In contrast, the plinian eruption that occurred after the landslide and blast was similar to eruptions described in the 1978 hazard booklet and countless preclimactic 1980 briefings for public officials and the news media. Tephra blew to the east-northeast and blanketed large areas of eastern Washington, as anticipated in the booklet and in 1980 warnings. Mudflows, too, followed paths anticipated in the hazards booklet, even though that of the North Fork, Toutle River, had an unexpected origin by dewatering of a debris avalanche deposit. Effects on downstream towns were more or less as expected.

On balance, the long-range forecast was as good as geologic exposures at that time would have permitted; the significance of the bulge and possibility of a lateral blast were underestimated; and the short-term forecast of an actual date of failure was simply not possible. In retrospect, closer study of reports from Galunggung, Raung, Bandai, and Bezymianny might have focused more discussion on the possibility of a large landslide and lateral blast.

After the climactic eruption of May 18, 1980, five smaller explosive eruptions occurred through the summer months and, after those, 16 episodes of dome growth occurred until October 1986. All of these smaller eruptions were anticipated and warnings were issued. The most precise and prescient of these warnings were a set of four in March 1982 (Figure 2). The first warning, a factual, nonpredictive statement issued on March 5, described an increase in seismicity and "slow" ground deformation. On March 12, scientists predicted that if seismicity and ground deformation continued to increase, an eruption was likely within the next 3 weeks. This second statement also noted differences from earlier episodes that implied the potential for pyroclastic flows and rapid melting of snow and ice. The third warning was issued on March 15 for "an eruption, most likely of the dome-building type . . . within 1 to 5 days." The possibility of explosive activity was mentioned in

press interviews, but omitted in the formal statement because of intense media response to the March 12 prediction. Finally, at 0900 h on March 19, scientists predicted that "an eruption would begin soon, probably within 24 hours." A moderate-sized explosive eruption occurred at 1927 h on March 19, generating a mudflow that traveled >35 km down the North Fork, Toutle River, and buried a number of pieces of heavy earth-moving equipment that had been left in the river bed by a skeptical contractor.

For the postclimactic period of eruptions at Mount St. Helens, three broad types of warnings were issued: "predictions," "forecasts," and "factual statements." "Predictions" were relatively precise, confident, short-range warnings of the time, place, and type of expected eruptions, based on interpretation of monitored changes. "Forecasts" were less-precise, longer-range projections of activity based on historical and geologic records of previous eruptive episodes, or still-ambiguous unrest, and on comparisons with eruptions elsewhere in the world. "Factual statements" were issued at an early stage of unrest or at any other time when trends were not yet well enough defined to issue a prediction or forecast. In this article, "predictions" and "forecasts" are treated as a single spectrum and called "forecasts."

In late 1980, when it became apparent that hazards at Mount St. Helens were diminishing faster than public apprehension and that adjectives of "low" and "high" hazard now had greatly different meanings to geologists and officials, an effort was made to quantify hazards and risks to individual life around the volcano. Though crude, and with order-of-magnitude uncertainties, these estimates helped officials to see that, between eruptions, risks in most areas around the volcano were by then low enough to be acceptable.

## B. Mount Pinatubo, Luzon, Philippines

Mount Pinatubo was first recognized as a potentially active volcano in the late 1970s and early 1980s during safety studies for a nuclear power plant and exploration for geothermal resources. It was officially designated as "active" in 1988, but with little publicity and to little effect. In early August 1990, two weeks after a M=7.8 earthquake along the Philippine Fault 100 km to the northeast of Pinatubo, highland residents noted a new, steaming ground crack on the upper northwest flank of Pinatubo. Earthquakes were also felt, but the seismic network was insufficient to say whether these were of local origin or distant aftershocks. A cursory field inves-

tigation noted a new landslide and attributed it to the regional earthquake, with no further significance.

Earthquakes began to be felt again around March 15, 1991, and, on April 2, phreatic explosions opened a set of craters along a fissure across the northeast flank of Pinatubo. In response, the Philippine Institute of Volcanology and Seismology (PHIVOLCS) began monitoring seismicity, steaming, and stream chemistry, and recommended evacuation of villages within a 10-km radius of Pinatubo's summit. U.S. Geological Survey scientists were invited to help and arrived in late April. On May 13, the team adopted a five-level alert scheme (Table I).

As the alert levels were raised, zones of recommended evacuation were also expanded. On June 7, when level 4 was declared, the radius for evacuation was expanded to 20 km, and on June 14, as large explosive eruptions and strong seismicity continued, the recommended radius of evacuation was expanded to 30 km. Most of Clark Air Base (spanning a distance of 15 to 25 km from the summit) had been evacuated on June 10, and many villages between 10 and 20 km distance were also evacuated before and after the evacuation of Clark. Before nightfall on June 14, about 85,000 persons, including >14,500 from Clark Air Base, had moved to safe, distant areas.

A probability tree for pyroclastic flow hazard on the east side of Pinatubo was prepared on May 17 and updated on June 10 for select civil defense and military leaders (Figure 3). They found the tree helpful, though, in retrospect, the probability estimates were too low. The tree was not used for the larger group of warning recipients, mainly for lack of the time that would have been required to fully develop and explain a comprehensive Pinatubo tree.

Official and public skepticism remained a serious problem at Pinatubo until large explosive eruptions began on June 12. Some of the hardest skeptics remained unconvinced until the climactic eruption on June 15. No single action overcame that skepticism, but solid data, public warnings, blunt talk in private meetings with officials, and the powerful first IAVCEI video all helped.

Pre-eruption warnings at Pinatubo saved many lives and much mobile property, including military aircraft. The decisions to evacuate were high-stakes decisions and could not be taken lightly. Both scientists and officials were apprehensive about the possibility of false alarm. It is a credit to the scientists involved that the warnings were correct, and a credit to the officials that they were ultimately willing to order the necessary evacuations. Credit also goes to several Catholic nuns who worked as effective liaisons between scientists and the highland people who lived on Pinatubo.

TABLE I Alert Levels for Mount Pinatubo, May–June 1991<sup>a</sup>

Alert level	Criteria	Interpretation
No alert	<i>Background; quiet</i>	No eruption in foreseeable future
Level 1	<i>Low level seismicity; other unrest</i>	Magmatic, tectonic, or hydrothermal disturbance; no eruption imminent
Level 2 (May 13)	<i>Moderate level of seismicity, other unrest, with positive evidence for involvement of magma</i>	Probable magmatic intrusion; could eventually lead to an eruption
Level 3 (June 5)	<i>Relatively high and increasing unrest including numerous b-type earthquakes, accelerating ground deformation, increased vigor of fumaroles, gas emissions</i>	If trend of increasing unrest continues, eruption possible within 2 weeks
Level 4 (June 7)	<i>Intense unrest, including harmonic tremor and (or) many “long-period” (low-frequency) earthquakes</i>	Eruption possible within 24 hours
Level 5 (June 9)	<i>Eruption in progress</i>  (Note that large-scale explosive eruptions began June 12; climactic eruption occurred on June 15)	Eruption in progress
Stand-down procedures		
In order to protect against “lull before the storm” phenomena, alert levels will be maintained for the following periods after activity decreases to the next lower level:		
from Alert Level 4 to 3—Wait 1 week		
from Alert Level 3 to 2—Wait 72 hours		

<sup>a</sup> Alert levels are defined subjectively, based on changing rates of unrest and interpretation of processes and “time-to-eruption.” (From Newhall and Punongbayan, 1996.)

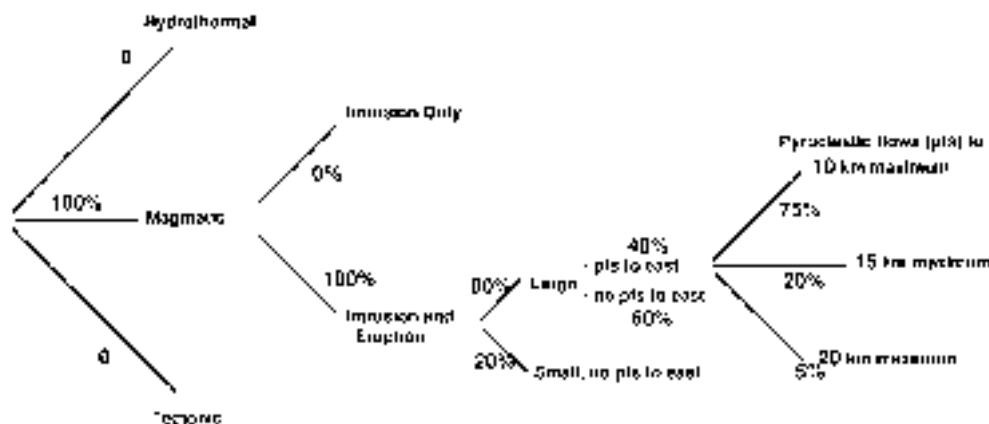

FIGURE 3 Logic tree to assess the probability of pyroclastic flows reaching Clark Air Base and adjoining cities of Angeles and Mabalacat. The first version of this tree was prepared and presented to civil defense and military leaders on May 17, 1991, during what was then still low-level, steady-state unrest. The update of June 10 (shown) was used for internal discussions only because the necessary evacuations had already been ordered. The probability that a pyroclastic flow would reach into these populated areas ( $\geq 15$  km from the summit) within one year was judged to be about 1% on May 17, and about 8% on June 10. If the tree had been updated after the explosive eruptions of June 12–14, 1991, this estimate would have risen significantly.

After the climactic eruption of June 15, 1991, and a period of smaller ash eruptions, the main hazard at Pinatubo became rain-induced lahars and flooding. Enormous volumes of loose pyroclastic debris were washed from the volcano's slopes into densely populated, low-gradient lowlands. River channels were immediately choked with sediment and lahars began to spread. Rainfall and streams in the lowlands were unable to drain because the river channels were full of sediment, so flooding was also widespread. Two kinds of lahar warnings were used. The first was a map of areas that would be subject to lahars and flooding, and a companion intermediate-range estimate of the volumes of sediment that would be brought into the lowlands each year. The second was the immediate warning of heavy rainfall and lahars, as detected by telemetered rain gauges and acoustic flow sensors (inexpensive, high-frequency seismometers installed near flow channels). Regrettably, though, vandalism and official skepticism kept this network of instruments from ever being used to its full potential. Manned police watch stations were also established at the heads of alluvial fans, and these tended to supplant, rather than complement, the instrument-based warnings.

### C. Long Valley Caldera, California, USA

A period of protracted unrest began at Long Valley in 1978 and continues to this writing (March 1999) with neither eruption nor obvious escalation or diminution. USGS, state, and university scientists installed additional instruments immediately after four  $M = 6$  earthquakes in May 1980, just 1 week after the major eruption of Mount St. Helens. Initially, it looked as if the unrest might have been of wholly tectonic origin, related to basin and range extension. Now it appears that magma intrusion also occurred, including an intrusion in 1989 beneath Mammoth Mountain. A new aspect of the unrest began in 1990—increased outgassing of magmatic  $\text{CO}_2$  that has killed trees in several patches around Mammoth Mountain. There is, as yet, no basis on which to forecast either an eruption or an end to the unrest.

In this difficult situation in which the causes of unrest are not entirely understood, USGS and State of California scientists have had to advise officials and residents of the affluent resort town of Mammoth Lakes, California, about areas and levels of danger. Messages of volcanic hazard are never welcome in resort towns, and Mammoth Lakes was no exception; in recent years, though,

patient and sensible liaison between scientists and officials has developed greater mutual respect and more serious contingency planning. After initial hostility from some local business owners and residents, and a USGS retreat from its early warning system, a new set of alert codes has been established. Higher alert levels are invoked if unrest exceeds preselected thresholds. The current color codes (Table II) are simplified from an earlier set of letter codes, but the principle remains the same. Unlike subjective schemes at other volcanoes, the Long Valley color codes are determined by preset thresholds of seismicity, ground deformation, and other change. Between green and orange, the chief scientist can override the preset criteria to set the alert code at whatever level team scientists believe to be correct.

Specific actions within the USGS monitoring team are keyed to alert levels, as are some mitigation actions by local and state officials.

To complement the alert levels, a hazard map shows areas that would be affected in the event of eruptions like those which occurred  $\approx 500$ –600 years ago in the area. The town of Mammoth Lakes is vulnerable, so its residents are staking their hopes on the short-term alert levels.

One of the difficult problems at Long Valley caldera is the huge range of sizes of past eruptions. The most recent eruption occurred about 250 years ago from an island in nearby Mono Lake. This eruption was small and, even today, would have little impact. Moderate-size, Holocene explosive eruptions of the Mono-Inyo chain are the basis for emergency planning. The largest known eruption from Long Valley—the caldera-forming Bishop Tuff eruption of  $\sim 700,000$  years B.P., sent pyroclastic flows and surges over much of the area, and ash from that eruption fell from coast to coast across North America. Despite its huge potential effects, the long-range probability of another Bishop Tuff eruption is judged to be so small ( $10^{-5}$  or  $10^{-6}$  per year) that no serious plans are being made for such an event.

Another difficult aspect of the unrest at Long Valley has been its long duration. After a time, usually quite short, citizens may stop listening to warnings. Strident warnings, especially if they are false alarms, can easily reduce citizen responsiveness when an eruption truly is imminent. Most warnings at Long Valley have been intentionally low-key to avoid this problem. Unlike the crises at Mount St. Helens and Mount Pinatubo, which climaxed within about 2 months of their start, unrest at Long Valley has continued for nearly 2 decades and shows no indication that it has climaxed or will end soon. Ironically, as unrest continues and false alarms are avoided, some skeptics have become believers and the

TABLE II Color-Coded Alert Level Scheme Used at Long Valley (Modified July 16, 1997)<sup>a</sup>

Geologic behavior	Condition	USGS response
<i>Typical behavior since 1980 includes:</i> <i>Background.</i> As many as 10 to 20 small earthquakes with magnitudes (M) less than 3 ( $M < 3$ ) per day and uplift of the resurgent dome at an average rate of about 1 inch per year. <sup>b</sup>	Green (no immediate risk)	<i>Routine monitoring</i> , plus information calls to USGS personnel and town, county, state (California OES, State Geologist), and local federal agencies (USFS, BLM) regarding locally felt earthquakes and notable changes in other monitored parameters such as ground deformation, fumarole activity, and gas emissions.
<i>Weak unrest</i> (likely to occur several times a year). For example, increased number and (or) strength of small earthquakes or a single felt ( $M > 3$ ) earthquake.		
<i>Minor unrest</i> (likely to occur a few times a year). For example, a swarm with several $M > 3$ earthquakes.		
<i>Moderate unrest</i> (likely to occur about once a year). For example, a $M > 4$ earthquake or more than 300 total earthquakes in a day.		
<i>Intense unrest</i> (may occur about once per decade). For example, a swarm with at least one $M = 5$ earthquake and (or) evidence of magma movement at depth as indicated by an increased rate in ground deformation.	Yellow (watch)	<i>Intensified monitoring.</i> Set emergency field headquarters at Long Valley caldera. Initial WATCH message sent by USGS to California OES, which promptly informs local authorities. (Includes above information calls.)
<i>Eruption likely within hours or days</i> (may occur every few hundred years). Strong evidence of magma movement at shallow depth.	Orange (warning)	<i>Geologic hazard warning</i> issued by USGS to governors of California and Nevada and others who inform the public. (Includes WATCH response.)
<i>Eruption underway</i> (may occur every few hundred years).	Red alert	<i>Sustained on-site monitoring and communication.</i> Maintain intensive monitoring and keep civil authorities informed on progress of eruption and future likely development.

<sup>a</sup> Alert levels are defined objectively, but "time-to-eruption" is interpretive. (From U.S. Geological Survey, 1999.)<sup>b</sup> Details of criteria for each parameter are given in U.S. Geol. Survey Open-File Rept. 91-270. After unrest decreases, watch and warning downgraded after 14 more days, and alert after 1 more day.

town is now better prepared for an eruption than it was earlier in the crisis.

## GLOSSARY

- alert** A condition of heightened watchfulness or preparation for action. A warning method or system to make people aware of impending danger.
- alert code** A set of rules or a system used for transmitting alert messages requiring brevity and clarity. The symbolic arrangement of instructions in a warning system.
- consensus** General agreement in the diagnostics and the prognosis of the majority of scientists involved in the study of an episode of volcanic activity. Consensus of the involved scientists is essential for the decision making of authorities.
- crisis** An unstable situation of increased danger or difficulty. A crucial stage in the course of volcanic unrest, when the threat of an eruption, or the possibility of an eruption, exceeds some reference level.

**critical phase** A crisis situation or point in time when a critical decision must be made. Time in which decisions regarding the protection of population must be taken in light of developing volcanic activity.

**disaster** Calamity. An event produced by a natural phenomenon resulting in great loss and a state of extreme ruin and misfortune, capable of breaking the fabric of society.

**pre-event** Period of time when there is significant evidence that a natural phenomenon that may cause a disaster could occur.

**preparedness** A state of readiness or preparation for use or action in the case of volcanic activity or any other threat. It involves a clear understanding by the population and authorities of the natural phenomena and their destructive effects.

**return code** A set of rules or a system used for transmitting brief and clear messages about the reduction of a threat resulting from the decline of the volcanic activity.

**vulnerability** The susceptibility of physical and human systems to be affected by hazardous natural phenomena. It can be expressed as a probability of damage, or as the proportion of the total exposed assets expected to be affected by a given manifestation.

POTENTIALLY DESTRUCTIVE phenomena such as volcanic eruptions occur independently of any human action. Disasters may occur when a social group fails to respond to a threatening situation resulting from volcanic activity or any other natural manifestation. Society may thus react to a threat and reduce the possibility of disaster. Volcanic crises management means developing a degree of social organization and a set of response measures aimed toward the mitigation of the effects of an eruption.

## I. INTRODUCTION

Volcanic disasters, as well as other natural catastrophes, were once considered as Acts of God, reflecting the inevitability not only of the eruption, but also of the related damage and destruction. Nowadays, society has as one of its main goals the reduction of risk to life and property, and expects scientists to provide knowledge and technologies aimed at increasing protection against natural hazards. Consequently, governments are expected to implement preventive measures for the reduction of risk and plans for the management of emergencies in order to minimize the effects of the natural events.

Volcanic crisis management may be defined as the set of actions involving the vulnerable sectors of the society, the scientists in charge of assessing the volcanic hazard, and the government through its civil defense or civil protection bodies. These actions are directed toward the prevention and reduction of disaster when volcanic activity develops, or when there is sufficient evidence that an eruption may occur.

Volcanic disaster reduction and crisis management involve very complex and uncertain situations, on both the scientific and the management sides; although eruptions with catastrophic consequences still occur, the cases of successful management of large eruptions with a minimum number of victims are increasing in number. However, according to UNESCO figures, the average number of fatalities per year has been larger this century than it was in past centuries, indicating that population vulnerability has grown at a rate higher than disaster-reduction capabilities. Increasing population in hazardous areas, attracted by the fertility of the volcanic soils and by the availability of generally cheap land, has been one of the main causes of disaster in recent times, for there is no evidence that the frequency and intensity of volcanic eruptions have increased. Effective prevention

measures and crisis management should thus be further improved and extended.

Although at first sight a disaster appears to derive from an unexpected intensity of a given phenomenon (which may be an outcome of a lack of preparedness), disasters, or at least serious crisis managing problems, often result from the inadequate behavior of different social sectors, even in populations that rely on some degree of preparedness. Preparedness and response plans must then be continuously revised in light of worldwide experiences. Particularly, all possible situations before and during a volcanic crisis must be carefully considered and at least some procedures for managing a possible crisis should be designed for any volcano that may have some potential of erupting.

A natural phenomenon, such as a volcanic eruption, may generate a number of manifestations—over different time scales—that can affect different sectors of society in a variety of ways, and with different degrees of intensity. Should a volcanic crisis develop, its management involves factors of very different natures, some depending on the degree of previous preparedness. The number of variables involved makes it difficult even to define the problem for which the management plan is to be designed. Dealing with it may prove to be rather difficult, particularly when a large population is at risk.

Ideally, the logical solution to the problem of volcanic hazards would be constructing realistic scenarios based on the study of previous episodes of activity and on elaborate computer simulations, and implementing relocation programs to reduce the threatened population to zero—or at least to a minimum—before any eruptive activity develops. In real life, we are not aware of any place in the world in which this kind of solution can be effectively implemented. The land attachment of people, the difficulty (most times impossibility) of finding alternative places, and many other cultural, economic, and social factors force scientists and officials to look for solutions that permit large populations to live together with a potentially active volcano. Some level of risk acceptance depending on the degree of disaster prevention should thus be defined and specific emergency management plans should be developed to be put into action when that level is exceeded.

A general methodology for management of eruptive crises is not available nor possible due to the great variety of situations deriving from differences in physical settings and, mainly, in social, cultural, economic, and political conditions. However, some basic components of the management plan can be identified, together with some steps necessary for its successful implementation. These steps result from the careful analysis of recent

volcanic crises and the reasons for the success or failure of their management.

Volcanic crisis management may be considered as an evolutionary process involving two phases, with the following major components:

1. Pre-event (or precritical) phase (preparedness measures):

- Risk assessment, hazard and risk mapping, and postulation of expected scenarios
- Volcano monitoring
- Emergency planning

2. Critical phase (operational measures):

- Alert, communication, and information procedures
- Response—implementation of emergency measures
- Defining the end of the critical phase

During the evolution of a volcanic crisis these components have different degrees of relevance. The quality of a crisis management plan, measured by its success in mitigating damage (from the eruption or from the countermeasures), depends on the extent to which different sectors of society involved react to the countermeasures in expected ways inferred from adequately constructed scenarios.

## II. PRE-EVENT MANAGEMENT

### A. Preparedness

Preparedness may be defined as a state of readiness in the case of volcanic activity. It involves a clear understanding by the population and authorities of the related phenomena and their destructive effects. It also involves the design of preventive measures based on that understanding and response plans in case major eruptive activity develops.

If the population and authorities decide to adopt a policy of living together with the volcano, a proper level of risk acceptance must be defined. To do so, some basic components are needed:

- A long-term risk assessment, which may be depicted as a risk map that portrays likely eruptive scenarios, and procedures to disseminate that information
- A short-term risk evaluation device, namely a monitoring system and a procedure for continuous dissemination of the surveillance assessments

- An operative plan based on the risk assessments
- A decision-making process and an operative plan to respond to a nonacceptable level of risk

The first step of the preparedness plans for disaster reduction must be done well before any expected eruptive crisis in the preventive phase. This is the assessment of risk, understood as a combined measure of hazard and vulnerability.

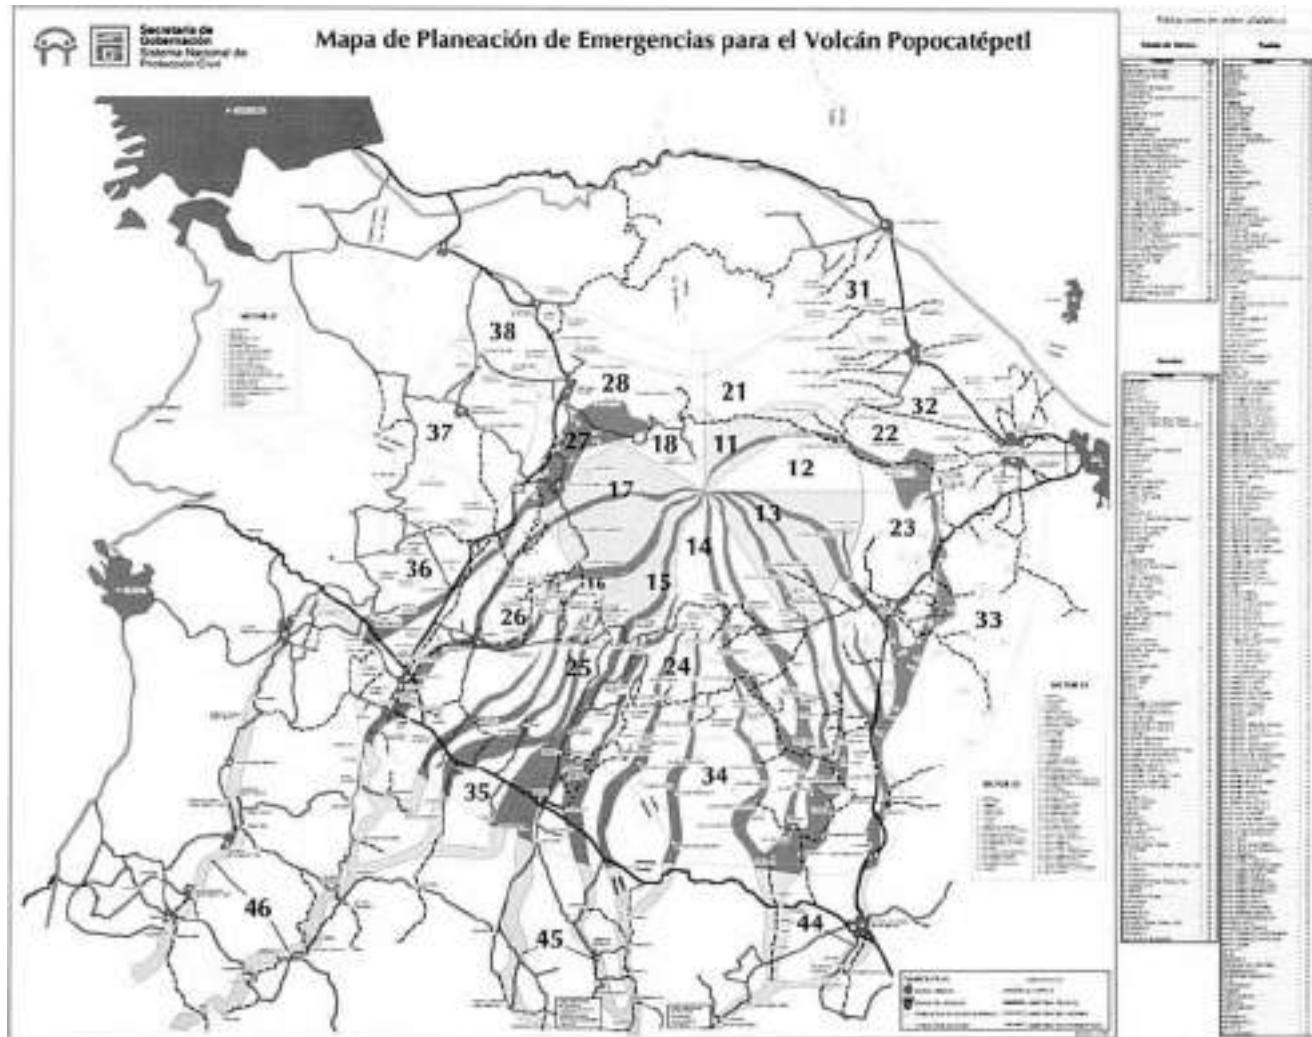

### B. Hazards Assessment

After identifying the volcanoes that have a potential to produce eruptions, a thorough knowledge of the characteristics of each volcano and of its past activity allows postulation of eruptive scenarios with their associated probability of occurrence based on statistical evidence. This involves thorough geological mapping and dating of older eruptive deposits. Computer simulations can help to include some new possible situations that may occur.

The ultimate product of these studies is a hazard map depicting the areas that could be reached by each type of eruptive manifestation. This map should include the probability that a given area may be affected in a given way. The large amount of information contained in this system makes it difficult to handle as a conventional printed map. Geographic information systems (GIS) allow a more efficient manipulation of the information. However, the conventional printed map cannot be discarded, for it is still the best way to transmit the hazard information to large sectors of the authorities and population. It is also very useful to divide each hazard area into sectors and consider the possibility of setting different levels of alert in different sectors for particular scenarios (Figure 1). A separate probability tree is a very useful tool for describing the probability of different scenarios and a very helpful support for decision making. It relates each eruptive scenario with an assigned probability, and also describes the possible evolution and concatenation of scenarios. Assigned probabilities must be updated as the crisis evolves.

### C. Vulnerability Assessment and Reduction

Because natural phenomena and their associated hazards can hardly be modified, risk mitigation is mainly related to the reduction of the hazard exposure and of the vulnerability of the exposed systems. Vulnerability is de-

**FIGURE 1** A hazard-emergency planning map for Popocatépetl volcano. The shaded regions depict the areas around the volcano that may be directly affected by eruptions of different intensity and different probabilities of occurrence. These areas have been divided in numbered sectors. The first digit indicates the level or risk of the sectors, and the second its azimuthal position. Regions beginning with a 4 are threatened by lahars. The towns in each sector are listed on the right.

fined as the susceptibility of physical and human systems to being affected by a natural hazard. Formally, it can be stated in terms of a probability of damage, or as a percentage of the total exposed assets expected to be affected by a given manifestation.

Assessing vulnerability and expected damage for each possible eruptive scenario is essential for the design and implementation of preparedness and emergency-management plans. A thorough gathering of the physical and demographic information on the region at risk is fundamental to assess vulnerability and to design the most effective measures of risk reduction. This information should be added to the GIS database.

Specifically, among the most effective measures for volcanic vulnerability reduction are those directly affecting the public. These measures should aim to achieve a proper response from the population in the threatened area, mainly through building a collective consciousness about the existing hazard, the implementation of a policy of land development (discouraging new settlements and encouraging emigration into safer areas), and the careful design of plans for a timely evacuation. Frequent rehearsals of the emergency operations for different scenarios are necessary for the proper functioning of the plan.

Dissemination of properly explained information about the phenomenon, its reach and effects, and the

prevention plans should thus be one of the top priorities in any preparedness plan. Specifically, the hazard map and the main measures of self-protection and response to a volcanic emergency must be widely distributed.

Some difficulties in this dissemination process may be anticipated. For instance, in highly developed, industrialized countries, the possibility of land devaluation may sometimes pose a problem in the handling of this information. In developing countries, finding economic resources for these measures is always a problem. Sometimes political problems, particularly when the volcano is located at or near a border region, may arise. In these cases, constructing a responsibility matrix, resulting from an agreement among the involved parties, and disseminating it are important parts of preparedness.

Another important step for vulnerability reduction is the implementation of the so-called structural measures, related mainly to engineering works aimed at protecting structures and their inhabitants. Although not much can be done in this respect for the safekeeping of structures from the most severe eruptive manifestations, such as pyroclastic and lava flows, protection from the fall of tephra can be achieved with proper roof structure and coating at reasonable costs.

Some of the most destructive volcanic manifestations are mudflows or lahars. The energy and range of lahars may be reduced through barriers to retain or deviate solid materials in the mudflows. These constructions are rather complex and expensive. However, they have been extensively implemented in several countries; for example, in Japan a general technology (SABO Engineering) has been developed for this purpose.

#### D. Monitoring: Minimum Instrumentation Needed in the Pre-event Phase

A monitoring system aims at gathering the maximum relevant information about the volcanic activity in order to detect premonitory signals of an impending hazardous event. For that purpose, it is important that the monitoring system be in place well in advance of the eruptive crisis in order to establish a baseline of activity to which anomalies can be related.

Experiences in eruptive crises obtained in the past decades have demonstrated that appropriate monitoring and surveillance systems are essential parts of volcanic crisis management. These systems consist of the instrumentation of the volcano with specialized measuring equipment adequate for timely detection of any geochemical or geochemical changes of the volcano for cor-

rect decision making and management of a possible emergency.

Once an active and potentially hazardous volcano has been identified in a certain region, a minimum monitoring system should be implemented to allow the detection of the first symptoms of reactivation. However, setting up, maintaining, and updating a volcano monitoring system represents a significant expense. Also expensive is maintaining a continuous operation in the long term, which requires a stable institution and trained personnel. To ensure its proper operation, volcano monitoring must be included in a nation's development planning as part of comprehensive disaster prevention programs. In view of other high-priority needs, the conditions for permanent monitoring are often difficult to achieve in developing countries without technical and economic international cooperation.

The minimum monitoring system for a given volcano depends on the hazard and risk levels, its eruptive history, the availability of economic and technical resources, the location and access difficulties of the volcano, and other aspects. It is generally accepted that the reactivation of a volcano usually involves a progressive appearance of certain unrest signals or precursors. A minimum instrumentation should aim at timely detection of these early symptoms of reactivation and allow setting of a baseline against which any unusual activity can be compared. Precursor signals are sometimes strong enough to be perceived by people living close to the volcano, for example, noises, vibrations, gas emissions or fumaroles, water level changes in wells and springs, deformations, and opening of fractures. In other cases, these signals are very small and can only be detected by sensitive instruments. Among the most important symptoms of unrest that can be measured with a basic monitoring system are changes of the seismicity, volcano deformations, and chemical changes in springs or fumaroles.

A basic monitoring system should consist of one, or preferably several, seismic and deformation sensors located close to the crater of the volcano. A good choice is starting with something simple and inexpensive and gradually upgrading the monitoring system as experience is gained and more and better data are required for specific scientific purposes. Discussion of several measurement techniques is beyond the scope of this article and is found in other chapters. A complete description of instruments and techniques used by the USGS to monitor volcanoes, with emphasis on seismic and geodesic measurements, may be found in the work of Ewert and Swanson (1992). In general terms, the type of instrumentation that is convenient for monitoring

purposes is not necessarily the same as that which would be needed for research on basic volcanic behavior.

During the process of selection and installation of a basic monitoring system, several factors should carefully be considered: reliability of the equipment, protection, site selection (geology and noise levels), access, maintenance, etc. Also, one has to take into account that these systems might need to be operative during long periods of time (most likely years), sometimes in harsh environments, before the volcano of interest shows any sign of reactivation. This permanent surveillance, monitoring, and instrument maintenance can become tedious. Especially the absence of volcanic activity could induce lack of motivation, lead to budget cuts for operation and maintenance, or even complete abandonment of the system with the possible consequence of failing to detect any critical precursor activity which might lead to a short-term eruption. It must be emphasized that once an eruption is in progress, it is usually too late or impossible to implement the desired monitoring system. There are many examples in the literature of volcanic disasters that could have been prevented if minimum monitoring systems had been operating. One such example was El Chichón volcano, located in the southeast part of Mexico. It erupted in 1982 causing a death toll estimated to be around 2000, though only 122 bodies were found (Figure 2). Had proper monitoring systems been instrumented on this volcano in the early stages

before the eruption, precursor activity could have been detected and adequate countermeasures implemented to save the lives of many people. However, it is important to point out that, by the definitions accepted at that time, El Chichón was considered a low-risk volcano. Priority criteria for setting monitoring instruments on different volcanoes should thus be carefully reviewed at regular intervals.

### E. Scientific Advice

The organization of a scientific group in charge of hazard assessment and responsible for providing specific recommendations to the authorities must be included in any preparedness plan. It is common that volcanologists, especially when they are specialized in different aspects of the volcanic activity, such as geology, seismology, and geochemistry, have rather distinct views about the actual risk and give different opinions to authorities and media. Great confusion could arise from such a situation, causing a general disbelief about the capability of scientists to make a sound assessment of the risk or a reliable forecast of an eruption, eventually leading to a poor response to warning and evacuation orders. An organization that guarantees scientific consensus is thus essential.

A framework in the disaster prevention scheme must be established in advance of any volcanic emergency.

**FIGURE 2** Pyroclastic flow deposits at the foot of El Chichón volcano, near the town of Francisco León. The flows produced during the eruptions of April 3 and 4, 1982, descended along the valley and devastated several towns. The flow deposits also dammed the river shown in the photograph, and the accumulated water and debris produced lahars 6 weeks later.

This may help to preclude the possibility of scientific groups divided by competition for the attention of the media and authorities, which can be particularly harmful. An example of such a situation is the case of La Soufrière volcano on the eastern Caribbean island of Guadeloupe in 1976, where the differences of opinions among groups of scientists, greatly emphasized by the media, caused confusion, misunderstandings, and incorrect decisions leading to a situation in which about 72,000 people were evacuated for several months at a very high cost without a clear definition of the actual level of risk. No eruption followed a set of improperly evaluated volcanic manifestations.

In many cases, there is an official agency responsible for monitoring and risk evaluation. It is necessary that all external specialists channel their findings and opinions through such an official body. A suggested procedure is to create a scientific advisory committee where all recognized specialists, local and visiting, can present the results of their studies and discuss their opinions with the purpose of reaching a consensus about the evaluation of risk, forecasts, and recommendations to be given to authorities. It is also convenient that the speaker for the committee be a representative of the official body and should make efforts to reflect the most important positions of the specialists, without generating an impression of uncertainty and confusion.

## F. Alert and Communication Procedures

Another essential part of volcanic risk preparedness is the definition and implementation of an alert code. The basic function of an alert code is to transfer the consensus of the scientific advisors to the responsible authorities, so they have the essential means for decision making. Then, the authorities should have efficient ways to communicate the scientists' consensus and their own decisions to the vulnerable population so it reacts to the authorities' actions and recommendations in a knowledgeable way. Usually, the consensus and the authorities' decisions are communicated to the population through an alert code based on colors or numbers, generally with three to six levels. A small number of levels could make it difficult to define the proper hazard level of a given volcano. Nonetheless, a small number of levels leaves less options to the population, reducing the chances of inaction derived from an ambiguous perception of the risk.

Recent experiences show the convenience of using a combined code in which a six-level scale is used to

communicate the hazard between the scientific advising body and the civil protection or civil defense authorities. The vulnerable population is advised through a three-level color scale. In this way the first multilevel scale of the code reflects the state of the volcano, whereas the second scale reflects the level of alertness of the population. As an example of this type of combined code, the so-called traffic light alert, used at Popocatépetl volcano, is shown in Table I. The actual process of communication of the alert levels by itself represents a difficult problem, similar to the dissemination of a hazards map, which must be addressed in the precritical phase. Public campaigns of information, not only on the volcanic phenomena but also on the alert code and the preventive actions, should be started in regions neighboring potentially active volcanoes in quiet periods. An improved confidence in the management may be obtained through direct contact of scientists and government officials with local authorities of communities in the hazard area and persons who have influence on public opinion.

Summarizing, the alert, communication, and warning procedures can be done in different ways, according to specific social, economic, and cultural conditions. Perhaps the common denominator for the transmission of the actual risk condition would be a systematic redundancy of information leading to the reduction of misunderstandings to a minimum. This can be achieved by establishing a communication routine consisting of periodic bulletins briefly explaining, with simple words, the state of the volcano—as determined by a scientific committee—and the level of alert of the population. This develops among the population an awareness of the relation between the level of hazard of the volcano and their level of alertness. Bulletins containing the same information may be issued in different formats and should be handed to authorities and media, and can also be posted at sites easily available to the general public, such as Internet sites and telephone mailboxes.

---

## III. CRITICAL PHASE MANAGEMENT

### A. Changing to a Critical Phase

In general terms, the procedure for declaring a critical phase begins when the monitoring system detects any unusual activity on a volcano and a reasonable suspicion is shared by the members of the scientific advisory committee that it could be a precursory manifestation of a possible eruption.

**TABLE I** The “Traffic Light” Alert Code Used at Popocatépetl Volcano<sup>a</sup>

<i>Alert level for the communication between the scientific committee and the civil protection system</i>	<i>Possible associated phenomena (may change according to the type and evolution of activity)</i>	<i>Actions recommended to be taken by civil protection authorities</i>	<i>Alert level for the public and general recommended actions</i>
Green phase 1	• The volcano is dormant	• Develop preparation plans; inform the public about the volcanic phenomena; install a scientific committee; install a basic monitoring system; develop risk mapping; develop emergency plans	Green (normality) • Stay informed • Locate yourself in the hazard map • Memorize signals of Evacuation routes Meeting places Shelters • Attend training courses • Participate in exercises and drills • Promote relocation of settlements in high-risk areas
Green phase 2	• Moderate increase in background seismicity, fumarolic activity, minor changes in the composition or temperature of fumaroles or springs	• Increase monitoring; promote sporadic meetings of the scientific committee; revise communication procedures between scientists and authorities; revise emergency plans; give more information to the public on volcanic risk	
Yellow phase 1	• Significant increase in the above parameters • Low-magnitude earthquakes • Some deformation • Clear increase in fumarolic activity • Nonexplosive lava emissions at low rates • Low-level ash emissions	• Promote frequent meetings of the scientific committee; increase consultations between scientists and authorities • Test availability of personnel and equipment involved in evacuations • Test logistic capabilities • Limit access to the volcano, according to recommendations of the scientific committee	
Yellow phase 2	• Significant increase of the above parameters • Moderate phreatic or magmatic explosions If some eruptive activity is already in progress, evidence of increased magmatic activity: • Increased volcanotectonic seismicity ( $M \sim 2-3$ ), tremors • Significant deformations • Significant chemical changes in gas, water, or rock samples	• Warn local, regional, and federal civil protection authorities • Set watch shifts • Define a larger radius of limited access to the volcano area • Warn airborne traffic systems	Yellow (alert) • Stay continuously informed • Visit the safety areas, meeting places, and shelters • Observe instructions from authorities • Stay alert and prepared for a possible evacuation
Yellow phase 3	• Acceleration of the rate of seismic energy release • Larger volcanotectonic earthquakes ( $M \sim 3-4$ ), tremor signals of increased amplitude and duration or lower frequency • Important or rapidly changing deformations • Extensive chemical anomalies • Increased rate of lava production • Increased rate of explosive activity • Eruptive columns exceeding 5 km above the volcano summit	• Make public announcements of the volcano evolution and the adopted measures • Prepare emergency personnel and shelters • Implement specific measures in the more vulnerable regions • Alert air traffic controllers • Extend radius of limited access to the volcano	
Red	• Solid evidence of large increase in the magma rate production • Increased volcanotectonic activity ( $M > 4.5$ ) • Tremors detected in remote seismic stations • Very large deformations • Development of major explosive eruptive activity (VEI $\sim 3-4$ ) • Eruptive columns exceeding 10 km above the volcano summit  • Solid evidence of large amounts of magma accumulating in the volcanic cone • Major volcanotectonic earthquakes (magnitude 5 or more) • Very large deformations, or development of major explosive eruption (VEI = 5 or more) • Eruptive columns more than 15 km above the volcano summit	• Selective evacuations in threatened sectors, according to recommendations of the scientific committee • Encourage self-evacuation • Start preventive measures in other sectors • Start preventive measures against ashfall in metropolitan areas around the volcano • Start preventive actions to protect energy, water, and communication lines in the risk area • Alert air traffic controllers  • Selective evacuations of threatened sectors, according to recommendations of the scientific committee • Start preventive actions against heavy ashfall in metropolitan areas around the volcano; start extraordinary measures to protect energy, water, and communication lines • Alert air traffic controllers	Red (alarm) • Attend and follow instructions of authorities • Go to security areas, meeting places, or shelters • If you can leave the risk by your own means, do it! • Stay permanently informed about the situation

The decision-making process that defines a critical phase involves, first, the way scientists in charge of monitoring and evaluating volcanic activity recommend to the authorities some major emergency measures, such as an evacuation. Then, the recommendation evolves into a decision of declaring an emergency condition, and corresponding actions are taken by the concerned authorities. Clear responsibility assignment and a timely response are essential to the proper functioning of this stage. Matters become more complicated when authorities of different ranks and jurisdictions become involved, at municipal, state, or federal levels.

Therefore, the rules for responsibilities in the decision-making process must be established well in advance of crises, and must be clearly specified in the alert code and in the operative response plans.

Should a situation of slow buildup of the volcanic activity persist, a more complete and permanent monitoring network should be immediately implemented to acquire the necessary information needed, first, to better understand the physical processes and, second, to manage an eventual emergency.

## B. Critical Phase Monitoring and Alarm

An optimal volcanic surveillance is best obtained by using a combination of measuring schemes. The most common and widely used types of high-profile monitoring systems will be described briefly.

- *Visual surveillance.* This consists of a continuous observation and recording of the volcano by means of video and photographic cameras, as well as frequent visual reconnaissance missions from the ground and air (including satellite pictures) from which any conspicuous anomaly can be detected. Lava, debris and mudflows, ash emissions, fumaroles, dome growth, landslides, deformation, ice and snow changes, and weather conditions, among others, are phenomena which can be observed and qualitatively assessed. As an example, a real-time picture, posted on an Internet web page, has been used by the monitoring system of the Popocatépetl volcano in Mexico (Figure 3).

- *Seismic monitoring.* Seismic stations provide fundamental information about the internal structure of the volcano, its state of activity, and the way it changes. Recording of seismicity can be done locally, using autonomous portable instruments at lower-risk locations, or remotely, through radiotelemetry links into a central recording station. From a crisis management point of view, several signals from standard low-cost instruments are preferred to one sophisticated but expensive broadband seismograph.

- *Geodetic monitoring.* Deformation is the other physical parameter that provides fundamental information about the internal state of the volcano and supplies additional insight on the expected dimension of the developing process. Usually, its measurement is done using conventional geodetic methods (leveling, trilateration, EDM, dry tiltmeters, GPS, etc.). Only a few deformation data, like electronic tiltmeter readings, can be continuously telemetered to a central monitoring center.

- *Geochemical monitoring.* This implies frequent chemical analyses of gases, water from springs and crater lakes, volcanic ash and rocks, and, in general, all volcanic materials that may provide information about the evolving state of the volcano. Remote sensing by means of satellite images and ground or airborne spectrography (COSPEC, LICOR, etc.) are remote methods for measuring concentration of gases, like SO<sub>2</sub> and CO<sub>2</sub>, emitted by a volcano.

- *Hydrometeorologic monitoring.* Monitoring weather conditions (temperature, barometric pressure, wind speed and direction, rainfall, etc.) on a volcano is very important for the forecasting and detection of ash plumes and mudflows produced by rain or melting of glaciers and snowcaps. Doppler radar is being used in different sites to detect heavy rainfall, as well as dense ash emissions rich in coarse clasts. Additionally, flow and lahar detection systems, installed along different drainage paths of the volcano, are devices which should definitely be considered if there is any indication that potentially destructive flows might be triggered by the volcanic activity, as occurred at the Nevado del Ruiz volcano. Fast-response barometers for detecting and measuring pressure waves from volcanic explosions are also quite useful.

---

<sup>a</sup>The left column includes six levels or phases reflecting the state of the volcano. The second column associates those levels to observed phenomena. Since the relevance of different volcanic manifestations changes as the activity evolves, these associations are kept flexible. The third column describes some general recommendations to the authorities. Detailed instructions should be included in an operative plan. The column at the far right describes the level of public alertness in terms of a simple color scale. It is assumed that a minimum number of options left to the population reduces the ambiguity in the perception of the risk, and thus the chances of misunderstanding the importance of a threat.

**FIGURE 3** A real-time picture (and a photo album of past events, which is not shown) posted on an Internet web page has proved to be useful tools for communicating the evolution of the volcano activity to the public. Similar web sites may be found for other volcanoes of the world.

- *Other measuring and monitoring systems.* Detection and study of gravity and geomagnetic anomalies, temperature of the volcanic edifice, domes and plumes, concentrations of soil gases such as radon and other tracers, and groundwater levels provide additional and important information on the state of a volcano. Some of these usually involve a higher number of support staff and sophisticated and costly measuring equipment, and therefore cannot always be widely implemented.

- *Data processing and internal alarm systems.* A well-equipped and centralized data collecting and processing facility is essential for a volcanologic observatory, defined as the main source of information for the scientific advisory committee during a critical stage. Four aspects are important in a center: display systems, data processing, alarms, and communications.

1. *Display.* To be able to quickly assess the state of activity, a convenient and efficient display system of the continuously acquired signals should be implemented. Computer screens, drum and chart recorders, TV and radar monitors, etc., need to be arranged in such a way to provide a proper display. Real-time data such as seismic energy or tilt should be represented as plots, histograms, or any other analog display which allows a user to easily recognize a change of a variable and perceive its trend.

Because seismicity is one of the main monitored parameters of a volcano, most observatories use drum recorders as primary devices to display and record on paper the seismic signals. Any sign of activity can be detected at a glance, and signals of the same event can be readily compared on different stations and correlated with other monitored parameters. If, in addition, a visual image of the volcano is displayed on a monitor close to the drums, an optimum combination of visual tools to detect and judge the internal condition of the volcano and its external effects is obtained (Figure 4).

2. *Data processing.* Among others, basic data processing routines commonly used in a crisis condition are seismic-energy release rates, event detection and location, and spectral analyses. These data, together with other measurements like tilt, temperature, SO<sub>2</sub> values, etc., should be integrated in databases for quick display and analysis. Data are optimally handled and managed using local computer networks linked to the Internet. Thus inspection, supervision, and monitoring can be accomplished locally and remotely, and information efficiently disseminated and exchanged with other scientists and observatories.

3. *Monitoring alarms.* Computer systems that process volcanic information can easily be adapted with auto-

**FIGURE 4** Display of the monitoring system of Popocatépetl volcano. The analog seismic drum recorders on the right record signals received from stations located near the crater. In the central part, the radio-receiver bank allows quick checking of the transmission status of the signals. Above it, a television set displays the real-time image of the volcano, which is continuously recorded on tape. On the left a Doppler radar, installed by the U.S. Geological Survey, allows detection of larger ash emissions. Seismic data are digitized and analyzed by a set of computers. Visual and radar images are also digitized and put on the Internet.

matic alarm and dial-up systems providing audible signals and warnings when one or more of the monitored parameters exceed a preset threshold. Alarms can be triggered by seismic activity, deformation signals, detection of mud, water, or pyroclastic flows, ash emissions, etc. Such alarm systems are key elements, especially for personnel on duty in an observatory, to warn workers of a sudden volcanic unrest and allow them to respond according to pre-established procedures, triggering in turn other alarm signals and devices to alert other scientists, authorities, emergency agencies, or the threatened population. To discriminate seismic activity originating at the volcano from other nonvolcanic sources, like regional earthquakes, which could falsely trigger an alarm, one or several signals from remote seismic stations should be considered to inhibit the alarm upon detection of a regional earthquake. An ideal automatic seismic-alarm system should also be able to recognize seismic patterns or signals. In practice, even though sophisticated devices and early warning techniques are available, a fully automatic fault-proof alarm system cannot be used without human judgment, and in most cases cannot be used to automatically start an emergency plan or evacuation procedure. It should be used only to assist and alert personnel of a possible critical situation.

*4. Communication.* Proper and sufficient communication services like telephone lines, faxes, access to the

Internet and e-mail, modems, and voice-band radios should be available to effectively manage an observatory. Particularly during an emergency, insufficient communication channels to contact authorities, officials, and members of a scientific committee, as well as to issue reports and provide information to the media and the general public, are usually critical aspects often underestimated when setting up an observatory or emergency management center.

### C. Response to Monitoring Alarms

When a monitoring alarm goes off at any time, the problem arises of how to respond to this alarm and decide what action to take within the volcano observatory. It is likely that monitoring alarms may result from false triggers induced by momentary states of unrest of the volcano, and consequently would not imply starting a pre-established emergency plan involving authorities and the general population. Judging whether a signal is just a minor event of no serious consequence or a critical precursor indicating the onset of a more important manifestation is a crucial problem, and a few basic guidelines can be proposed in terms of some assumptions.

First, it is assumed that an adequate monitoring system exists, with sufficient instrumental diversity and reliability to be able to detect and correlate different signals and patterns detected on a volcano. Secondly, it is assumed that a moderate to large eruption would produce significant changes of different parameters. If an internal volcanic process is developing, it is unlikely that deformation, seismicity, and visual effects, like ash and gas emission, might change independently, or a mudflow be produced without heavy rainfall or any seismic indication of an instability or melting of a glacier. Therefore, a major change in the state of equilibrium of an active volcano will in most cases be detected by different monitoring devices. Third, it is assumed that a limited number of trained scientists, namely the members of the scientific advisory committee, are dedicating most of their time to volcanic-hazard assessment, and that other staff, in different fields and with differing levels of training, are available to maintain an around-the-clock volcano surveillance.

Experience has shown that keeping two watch levels may help to deal with possible situations of monitoring alarms, particularly when the volcanic unrest has extended for some time. A pool of watchers may be programmed to keep an around-the-clock "operative" watch. The usually larger general staff pool takes the

direct watch, keeping a continuous presence in the monitoring room with shifts of 6–8 hours. Two or more scientists take the “permanent” watch, making themselves available around-the-clock in shifts of a week or so. Should the operative watch detect any unusual manifestation, it calls the “permanent” watch, who has the responsibility of making a preliminary assessment of the situation. If judged necessary, this person may call other members of the scientific committee and decide whether a meeting is necessary or whether immediate actions should be recommended to the authorities. How to organize such a group and implement a specific action plan depends on many local circumstances and policies.

#### D. Communication and Information about the Critical Condition

Once a critical condition is identified, the consensus of the scientists or scientific committee in charge must be transmitted to the authorities in a clear and unambiguous way. Even when a consensus has been attained in that respect, the opinions of individual scientists may have important divergences. A delicate balance must be held between the right of individual specialists to make public their own views by direct access to the media and the need of giving to the population a unified position. It is particularly important that the position be expressed in a language that can be understood by the great majority of the population with a minimum content of technicalities. The risk to life and wealth is such a critical issue to the threatened people that messages can be easily misinterpreted, rumors can spread immediately, and contending opinions dispersed, leading to confusion and disbelief.

The high credibility of the scientific group in charge of the risk evaluation and recommendations is essential for a quick response to warning and for the success of the emergency plan. The failure of the warning about the great mudflow produced by a relatively moderate eruption of Nevado del Ruiz in 1985 has been mainly attributed to the disbelief or lack of understanding of people and authorities about a recommendation by the scientific group to evacuate areas that could be affected by a large lahar (Figure 5). The communication of the critical condition was not made clear and strong enough, and the perception of the risk by the population at risk differed from that of the scientific community.

To prevent information mishaps, a single voice must act as speaker for the scientific group. Ideally, the highest ranking officials of the civil protection or civil defense

**FIGURE 5** Over 21,000 people were killed when mudflows devastated the city of Armero (Colombia) in November 1985. The disaster occurred despite the existence of basic volcanic emergency management elements and resulted from misunderstanding and indecision. (Photo courtesy of Omar D. Cardona.)

body should attend the decisive meetings of the scientific advisors to hear directly the assessment and recommendations about the crisis. Otherwise, the person assigned as speaker for the scientists to the authorities must corroborate that the scientists’ consensus has been fully understood by the officials.

Whether the speaker for the scientific committee should advise directly the population at risk or should the alert to the population be issued by the civil protection authorities after a recommendation of the scientific group depends on the design of the responsibility matrix and the local legal framework. Since major decisions involving displacements of people involve aspects other than volcanological, a careful balance must be achieved to define this responsibility, considering the social aspects, better understood by the authorities, and the delays involved in longer chains of information.

A particularly sensitive issue in this regard is the position of international specialists determining risks of eruption in a developing country. Their opinions are sometimes given more credit by the media, the authorities, and the public than those of the local scientists in charge of the problem, and can again give rise to confusion and lack of credibility. A code of ethics should be established and promoted among the international volcanological community regarding procedures for giving opinions about the risk and forecast of eruptions to the public. Such procedures should consider that the opinions and facts on which they are based should be first submitted to the local body in charge of the risk evaluation or to the scientific advisory committee before being given to the public or the local authorities. One of the International Association of Volcanology and Chemistry of the Earth's Interior commissions has prepared a document on the professional conduct of scientists during volcanic crises in which some of these subjects are addressed.

Media play an increasingly important role in this problem, for there is a tendency to overemphasize any discrepancy among scientists, or between scientists and authorities. The roles of the speakers for the scientific group and for the authorities become crucial in transmitting the best estimate of the hazard condition and the existing countermeasures. When transmitting this infor-

mation, the speakers should take into account that the attitude of local media is generally different from those having a national or international reach. News intended for people external to the problem tends to highlight the most negative aspects of the situation and to exaggerate the extent of risk, thus causing serious consequences for people involved in the crisis. For instance, in the crisis of Popocatépetl (1994–present) there has been a clear trend by national and international media to overemphasize the risk to Mexico City, which is located farther than 65 km from the volcano, thus giving more emphasis to the most catastrophic scenarios, with a low probability of occurrence, than the more probable ones affecting the vicinity of the volcano (Figure 6).

An effective way to keep a stream of reliable information to the media is establishing a more intense routine of daily (or more frequent) bulletins with different formats but containing the same information. In this way, unexpected calls or interviews from media, which sometimes have to be attended by staff of the permanent watch that may not be experienced in dealing with media, can always be addressed to the official report, keeping in this way a single source of information. The bulletins should contain information about the scientific committee's assessment of the state of the volcano and the level of alertness of the population. Additionally, keeping a frequently updated Internet web page and

FIGURE 6 Popocatépetl volcano is located in central Mexico about 68 km away from downtown Mexico City. D.F. is the Federal District, which includes most of its metropolitan area. Over 20 million people live in the 250-km square area shown in the insert.

telephone voice mail source with the same information as the bulletins has proven to be very efficient in dealing with the large demand for information.

### E. Decision Making and Operative Plans

The decision-making criteria for establishing an emergency condition depend on different factors. A fundamental one is the degree of risk acceptance defined by the operative emergency plan. This level should be the result of a consensus between the scientific group and the civil protection authorities. In general terms, given the above conditions, the level of risk acceptance would be directly related to the quality of the monitoring, the efficiency of the warnings, and the logistic capabilities of authorities and the population.

It is expected that an elaborate monitoring system may detect early volcanic manifestations that could be interpreted as precursors to hazardous eruptive activity. In general terms, it also may be expected that the earlier this interpretation is made, the higher the probability of having a false alarm. On the other hand, an inefficient warning procedure or insufficient logistic capabilities may result in a long delay in the implementation of response actions. Looking for a compromise among these factors is a task that should be addressed from the earliest stages of the detection of increased activity, and must be updated according to the evolution of the activity.

Another factor is the geographic, economic, and urbanization situation around the volcano, which imposes different conditions on the decision making and emergency management. For instance, about 2.7 million people live within a radius of 15 km around Vesuvius (a similar number would be at risk in the case of volcanic reactivation of the Campi Flegrei), 1 million within 40 km from Popocatépetl, and about 530,000 within 20 km of Sakurajima. Mobilization or a general evacuation of such a large number of people requires a very complex operation. In addition, these cases face particular problems. For instance, while the population at Pozzuoli or near Vesuvius is mainly urban and high-income, and it can rely to a great extent on alert communication channels and its own resources for an evacuation, the high population density adds special difficulties of automobile traffic flow in an emergency. In contrast, the population around Popocatépetl is mainly rural and low-income, scattered in hundreds of small villages, with great differences in culture and even language, thus making the dissemination of information and alert communications

particularly difficult, and requiring great support for the evacuation. The emergency plans cannot be transferred from one volcano to the other, and the decision-making criteria should take into account the social and economic conditions, as well as the extent of the population.

Once a critical condition has been declared by the scientific group and communicated to the authorities, the decision of declaring an emergency condition to the population must be addressed by the authorities in terms of the emergency plan, defining all tasks involved in each operative phase, such as priorities of evacuation (what places should be evacuated first), rescue, and relief. It must be clearly defined who is in charge of each task, how to mobilize the necessary resources for the plan's implementation, and how to coordinate with other groups. The main parts of the plan are those related to warnings, transportation, shelter, and health and food services. In this case, a map with the hazard areas divided in sectors (Figure 1) may be helpful in allocating levels of risk to each sector and assigning specific tasks and responsibilities.

The way the volcanic activity develops and reaches a critical stage has a great influence on the management of the situation. If the activity shows a clear trend toward a major event, with convincing evidence of impending hazard, it is easier for scientists to obtain the support of the authorities, and thus the support of the population and task forces for the implementation of the emergency plan. The 1991 Pinatubo and the 1994 Rabaul crises are good examples of situations in which the clear consensus of scientists and authorities led to successful management of the emergency.

In some cases, the increased activity fluctuates for a time that may extend for several years, with contradictory signs of a possible evolution toward a major eruption. In a situation like this, there is enough time to organize, test, and improve the emergency management plan, but on the other hand, it is difficult to maintain the consciousness and preparedness of the population and the authorities. There is an increased possibility of false alarms and of growing differences of opinion among scientists which may result in loss of credibility by the population. Several cases of slow development of activity and of misleading signals of an imminent eruption exist, as happened at La Soufrière in Guadeloupe. Popocatépetl volcano had a sharp increase in activity in late 1994 and since then has shown large fluctuations, several times reaching stages that were close to an evacuation order, causing great unrest among the population. The persistency of a state of intermediate alert has also caused some loss of interest in the warning signals among the population.

## F. Return to a Subcritical Phase

A decision as difficult to make as declaring the start of a volcanic emergency condition is declaring the end of the emergency condition. Once a major eruption has started, it may be followed by periods of quietness that may not represent the end of the eruption. There is an increased difficulty in assessing the state of the volcano, for the remaining activity may obscure precursors to new eruptive episodes. Additionally, some social pressure may build up from the population and authorities to return to a normal state, particularly if the eruptive event was not very intense, few or no external manifestations can be viewed by the public, or people have remained in shelters for a long time. This pressure may be high enough to exceed the authorities' actions and recommendations about remaining in safe areas. On the other hand, the decision of allowing the return of evacuated people can only be made in the context of the type of eruption and its evolution. This may result in conflicting situations in the way in which the information on the existing hazard is transmitted to the affected population.

To deal with this, in some cases, it is possible to define a "return" alert code in which the actions recommended to the authorities and population are equally simple as those in the "direct" alert code, but different, and strongly dependent on whether the mobilized population is urban or rural. Although such a "return" code may be designed in the pre-event phase, or during the onset of the critical phase, it is difficult to establish a program and disseminate it to the population in those stages. A more practical solution would be to work out a version of the code for the authorities in which some actions of partial or gradual return may be defined, under additional security conditions.

This "return" code has to take into account the current degree of acceptable risk. If some level of hazard (understood as the probability that a hazardous eruption may occur in this phase) has been defined, the only way to stay within the level of acceptable risk is by reducing vulnerability through the reduction of exposure. For instance, if a rural area was evacuated, and the eruptive activity decreases, but there is no evidence that it has ended, a "return" alert code may define a condition under which it is possible to allow part of the population to return and work during the daytime in specific relatively low hazard areas. This would help to reduce the degree of economic effects of the region, a factor that must also be taken into account in the definition of acceptable risk.

In these kinds of actions, all scenarios must be care-

fully considered, and if there is any evidence that hazardous events may occur without any precursory activity (as for instance, in dome collapse), the return should be delayed.

---

## IV. SUMMARY

Managing a volcanic crisis requires a preparation involving the elaboration of an organized set of actions for use in the case that volcanic activity develops. This pre-eruption phase includes scientific work aimed at the identification of hazardous volcanoes, the elaboration of risk scenarios, and the installation and operation of monitoring devices. The scientists involved in these tasks should become the core of a scientific committee acting as an advisor to the authorities in charge of the safety of the population. It also includes social work involving communication procedures that guarantee a clear understanding by the population and authorities of the natural phenomena and their destructive effects, and developing an operative plan in which the responsibilities of scientists, authorities, and the population are defined and the actions to be taken for different scenarios are clearly specified.

Should an eruption develop, or clear evidence of precursory activity detected, a warning of the critical condition must be declared and communicated through an appropriate alert code. Alarm methods have to be developed to make sure that the information through the communication chain, monitoring–scientists–authorities–population, is clear and unambiguous. In reply to the alarms, response plans should be implemented and the programmed measures taken according to the responsibility matrix defined in the operative plan. When the volcanic activity stops or declines, a return to a subcritical phase has to be designed according to the evolution of the eruption.

## GLOSSARY

**acceptable risk** A risk for which, for the purposes of life or work, we are prepared to accept as it is with no regard to its management. Society does not generally consider expenditure in further reducing such risks justifiable.

**ALARP** Acronym for a principle that specifies that risks should be As Low As Reasonably Practicable.

**disaster relief** Disaster relief has two broad aims: (1) to save life, ameliorate suffering, and salvage what remains from the immediate crisis—in broader terms, to return afflicted communities to the predisaster status quo—and (2) to increase disaster resilience by improving warning systems, strengthening infrastructure, etc.

**hazard** The annualized probability of the specific volcanic hazard—tephra fall, pyroclastic flows, lahars, etc.—occurring in the area under consideration.

**insurance** A common method, at least in developed countries, by which the losses produced by a volcanic eruption

or other natural hazard can be distributed across a group much broader than the group suffering direct losses.

**risk** Risk = Hazard × Vulnerability.

**risk management** A chain of activities progressing through the sequence of risk identification → risk analysis → risk reduction → risk transfer, and aimed at minimizing the risk of loss of life and/or damage resulting from volcanic hazards.

**tolerable risk** A risk that society is willing to live with so as to secure certain net benefits in the confidence that it is being properly controlled, kept under review, and further reduced as and when possible.

**vulnerability** The average degree of loss, expressed on a scale of 0.0 to 1.0, to elements exposed to a hazard.

**V**OLCANIC HAZARDS AND their consequences are best viewed in a risk management framework where identification → analysis → reduction → transfer are the important elements in the risk chain. Careful identification and analysis of volcanic risks is required before risk reduction strategies are implemented. Proactive risk management will involve volcanologists in strategic planning and in interpreting the characteristics of volcanic hazards for emergency managers and others vitally concerned with reducing the potential consequences of eruptions.

## I. INTRODUCTION

The fundamental equation of risk reduction is

$$\text{Hazard} \times \text{Vulnerability} = \text{Risk.}$$

Hazard refers to the annualized probability of the specific volcanic hazard—tephra fall, pyroclastic flows, lahars, etc.—occurring in the area under consideration. Vulnerability can be described as the average degree of loss, expressed on a scale ranging from 0.0 to 1.0, to elements exposed to the hazard—for example, humans, buildings, agriculture, and other economic activity. More commonly, no attempt is made to attach units to this equation and it merely provides a simple shorthand emphasizing the two components to risk—hazard and vulnerability.

Three types of adjustment can be made to reduce the risk associated with the occurrence of natural hazards:

1. The hazard itself can often be modified, though this is only rarely possible in the case of volcanic hazards
2. Vulnerability to the impact of the hazard can be modified—for example, modifications to houses that improve resilience under ash loads, the protection of crops under plastic sheeting, the diversion of lahars, land-use planning, or broadcasts of volcano weather forecasts allowing local inhabitants to plan daily activities
3. The loss associated with damage produced by an eruption can be “distributed” to a wider community through disaster relief and/or insurance

Despite the range of adjustments that can be made, doing nothing is still the most common form of adjustment to natural hazards risk.

Management strategies that involve modifications to vulnerability or insurance can be described as proactive, those focusing on disaster relief as reactive, and those where nothing is done as inactive. Despite the International Decade for Natural Disaster Reduction, most of the efforts of the United Nations and those of national and local emergency managers are still reactive or inactive.

Ideally, risk management efforts are proactive and designed to minimize risk before the impacts of volcanic hazards are experienced. The purpose of volcanic hazards risk management can be stated as:

1. To minimize the risk of loss of life from structure collapse or damage in the event of an eruption
2. To facilitate appropriate warning and evacuation systems

3. To protect food-producing areas and other areas of significant economic activity

4. To improve the expected performance of structures and lifelines

5. To improve the functional capability of structures and lifelines that are essential to posteruption recovery during and after an eruption, and to minimize the risk of damage to hazardous facilities

Ideally, risk management for volcanic hazards will involve a wide range of stakeholders including volcanologists; local and national governments; utility companies and transport and communication providers; representatives of business, construction, education, health, tourism, finance, insurance, and the agricultural sectors; professional organizations and researchers; volunteer and community organizations; the media; and international organizations. Part, possibly a large part, of risk management involves focusing the divergent agenda, priorities, and energies of these groups.

The attitudes of all stakeholders to risk and to risk management will be influenced, perhaps markedly, by their risk perceptions. Cultural theories of risk recognize five broad categories of people as risk takers:

1. The individualist takes an optimistic view of history; building codes have been improved, so risk is decreased.
2. The egalitarian invokes the precautionary principle and presses for urgent action. Buildings are better, but exposure is increasing (more people and buildings and contents) so we need better land-use planning.
3. The hierarchist: everyone knows his/her place. Things are about right as they are, but more research and a slight change of course might be advisable. Building codes are good, but they could be better; more regulation required.
4. The fatalist: hopes for the best, fears the worst. Whatever risk reduction is done, building codes will not be good enough and the volcano will get you anyway.
5. The hermit: what volcano?

Certainly, the risk profiles of individuals, stakeholders or not, are more complex than these five caricatures suggest. Nonetheless, the risk management strategies adopted by groups of stakeholders may owe as much to cultural attitudes to risk as they do to scientific attitudes to risk. Risks to individuals arising from voluntary activities, for example, are often acceptable at levels up to 1000 times higher than those imposed involuntarily.

“Acceptable risk” has been defined as “a risk for which, for the purposes of life or work, we are prepared

to accept as it is with no regard to its management. Society does not generally consider expenditure in further reducing such risks justifiable" (IUGS, 1997, 12). Acceptable risk is distinct from "tolerable risk," defined as "a risk that society is willing to live with so as to secure certain net benefits in the confidence that it is being properly controlled, kept under review and further reduced as and when possible" (1997, 12).

In the late 1980s, Don Peterson suggested volcanologists have "an ethical obligation to convey effectively their knowledge to benefit all of society" (1988, 4161). Increasingly, volcanologists and other emergency managers can expect to find themselves concerned with issues such as "the standard of care of a reasonable practitioner," often embodied in the law of negligence. While risk reduction may be the major focus, it forms one link in the risk management chain that begins with risk identification and proceeds through risk analysis to risk reduction, and then (where possible) to risk transfer.

---

## II. RISK IDENTIFICATION

Volcanic hazards risk identification has two major components—recognition of the range of volcanic hazards that an area is exposed to, and identifying the elements of the environment that are vulnerable.

Table I identifies a range of volcanic hazards, itemizing those physical characteristics that may be significant from a risk viewpoint. Identifying the range of volcanic hazards that might be relevant at any one volcano, or site near a volcano, may not be a simple task. Maps, particularly hazard maps, where the nature of previous eruptions, oral histories, and results from tephrostratigraphic studies are taken into account together with expert judgments and the conclusions from eruption scenarios can be very useful. The intervals between successive eruptions can be so long that written histories are inadequate. Indeed, the eruptions of Lamington in Papua New Guinea in 1951, Heimaey in Iceland in 1973, and Pinatubo in the Philippines in 1991 indicate that repose periods of hundreds, even thousands, of years are not uncommon. Thus, considerable judgment is required in identifying *all* potential volcanic hazards.

The list of hazard characteristics in Table I, relevant to volcanic hazard risk management, is problematic. Although apparently comprehensive, volcanologists have made rather limited efforts to characterize volcanic hazards or to publish detailed posteruption reviews that

might be used to refine the list. Further efforts are required to ensure that this list is comprehensive.

The second aspect of risk identification involves vulnerability to a particular hazard or hazards. Major elements at risk might include people, houses, commercial and industrial buildings, disaster-relevant facilities, other infrastructure (roads, rail, bridges, airports, telecommunications, utilities, etc.), crops, and other economic activity. Vulnerability varies significantly from element to element. Nearly all elements show almost total vulnerability to pyroclastic flows. On the other hand, humans can often be evacuated from the path of an advancing lava flow, crops may be vulnerable to relatively light tephra falls only at specific growth stages, and a water storage and reticulation network may be vulnerable only at the single point where a pipeline is supported by a bridge across a lahar-prone stream.

Numerous factors contribute to the vulnerability of elements. For example, factors contributing to building vulnerability may include:

1. Locations in marginal and potentially hazardous areas, such as floodplains, where lahars, pyroclastic flows, lava flows, and/or CO<sub>2</sub> inundation may occur
2. Densely populated areas with older residential buildings that may be poorly maintained, illegally altered or extended, built to standards now considered inadequate, or substantially overcrowded
3. Poor design and/or construction quality
4. Locations adjacent to industrial complexes where potentially hazardous releases can occur

Any risk matrix or audit that takes account of spatial variability in hazard occurrence around a volcano and the comprehensive identification of hazards and the elements at risk is unlikely to be simple, unless the objective of the risk management is quite limited.

---

## III. RISK ANALYSIS

Risk analysis focuses on the magnitude and frequency of the consequences of volcanic hazards, as well as on the volcanic hazards themselves. Such analyses may begin with a reasonably quantitative understanding of eruption magnitude and frequency, based on a long historical and tephrostratigraphic record with good estimates of the Volcanic Explosivity Index (VEI) for each eruption. For example, data on historic lava flows from Mauna Loa have been used to produce a hazard zone map based on areal coverage, distance from active vents,

**TABLE I** Volcanic Hazard Characteristics Pertinent to Risk

Lava flows	<ul style="list-style-type: none"> <li>—Temperatures above ignition points of many materials</li> <li>—Velocities from a few tens of m/hour to 60 km/hour</li> <li>—Bury or crush objects in their path</li> <li>—Follow topographic depressions; can be tens of kilometers long</li> <li>—Noxious haze from sustained eruptions</li> </ul>
Ballistic ejecta	<ul style="list-style-type: none"> <li>—10+ km radius of vent</li> <li>—High impact energies</li> <li>—Densities &lt; 3 t/m<sup>3</sup></li> <li>—Fresh bombs above ignition temperatures of many materials</li> </ul>
Tephra falls	<ul style="list-style-type: none"> <li>—Downwind transport velocity &lt; 10 to &lt;100 km/hour</li> <li>—Exponential decrease in thickness downwind</li> <li>—Can extend 1000+ km downwind</li> <li>—Material &lt; 64 mm diameter at thermal equilibrium</li> <li>—Can produce impenetrable darkness</li> <li>—Compacts to half initial thickness in a few days</li> <li>—Surface crusting encourages runoff</li> <li>—Abrasive, conductive, and magnetic</li> </ul>
Pyroclastic flows	<ul style="list-style-type: none"> <li>—Concentrated gas-solid dispersion</li> <li>—Flow velocities up to 160 m/s</li> <li>—Emplacement temperatures &lt; 100 to &gt;900°C</li> <li>—Small flows travel 5–10 km down topographic lows</li> <li>—Large flows travel 50–100 km</li> <li>—Large flows climb topographic obstructions</li> </ul>
Pyroclastic surges	<ul style="list-style-type: none"> <li>—Low concentration but high kinetic energy</li> <li>—Radius of deposition 10–15 km</li> <li>—Climb topographic obstructions</li> <li>—Emplacement velocities &gt; tens of m/s</li> </ul>
Lahars	<ul style="list-style-type: none"> <li>—Generated with rainfalls &lt; 10 mm/hour</li> <li>—Bulk fluid densities 2–2.4 t/m<sup>3</sup>, sediment content 75–90 wt%</li> <li>—Peak flow rates &gt; 10,000 m<sup>3</sup>/s; velocities &gt; 10 m/s not uncommon</li> <li>—Increase turbidity and chemical contamination in water bodies</li> <li>—Rapid aggradation, incision, or lateral migration</li> <li>—Travel distances up to tens of kilometers</li> <li>—Hazard may continue for months or years after eruption</li> </ul>
Jökulhlaups	<ul style="list-style-type: none"> <li>—Can occur with little or no warning</li> <li>—Discharges may be &gt;100,000 m<sup>3</sup>/s</li> </ul>

*continues*

*Continued*

**Rock/debris avalanches**

- Sector collapse, minimum volume 10–20 million m<sup>3</sup>
- Travel distances 20–30+ km
- Deposits cover 100+ km<sup>2</sup>
- Emplacement velocities up to 100 m/s
- Create topography, pond lakes
- Can produce tsunamis in coastal areas

**Earthquakes**

- Maximum Modified Mercalli intensity of 8 or less
- Damage limited to small areas
- Damage dependent on subgrade conditions

**Ground deformation**

- Damage limited to 15–20 km radius
- Subsidence may affect hundreds of km<sup>2</sup>

**Tsunamis**

- Open ocean travel rate > 800 km/hour
- Exceptionally, waves to 30+ m
- Inundation velocities 1–8 m/s

**Air shocks**

- Up to 15-fold amplification of atmospheric pressure

**Lightning**

- Cloud-to-ground lightning from ash cloud
- Strikes related to quantity of tephra

**Gases and aerosols**

- Water vapor a major component
- SO<sub>2</sub> next most important
- SO<sub>2</sub>, H<sub>2</sub>S, HF, HCl (corrosive/reactive)
- CO<sub>2</sub> in areas of low ground or poor drainage
- pH of associated rainwater may be 4.0–4.5

ground surface slope, and sheltering topography. Similarly, at Mount Shasta, California, the proportion of concentric zones at 10, 20, and 30 km from the summit affected at least once in the last 10,000 years was used to estimate the future average frequency of pyroclastic flows and lahars. Consideration should also be given to whether eruptions “characteristic” of a particular volcano in terms of magnitude and style can be identified.

Studies combining hazard analysis with a thorough consideration of vulnerable elements (i.e., risk analysis) are relatively rare. At a general level, volcanic hazard maps have been combined with land-use capability maps to produce land-use suitability maps. For Miyake-jima volcano in Japan, such maps emphasize that areas with a high potential for crater formation and/or lava flows are suitable for only low-density, low-value uses.

Given the current state of information about hazard and vulnerability, much of the analysis is likely to depend on expert opinion. Order of magnitude estimates

may be sufficient for some risk analyses. For example, Table II estimates of the frequency of a range of volcanic hazards produced in VEI 4 eruptions in Papua New Guinea, lists estimates of the areas affected by each hazard in VEI 4 eruptions, and a building damage index based on the proportion of replacement cost. It is assumed that buildings are uniformly distributed across each of the hazard zones. The subjective estimates in this table are based on expert opinion.

The Relative Risk Index is the product of the frequency, the area affected, and the Building Damage Index, divided by the lowest nonzero value (that for gases and aerosols) and rounded. The order of importance column is a simple generalization of the Relative Risk Index, with 1 being the most important.

There might be considerable uncertainty and debate about some of the empirical values in the table, but the results in the final column are reasonably robust. For example, changing values in the first three columns by 10% changes little in the last column. The table indicates where risk management should be focused for the case in point. The "quick" analysis shows the overwhelming dominance of tephra fall as a risk to buildings, despite the gross underestimate of the area affected. Obviously, these estimates are unlikely to be appropriate

for volcanoes outside Papua New Guinea, or for eruptions with a differing VEI.

Similar tables could be constructed with specific relevance to an individual volcano and/or a specific building type, economic activity, human population, etc. In each case, the relative risk indexes, and possibly the order of importance estimates, would be different. Considerable refinement of this simple risk analysis is required, taking into account the spatial distribution of the items at risk in relation to the areas mapped as hazard-prone. In most cases it would be appropriate if the table or matrix reflected the views of a range of experts with differing backgrounds.

A number of limitations to the consistency or reliability of risk analysis deserve attention (after IUGS, 1997, 6):

1. Subjective judgments may result in values of assessed risks with considerable inherent uncertainty
2. The variety of approaches that can be adopted to assess risk can result in significant variance in outcomes if the same problem is considered separately by different experts (or even by different groups of experts)
3. Revisiting an analysis can lead to significant change

TABLE II Relative Risk Indexes: Papua New Guinea Volcanoes at VEI = 4

Hazard	Frequency (%)	Area affected (km <sup>2</sup> )	Building damage index (%)	Relative risk index	Order of importance
Lava flows	15	<2	100	10	3
Ballistic ejecta	20	20	30	50	2

<sup>a</sup> Deliberate underestimate of area affected.

<sup>b</sup> Coastal strip, 1 km wide.

due to increased data, applying a different method, or changing circumstances

4. Inability to recognize a significant hazard and the consequential underestimation of the risk

5. The results of an analysis are seldom verifiable, though peer review can be useful

6. The available methodologies are not widely accepted and thus there is sometimes aversion to their application

7. It is difficult to accurately assess risk for low-probability events

Uncertainties in risk analyses need to be noted. Uncertainty is commonly understated, with analysts being a lot prouder of their subjective answers than they should be.

#### IV. RISK REDUCTION

The primary aim of risk analysis is to identify those volcanic hazards and the associated consequences that most require risk reduction efforts. It is unlikely that many risks are regarded as acceptable, with further risk reduction efforts unjustified. However, tolerable risks need to be reviewed with reduction efforts applied where possible.

Tolerable risk criteria for volcanic hazards have not been established but some general principles can be applied (after IUGS, 1997, 9):

1. The incremental risk from a volcanic hazard to an individual or element should not be significant compared to other risks to which a person or element is exposed in everyday life

2. The incremental risk from a volcanic hazard should, wherever reasonably practicable, be reduced; that is, the As Low As Reasonably Practicable (ALARP) principle should apply

3. If the possible loss of life from an eruption of specified magnitude is high, the probability that that eruption might actually occur should be low as society has a particular intolerance to incidents that cause many simultaneous casualties

4. People will tolerate higher risks than they regard as acceptable when they are unable to control or reduce the risk because of financial or other limitations

5. Tolerable risks may vary from country to country, and within countries, depending on historic exposure to eruption hazards and a variety of cultural factors

Risk reduction can be achieved through hazard reduction or by changing the vulnerability of elements at risk. Examples of both sorts are given here.

##### A. Lava Flows

The speed of advance of a lava flow is primarily a function of slope, viscosity, and effusion rate. The rheological properties of lava are such that, if the thrust exerted by the lava issuing from an eruptive vent is significantly reduced, the most advanced lava fronts come to a halt. This suggests two modes of intervention that could be applied—slowing the advance and diverting the flow.

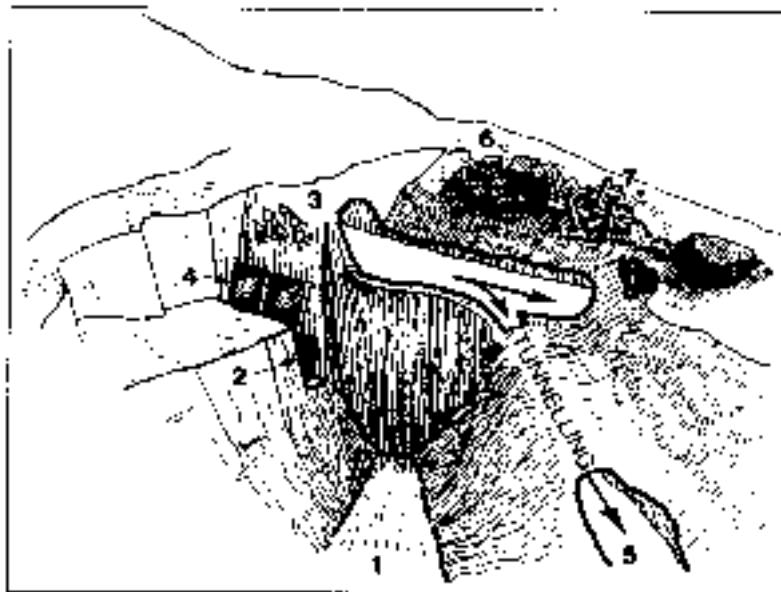

Water has been sprayed on advancing lava fronts at several eruptions. The most publicized of these was at Heimaey (Iceland) in 1973 where up to 32,400 t (metric tons) of seawater per hour were pumped onto the lava surface. Opinions diverge as to whether these efforts were instrumental in saving the harbor or of only limited success. In any case, abundant water appears to slow the advance of (thin) lava flows, buying valuable time for the evacuation of property or even the removal of frame buildings.

Numerous attempts have been made to divert lava flows using aerial bombing, particularly on Hawaii. In 1975–1976, 900-kg bombs failed due to imprecise bomb placement. The new generation of weapon guidance systems could overcome this difficulty.

Earth barriers have been built to force lava flows to accumulate and expand laterally. Even low-density barriers made from incoherent material such as scoriae, lapilli, and ash seem to work, effectively resisting the thrust of the flow. At Etna in 1992 a 21-m-high barrier constructed of incoherent material resisted lava flow advance for 4 weeks before it was overtopped. This and three smaller barriers allowed considerable time to be devoted to lava flow diversion.

Figure 1 illustrates the important elements of a successful lava flow diversion at Etna, involving the digging of an artificial channel with a steep drainage and blasting the wall of the active lava channel. Complete diversion of the 30 m<sup>3</sup>/s lava flow was achieved. With the experience gained in 1992, it is estimated that in similar circumstances a diversion could be accomplished in 10 days.

Successful lava flow diversion implies that areas that may be relatively risk-free are likely to be inundated. One community's risk reduction efforts may well increase risks at another! Since the first attempts at lava flow diversion at Etna in 1669, it has been apparent that risk reduction is not free of legal, social, or spiritual constraints.

**FIGURE 1** A successful lava flow diversion at Etna in May 1992. (1) An artificial channel 10 m wide and 15 m deep; (2) metal containers with 7000 kg of explosive placed into a trench against the thinned solid separation wall; (3) shaped charges placed against a massive lava bank; (4) steel plates interposed between the explosive and the trench filling; (5) earlier artificial channel where lava poured out spontaneously; (6) lava boulders piled on the left bank of the tunnel skylight; and (7) hedgehogs chained together and anchored with steel cables. ## B. Lahars

Lahars can produce alternating periods of rapid incision and aggradation and extensive areas of lateral erosion. Additional areas may be inundated by water ponded as a result of channel changes. Deposition on alluvial fan areas can inundate tens of square kilometers. Although more than 50% of the available sediment is likely to be transported in the first 5 years or so, the lahar hazard can persist long after an eruption has ceased. For example, lahars continued around Pinatubo in 1999, 9 years after the eruption.

As lahars can be produced by even a few millimeters of rainfall, opportunities for hazard reduction may be rare. However, drainage of crater lakes provides one such opportunity. At Kelut (Indonesia), a series of tunnels were completed in 1926 to reduce the volume of the crater lake after the disastrous eruption of 1919 when more than 5000 people were killed in lahars and 9000 houses were destroyed. Recently, the drainage system has been reinstated, restricting the lake volume to  $2.5 \times 10^6 \text{ m}^3$  (cf.  $40 \times 10^6 \text{ m}^3$  before the 1919 eruption). Similarly, the water level at Spirit Lake, near Mount St. Helens, has been regulated by a series of pipes and tunnels to control both water level and discharge.

Revegetation of slopes mantled with fresh tephra can also be effective in reducing the frequency and magnitude of lahar development. Ironically, vegetation often reestablishes first where tephra has already been stripped, exposing the pre-eruption topsoil. Aerial reseeding programs have been used in some cases. However, fresh tephra surfaces often develop an impermeable crust that encourages runoff (and lahar formation) and inhibits seedling growth. Tephra layers less than 15–20 cm thick can be plowed so that fresh tephra and topsoil are mixed, but encouraging water and seedling penetration of thicker layers is difficult.

Vulnerability to lahars can be reduced by using lahar flow warning systems, retention basins, engineered channels, and land-use planning. Warning systems based on acoustic flow monitoring systems, wire sensors, water level gauges, cameras, or seismographs are practicable where warning times are adequate to allow those at risk to reach refuge on high ground or in protected structures. Warning systems only reduce the vulnerability of humans and readily removable objects. Such systems also imply that an education system is in place to ensure that warnings produce appropriate human responses.

Retention basins, sand pockets, or Sabo dams have

been used around many volcanoes including Galunggung (Indonesia), Kelut (Indonesia), Mount St. Helens (USA), Usu, Unzen, and Sakura-jima (Japan). Some basins have been designed to hold as much as 200 million m<sup>3</sup> of sediment; others enclose areas as great as 10 km<sup>2</sup>. Many basins are cleaned out periodically, or at least are designed so that they can be. Retention basins are not suitable for the gentle slopes of large alluvial fans such as those around Pinatubo, because channels can migrate rapidly.

Engineered channels have been used in numerous situations. In the simplest cases, levees or dikes of unconsolidated earthen material are thrown up in (often) futile attempts to confine or divert lahars to existing channels. At Mayon (Philippines), lahars have sometimes ended up on the wrong side of the dikes designed to contain them. The failure of many poorly conceived structures of this type occurred around Pinatubo in the aftermath of the 1991 eruption. Nonetheless, even temporary structures may buy time, providing they are recognized as short-term countermeasures. Boulder-lined levees may be more effective, but as lahars can have bulk densities of more than 2t/m<sup>3</sup>, even large boulders can be readily entrained. The use of gabions is appropriate in some situations, though the wire baskets may not survive long where exposed directly to sediment-charged flows. Concrete levees are probably more effective (Figure 2; see also color insert).

Long-term countermeasures such as expensive concrete-lined and hydraulically efficient lahar channels have been constructed at Usu, Unzen, and Sakura-jima volcanoes in Japan (Figure 3). Frequently, sediment retention basins are incorporated into the design, with steel and concrete structures built to impede the passage downstream of successively smaller boulders and trees. The basic principle is to reduce the energy of the flow, trap the larger material, and reduce the volume. These systems are expensive to build and maintain, and suitable only for relatively small steep drainage basins where the long-term protection of assets with very high values is desirable. Living in harmony with the risk is likely to be the most "effective" countermeasure in many situations.

Reducing vulnerability by land-use planning or zonation is the most obvious and effective risk reduction methodology in many circumstances. Areas likely to be affected by lahars can usually be mapped using tephrostratigraphic techniques and geomorphic knowledge. Successful land-use planning depends on a clear understanding of the risk related to a specific eruption magnitude and character. Sadly, land-use planning is impracticable around many volcanoes, particularly in less-developed countries with high population densities

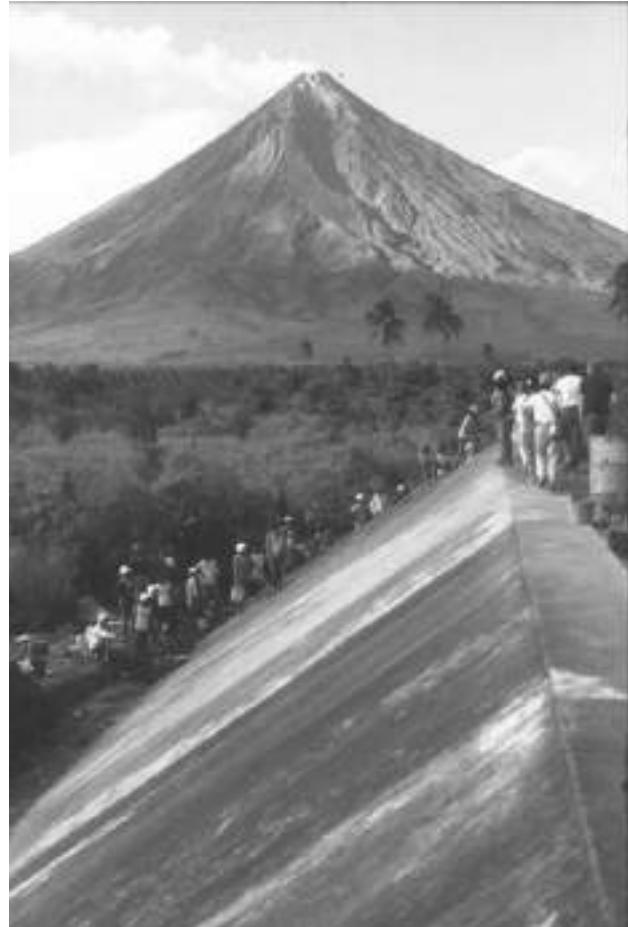

FIGURE 2 A concrete levee designed to retain lahars from Mayon volcano, Philippines. (Photo, R. Blong.) (See also color insert.)

concentrated on the fertile but lahar-prone volcanic soils. The extent of devastation by lahars around Pinatubo emphasizes the additional risks associated with large eruptions.

### C. Tephra Fall

Reduction of the tephra fall hazard is virtually impossible, but reduction of the consequences of tephra fall forms one of the prime risk management objectives (cf. Table II). While a wealth of information was gained from the Mount St. Helens (1980) eruption about ways in which ashfalls could be removed and the undesirable effects on specific structures, utilities, and agriculture minimized, on a global scale remarkably little has been translated into sound attempts to reduce risk *before* an eruption occurs.

**FIGURE 3** Sabo construction using piled steel, tetrapods, and reinforced concrete to form settling basins on the slopes of Usu volcano, Hokkaido, Japan. (Photo, R. Blong.)

Rather cursory investigations in Castillejos (Philippines), where about 200 mm of wet tephra fell during the Pinatubo eruption (1991), suggest that this was sufficient to cause partial or complete collapse of about one-third of roofs. A similar proportion received no damage or slight damage. Long spans ( $>5$  m), timber frames (as opposed to reinforced concrete frames), and steeper roof pitches were identified as factors contributing to greater damage. A similarly incomplete survey after the Rabaul (Papua New Guinea) eruption (1994) suggested that 80–90% of roofs sustained loads imposed by  $<200$  mm of wet tephra with little apparent damage,  $>50\%$  of roofs survived ash depths of 300 mm, and  $>50\%$  of roofs failed under loads of 500–600 mm. Thicker falls resulted in the collapse of most roofs, though steeply pitched roofs survived preferentially, contradicting the evidence from around Pinatubo. Even where roofs survived under loads of 500 mm, interior walls bowed and significant damage was produced to floors, electrical systems, and contents by the ingress of minor amounts of tephra through damaged portions of roofs.

In the Azores, roof materials have been tested to ascertain likely resistance to potential tephra loads. The use of upright props along trusses or purlins to spread tephra loads was recommended, along with the taping of plastic sheeting over windows and other openings and the provision of strengthened refuges within buildings (usually bathrooms are preferred for this purpose), in order to reduce risk to the inhabitants. Subsequent work in Montserrat has provided new estimates of the ranges of impact resistance of a variety of building materials from which survival rates for buildings with different roofing

materials and structures can be determined. Similarly, the proportions of roofs likely to collapse under tephra loads in different parts of the island have been estimated together with the locations of the sites where search and rescue will be most required.

Around Sakura-jima in southern Japan, where the volcano has been in eruption for more than 40 years, improved roofing tiles have been designed, allowing less ash to accumulate and less rain to be drawn in between tiles. Other innovations include a tunnel ventilation system which improves ventilation during ash falls. In areas at risk from ballistic ejecta, reinforced concrete or steel shelters have been erected for personal protection (Figure 4), and a model ash-resistant house has been designed.

In the Kokopo area, near Rabaul, an attempt has been made to develop a building code for commercial and public buildings. This code takes into account the fall of 100 mm of tephra with a return period of 1/500 years, equivalent to a 9.5% probability of occurrence in the 50-year life of the building. As Kokopo is located south of the caldera in an area where, it is believed, trade winds would only rarely deliver tephra, the design ash load is relatively low. Examples of the main provision of the proposed code are:

- Use steeper roof pitches ( $>45^\circ$ ), short spans in roof structure, short cantilever overhangs and eaves, simple roof designs, and roof-sheeting profiles with fluorocarbon polymer coatings noted for corrosion resistance and low frictional resistance
- Include snap-off awnings and gutters independent of main building frame

**FIGURE 4** A reinforced concrete shelter designed to resist the impact of ballistic ejecta, Sakurajima volcano, Kyushu, Japan. (Photo, R. Blong.)

- Utilize underground electrical supply (seal switchboards, etc.)
- Provide floor area elevated 300 mm above ground surface to prevent ingress of mudfills (squeezing of muddy ash under hydrostatic head through openings under doors during and immediately after ashfalls)

The Kokopo “code” appears to be the first attempt to include formally in the design of significant buildings the potential impacts of tephra fall. Refinement, so that it could be used in a variety of situations, would be a useful step in risk management for volcanic hazards.

#### D. Other

Limited opportunities exist for risk reduction in relation to other volcanic hazards. Pyroclastic flow paths can be estimated and avoided, at least for relatively small flows. Containing or diverting pyroclastic flows is problematic given the forces involved. Nonetheless, the construction of training dikes with interior tunnel shelters and nets and fences for directing hot ash clouds to control pyroclastic flows produced by dome collapse at Unzen (Japan) have been proposed. Much of the construction would be carried out using remotely directed construction equipment to reduce the risk to human operators. For rock/debris avalanches, one or more of the height/length formulas can be used to estimate potential run-out distances; possibly these areas can then be sterilized from high-risk land uses. Similarly, land-use planning and structural engineering measures can be used to reduce risks in tsunami-prone areas.

The hundreds of deaths in the degassing of Lakes Nyos and Monoun in Cameroon (1980s) led to detailed investigations and experiments. These indicated that the hazard could be reduced by degassing the bottom water of the lakes within a reasonable time using 140-mm diameter pipes. Although the solution is reasonably clear, and the problem moderately urgent, constraints, including the availability of finance and the difficulties of transporting heavy equipment to remote locations, mean that no hazard reduction has taken place to date.

Human vulnerability to most volcanic hazards could be reduced by prudent land-use planning. However, political and social realities dictate that land-use zoning that restricts occupation of areas where humans and structures are particularly vulnerable is only likely to occur where hazards are frequent. High-consequence, low-frequency volcanic events are unlikely to be in-

cluded in the zoning process in most countries. Nonetheless, in developed countries considerable attention has been paid to high-consequence, low-probability dam failure under probable maximum precipitation conditions. The potential consequences of such events have annual probabilities of  $<10^{-4}$ . High-magnitude, low-frequency volcanic events with similar annual probabilities, and a similar severity of consequences, deserve at least similar risk reduction strategies.

Table III provides a selected list of risk reduction strategies that can be, or have been, employed in relation to a variety of structures, utilities, machinery, and crops. Most of the strategies relate to reducing the effects of tephra falls, reflecting the fact that this hazard affects by far the largest area. Most strategies have been developed for protecting equipment, cleaning equipment, removing ash, and operating on reduced supply and/or increased demand. Most strategies have been developed reactively (after the event), but most can be proactive—as expected in quality risk management. In almost all cases, proactive risk management will involve volcanologists in strategic planning and in interpreting the characteristics of volcanic hazards (Table I) for emergency managers and others vitally concerned with reducing the potential consequences of eruptions.

---

#### V. RISK TRANSFER

In the risk management chain (risk identification → risk analysis → risk reduction → risk transfer), at some stage in the risk reduction process it will be recognized that there are a number of intractable risks. These are the risks that can be transferred to others—to other individuals, organizations, communities, institutions, entities, and/or governments. Often, the transfer involves only a portion of the risk; for example, rarely would either disaster relief or insurance involve a total transfer of the cost of damage. Disaster relief and insurance are the two broad ways in which risk is transferred.

#### A. Disaster Relief

Disaster relief has two broad aims: (1) to save life, ameliorate suffering, and salvage what can be salvaged from the immediate crisis—in broader terms, to return afflicted communities to the predisaster status quo—and

**TABLE III** Selected Risk Reduction Strategies

<i>Risk reduction strategy</i>	<i>Volcanic hazard</i>
Evacuate building contents	Lava flow, ground deformation
Improved fire resistance and reinforcement of disaster-relevant structures such as schools and civic halls	Projectiles, tephra falls
Place shutters, corrugated sheeting, and/or plastic sheets over windows and other openings; improve window frames and air-conditioning	Tephra falls
Remove tree branches above overhead power and communication lines	Tephra falls
Institute preventative management program for vehicles, machinery, filters, bearings, compressors, pumps, chains, switches, computers, and other electromagnetic equipment	Tephra falls
Revise emergency maintenance plan for power reticulation failures	Tephra falls
Remove dry ash from transformer insulators, bushings, etc., by air blowing, pressure washing, or brushing	Tephra falls
Plough switchyard gravel, bringing ash-free gravel to surface, to reduce step-and-touch potentials	Tephra falls
Allow household taxation deductions for ash removal	Tephra falls
Provide roofs for public school swimming pools and similar public areas	Tephra falls
Develop road clearance and traffic management strategies	Tephra falls
Develop water-use policies to cope with supply failures and increased demand	Tephra falls
Isolate storm water collection from sewage system	Tephra falls
Develop additional maintenance and monitoring for all sewage treatment equipment	Tephra falls
Clean roofs to prevent excessive tephra loads on buildings	Tephra falls, corrosion
Disconnect downpipes from roof water collection systems and seal tanks	Tephra falls, acid rains
Protect electromechanical systems from dust and corrosion; reduce maintenance intervals	Tephra falls, gases and aerosols
Review maintenance of clean areas in telecommunications centers; seal rooms with sensitive equipment	Tephra falls, floods
Install crossing gates on roads across lahar channels	Lahars
Reconsider bridge clearances; raise where necessary	Lahars
Revegetate unconsolidated tephra	Secondary lahars
Protect water supply intake structures in streams and initiate enhanced water quality management procedures	Lahars, tephra fall, and acid rain
Optimize lowered water levels behind water storage and electricity generation dams	Lahars, landslides
Cut off gas supply in areas where impacts expected	Lahars, pyroclastic flows, lava flows, ground deformation
Create refuges in air-tight below-ground cellars	Small pyroclastic flows
Increase resilience of disaster—relevant buildings	All
Improve and harden communication systems and information networks	All
Conduct evacuation and emergency management drills	All

(2) to increase disaster resilience by improving warning systems, infrastructure, etc. (in effect, risk reduction).

Disaster relief includes a wide range of activities from short-term search and rescue to long-term trauma counseling and resettlement. Typical relief activities include search and rescue; medical assistance; feeding, clothing, and sheltering evacuees, often for months or years; provision of clean-up equipment, material goods for house

repairs, and tools of trade; short- and long-term financial assistance; and resettlement in safer areas around the volcano or even to other parts of the country.

The number of players in disaster relief can be enormous. One estimate suggests that 246 organizations were involved in relief efforts around Mount St. Helens in 1980. Typically, charities, community organizations, local government, and national government play a role.

International organizations including foreign governments, nongovernmental organizations (NGOs), and United Nations agencies may also participate. Both the media and politicians can play significant multifaceted roles in the disaster aftermath.

Traditionally, disaster relief has been concerned broadly with the immediate disaster aftermath, perhaps extending over a period of several years as the emphasis changes from saving lives to recovery and reconstruction. All of these activities effectively transfer risk, whereby part of the cost of the disaster is borne by groups not immediately affected—the community, taxpayers, international charities, and foreign governments (and taxpayers).

In the last two decades, increasing efforts have been made by disaster relief organizations to increase the resilience of vulnerable communities to risk. This process has been hastened by the UN-declared International Decade for Natural Disaster Reduction (1990–1999). On a global scale it seems difficult to argue that these efforts have been successful, but there are numerous local examples of enhanced warning systems, improved resilience of houses to hurricanes and/or earthquakes, coordinated relief efforts, and emergency management.

## B. Insurance

Insurance is one of the most common methods, at least in developed countries, by which the losses produced by a volcanic eruption can be alleviated or distributed across a group much broader than the group suffering direct losses. Insurance allows rapid reinstatement of property as well as an infusion of funds into communities at a time when economic activity may have slowed. As insurers commonly reinsurance against catastrophic losses, in order to spread the risk, the costs of insurance claims from a single eruption could be distributed around the world.

Volcanic eruptions have never produced billion dollar insurance claims, though 29 other natural disasters around the world between 1970 and 1996 have. Although the total economic losses resulting from the 1980 eruption of Mount St. Helens reached about U.S. \$1 billion, only about 3% of these were insured losses. Similarly, around Pinatubo insured losses amounted to only about 4% of total losses. Numerous cities around the world—Kagoshima, Naples, Catania, Auckland, Quito, Managua, San Salvador, Mexico City, Bandung, Yokyakarta, Manila, Legazpi City, and Guatemala City,

for example—are close enough to volcanoes to suffer catastrophic losses. With the exception of Auckland, none of these cities has a high insurance density and insured losses would be low relative to total losses.

However, numerous other cities with high insurance densities—Tokyo, Yokohama, Vancouver, Seattle, and Portland, for example—have the potential to receive minor ashfalls that might produce limited direct damage but considerable business interruption. In a world where globalization of industry, just-in-time manufacturing, and electronic commerce are of increasing importance, an eruption on one side of the world that damages a component factory can trigger business interruption insurance claims from an assembly plant on another continent.

Individual corporations can also transfer risks by “Insuring” against potential losses from volcanic eruptions using hedges against currency and commodity values. The extent to which hedging against future eruptions actually occurs is unknown, but is likely to be small. Unlike the potential losses associated with earthquakes and hurricanes, the catastrophe potential of volcanic eruptions remains largely unrecognized by insurers or financial markets.

Insurance is clearly proactive in that coverage must be arranged before the impact of the event. Where insurance offers premium rates that reflect actual risks, there can be a strong incentive for risk reduction, rather than risk transfer. Of course, where the risk is regarded as excessive, insurers withdraw from the market, “red-line” the most exposed policies, or raise premiums to levels that customers find unacceptable. In Rabaul, 10 years before the eventual eruption, the seismic crisis of 1984 produced just these results—in effect, some insurers transferred the risk back to property owners, to the community, and to government.

---

## VI. CONCLUSIONS

1. Risk management for volcanic hazards involves partnerships between volcanologists and a wide variety of community stakeholders. Risk management involves an appreciation of cultural attitudes to risk as much as it does the quantification of risk. The sequence of activities—risk identification → risk analysis → risk reduction → risk transfer—provides a logical framework for risk management.

2. Commonly, after earthquakes, teams of earthquake engineers analyze building and lifeline perfor-

mance, adding to the global body of knowledge and influencing seismic codes worldwide. In contrast, post-eruption volcanological investigations have only rarely considered vulnerability reduction. Provisions to reduce the impact of tephra fall have rarely been incorporated into building codes.

3. There are numerous opportunities for the reduction of risk posed by volcanic hazards. These are likely to be particularly effective in the event of small to moderate eruptions.

4. Risk reduction can be reactive, for example, the posteruption development of engineering structures that divert or pond lahars or lava flows. Disaster relief alleviates suffering and reasserts the status quo. Proactive risk reduction and transfer, on the other hand, utilize the whole risk management chain to promote activities that minimize the risk of life loss, facilitate appropriate warning and evacuation systems, and improve the resilience of structures, lifelines, and economic activities.

- I. Noncrisis Public Education Programs
- II. Crisis Response
- III. Summary

---

## GLOSSARY

**"cry wolf syndrome"** An informal term for the phenomena where the public fail to respond to a warning after repeated false alarms.

**distress** A state of anguish brought about by some situation or event over which an individual has little or no control.

**imaginal** Exposure to a setting associated with distress in the imagination.

**intervention** Pre- or postevent action undertaken by responding agencies or groups to reduce the physical and psychological impacts of an event.

***in vivo*** Direct exposure to an actual setting associated with distress.

**multiple gating** A model of intervention designed to capitalize on available resources when addressing the needs of large numbers of people both before and following an eruption.

**PTSD** Post-traumatic stress disorder. An anxiety-based psychiatric disorder that follows exposure to an extremely stressful event.

**warnings** A message usually given to a specific community

or communities when a direct response to a threat is required.

**V**OLCANOLOGISTS REFER TO a "volcanic crisis" as the realm of events concerned with the awakening of a volcano, the building up to an eruption, the eruption itself, and the aftermath as the affected region recovers. Accordingly, the management of volcanic hazards can be divided into four distinct time frames. Noneruptive or quiescent times are the most common and afford the best opportunity to develop mitigation strategies and prepare society for an eruption. The crisis period is divided into three periods: pre-eruption, eruption, and posteruption (or recovery). During the crisis period, risk education and effective interventions are critical in reducing the adverse effects of volcanism on society.

---

## I. NONCRISIS PUBLIC EDUCATION PROGRAMS

### A. Background

Dissemination of information about potential volcanic hazards is important in encouraging an appropriate pub-

lic response and in reducing social impacts. Research over the past 2 decades has shown that the majority of the public do not engage in the self-protective measures recommended by civil defense authorities during non-crisis times. This finding may question the value of public education activities but there is good evidence that hazard knowledge and understanding lead to appropriate responses during a crisis (evacuation, warning compliance, etc). However, several studies have found that multiple messages, delivered by multiple agencies, through multiple channels, but carrying a consistent theme, can lead to an interactive personal search for more information. From this "personal information searching" emerges a personal definition of risk which in turn leads to protective behavior. A survey in New Zealand following the 1995 Ruapehu eruptions found that although some agencies are perceived as more credible than others as the source of volcanic-hazard information, no one agency has a monopoly on perceived credibility (i.e., different people recognize different agencies as the best source of information for volcanic-hazard information and warnings), and this finding supports the need for interorganizational cooperation in hazard education. Similar results have been found in the United States and Japan.

Schools play a vital role in natural hazard education, with volcanic hazards included in the science and geog-

raphy curricula (Figure 1). Research into the content of educational material suggests that the following ingredients are important: personalized information, facts about the likelihood and severity of the hazard, and practical precautionary measures. It has also been found that children involved in an education program discuss what they learned in such a program with parents or caregivers.

Volcanic eruptions are generally less common than other types of hazardous phenomena, such as floods or extreme weather; therefore, in most cases children (and adults) seldom gain personal experience of such events. The mass media provides a large amount of natural disaster news annually. Disasters that do occur provide an ideal opportunity for children (and adults) to gain an improved understanding of the event. But a note of caution: media reports often contribute to biased perceptions that exist among the public. The media frequently give uneven coverage focusing on high-impact, low-frequency events. There is commonly a bias toward reporting on the victims and not those who survived or who were only lightly impacted within the disaster area. The lack of valuable follow-up reporting when disaster-impacted communities successfully cope with their predicament is noteworthy. Thus, responding agencies need to plan for media involvement in order to promote messages that are aimed at assisting

FIGURE 1 School children visiting the Taupo Volcano Observatory, New Zealand. The public information center is popular with school groups and adult visitors. It proved extremely valuable during the 1995–1996 Ruapehu eruption as a venue for press conferences and providing updated information on the eruptions to the visiting public. [Photo copyright Institute of Geological and Nuclear Sciences Ltd.]

preventive efforts versus, for example, simply raising alarm.

### B. Designing and Monitoring an Education Program

Education programs about volcanic hazards (Figure 2) should be carefully designed in order to achieve the

desired outcomes, and monitoring can be put in place to assess their success. The planning process should address the following:

- Identification of existing education resources related to volcanic hazards and all current methods of disseminating public information on volcanic hazards
- Consideration of the appropriateness of current resources and methods of dissemination

- when and where the next eruption might be
- what to expect when a new volcano erupts
- what might happen in the Auckland Region if there's an eruption in the Taupo Volcanic Zone (TVZ)

Come along to a free public presentation on Auckland's Volcanic Hazards by Dr. Ian Smith, Volcanologist, Auckland University

at 7.30pm on Wednesday 18 October 1995  
at Regional House, 21 Parnell St (off K'Rd), New Zealand

NB: Parking available in Heaphy Lane, cnr Park St & Park Lane, off K'Rd or Park Lane, cnr K'Rd & Rd 80

For more details contact the Auckland Museum, Level 2, 171 Queen Street, Auckland, Tel: 09-206 2000, ext. 7191

**Ruapehu '95:- Volcanic Hazard Awareness Week  
16 - 23 October 1995**

**Auckland District Council ENVIRONMENT**

FIGURE 2 An advertisement for a public talk on volcanic hazards from the Auckland Volcanic Field. The talk was part of a national volcanic hazard awareness week organized to promote awareness of volcanic hazards in New Zealand.

- Development of new resources and methods of dissemination where required
- Identification of resources to staff and operation of media/public information functions

### C. Examples of Hazard Education Initiatives

#### 1. Mount Rainier Volcano, USA

In an effort to inform local inhabitants and officials of the volcanic and landslide hazards posed by Mount Rainier volcano (Washington, USA), the U.S. Geological Survey (USGS) has developed a multiyear educational program specifically for public officials, educators, the media, and the general public (Figure 3). The goal is to motivate each audience to (1) participate in the education effort, (2) develop personal emergency preparedness plans, and (3) develop emergency response plans for their communities. The USGS is using a range

of methods to achieve their goals, including permanent and temporary exhibits, annual workshops for educators, public talks, release of a video about volcanic hazards at Mount Rainier, and the release of printed material on the hazards. A mailing list keeps concerned citizens informed of new developments.

#### 2. Egmont Volcano, New Zealand

The Taranaki Regional Council in New Zealand has taken the lead role in raising awareness of volcanic hazards in communities around the Egmont volcano. A 2-year public education and awareness program was initiated in 1995 to promote public awareness of (a) the hazard and (b) the need to prepare for a volcanic event. The Egmont Volcanic Contingency Plan was the basis for the program, and this plan stressed the importance of four evacuation zones defined by the severity of the volcanic risk (Figure 4). Volcano-education kits were developed and distributed to every school in the region along with 36,000 volcanic brochures and 40,000 book-

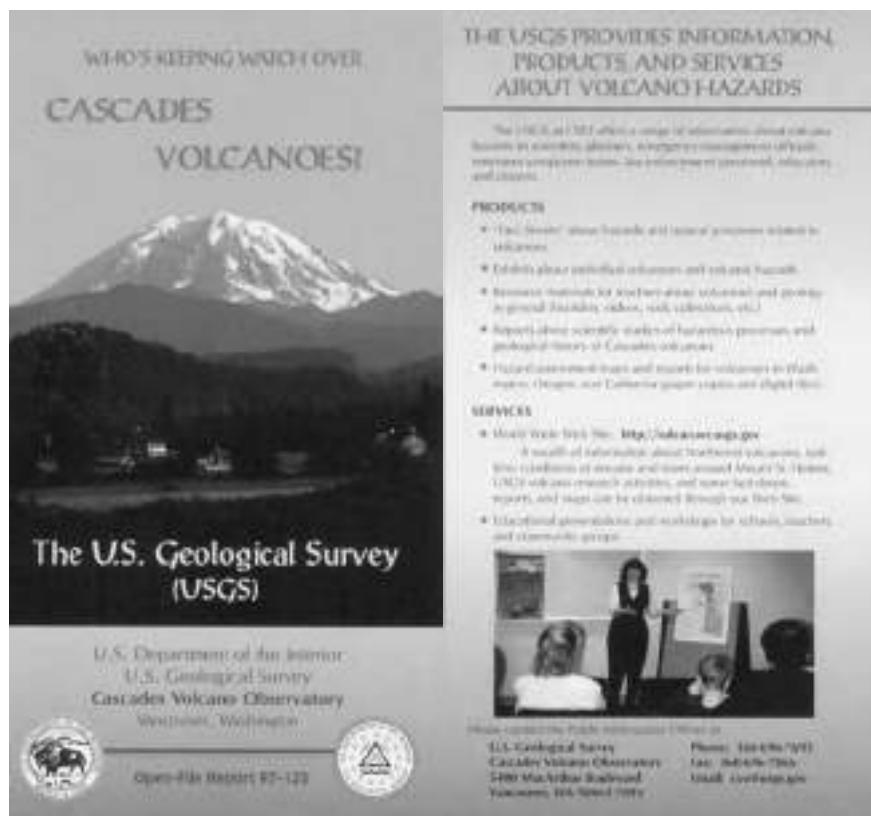

FIGURE 3 A brochure produced by the U.S. Geological Survey as part of their volcanic hazards education program.

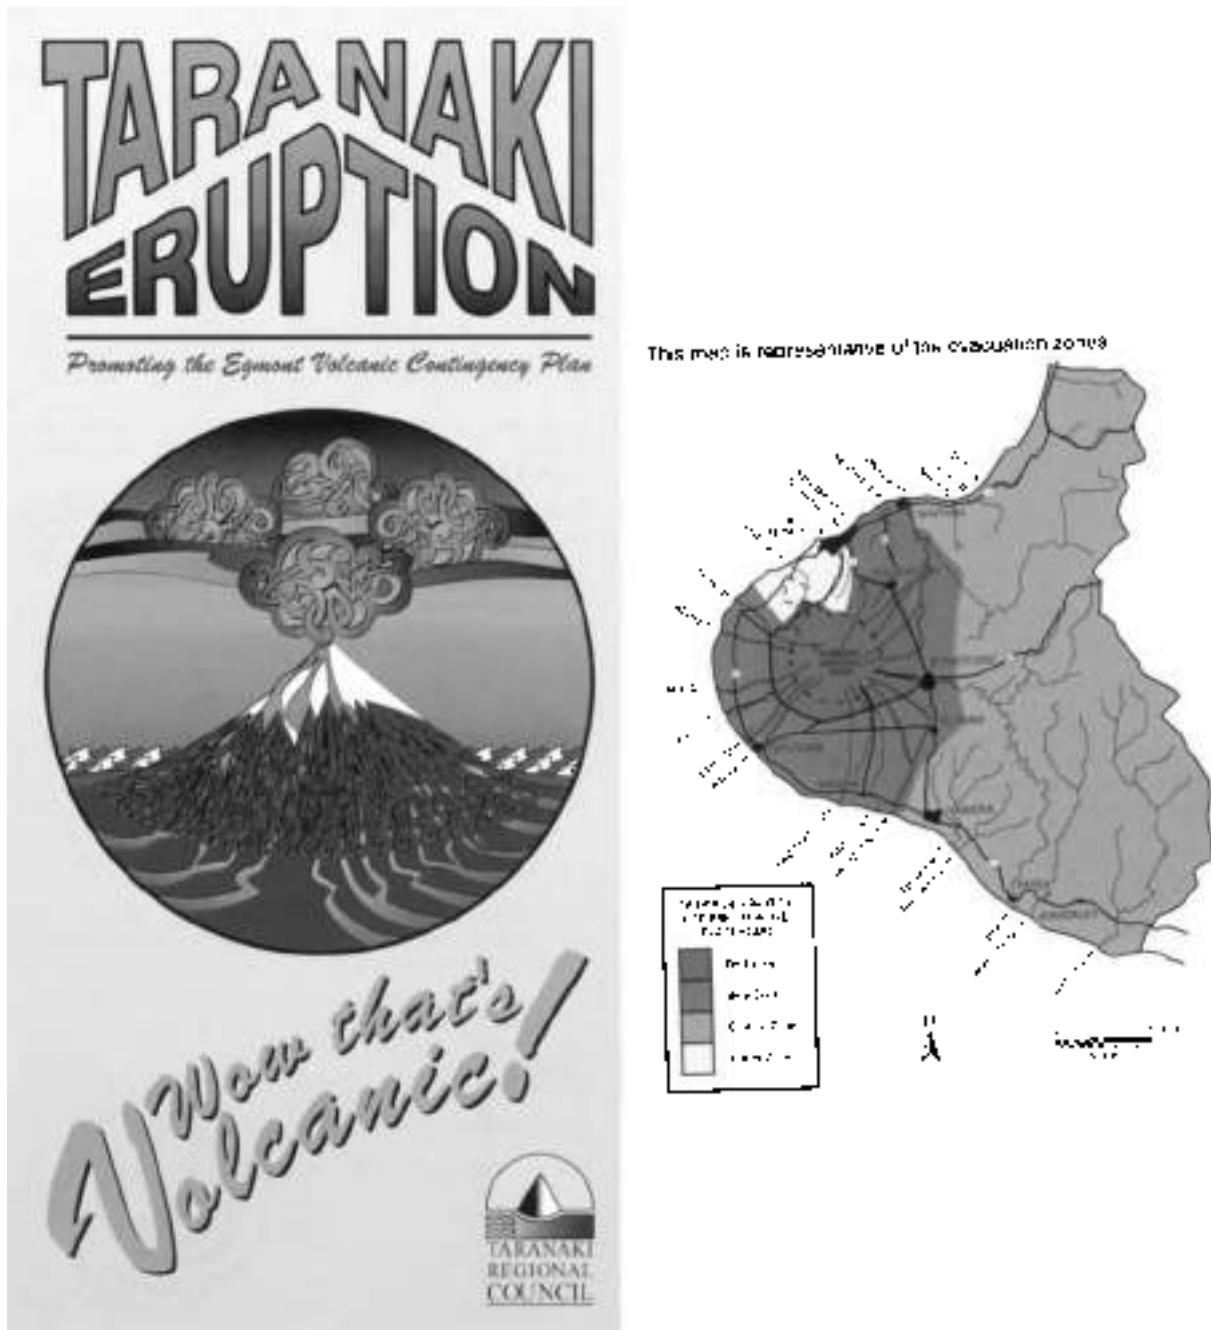

FIGURE 4 A brochure produced by the Taranaki Regional Council, New Zealand, as part of their volcanic hazards education program. The map shows the four predefined evacuation zones.

marks. Fifty copies of the video "Understanding Volcanic Hazards" were distributed to all public libraries for use by local communities, along with presentations to community groups by members of the civil defense staff. The Taranaki Eruption program survey completed

in August 1997 indicates that the level of awareness about volcanic hazards increased from 37 to 56% in the Taranaki region. The educational material is still available in the community and will be reviewed every 2 years.

---

## II. CRISIS RESPONSE

### A. Public Information

During a volcanic crisis, demand for information is intense and this demand will place a strain on all responding agencies. Experience during past eruptions has shown that a crisis period is not the best time to prepare educational material for the public. However, public information prepared in advance can be printed during the crisis (if required) and disseminated rapidly. Communications networks can be severely disrupted during and after an eruption, and therefore information about what to expect and what to do during an eruption must be distributed early. When an emergency is in progress, civil defense officials have to distinguish between sending messages which direct an emergency response and sending those providing public information about the emergency. It is important that responding agencies put information into the news instead of waiting for the media to discover their own "news" (i.e., the need for a media response plan or plan component).

During a crisis, systems often break down, data are misinterpreted, and conditions rapidly change, rendering previously released information "out-of-date." Incorrect or misleading information should be corrected by follow-up information, accompanied by explanations as to the origins of apparently "unreliable" information. When the current information is full of uncertainty (a common situation prior to an eruption and during an eruption) it is important to avoid making or disseminating unrealistic forecasts. This will lessen concerns about the "cry wolf syndrome," a concern common among many public officials. Rumor control is a critical function for agencies responsible for giving out public information, and these agencies should be proactive in identifying and correcting incorrect or misleading information. However, some caution is needed because immediate and harsh official denouncement of popular views may be counterproductive and treated with suspicion as the public often prefer to hear a range of opinions before drawing their own conclusions on a subject.

The social and economic impacts of adverse events are determined not only by direct physical consequences but by the interaction of psychological, social, cultural, and institutional processes that can amplify and attenuate the public response. This is commonly referred to as "social amplification of risk" and this was clearly evident during the 1995–1996 Ruapehu (New Zealand) eruptions. Much of this "social amplification" was fueled

by the media coverage which brought dramatic images of the eruption to people throughout New Zealand and the world.

### B. Warnings

Warning messages are usually given to a specific community or communities when a direct response to a threat is required. The response to warnings by individuals has been found to relate to (i) individual risk perception (understanding, belief, and personalization); (ii) the nature of the warning information (specificity, consistency, certainty, accuracy, clarity, media, frequency, etc.); and (iii) the personal characteristics of the recipient (demographics, knowledge, experience of the hazard, social network, and so on). A consistent and clear conclusion of social science research is that the warning message itself is one of the most important factors that influences the effectiveness of the warning system. Unfortunately one or more of the important attributes required of warning messages (specificity, consistency, certainty, accuracy, clarity) is usually deficient or missing during a volcanic crisis. Commonly specificity and certainty about the time and nature of the eruption are missing. Responding authorities must recognize this.

Five topics are important when constructing a warning message: (1) the hazard and/or risk, (2) guidance, (3) location, (4) time, and (5) source. The warning message must contain information about the impending hazard with sufficiently simple detail that the public can understand the characteristics of the hazard that they need to protect themselves from. The message should include guidance about what they should do to maximize their safety. The warning message must describe the exact location that is at risk and address the "when" aspect of the required response.

The final important dimension is the source of the information. Warnings are more likely to be believed if they come from "credible" sources. The public's perception of credibility of information sources is a subjective judgment and has been shown to be related to notions of expertise and trustworthiness. Three general bases on which credibility can be judged are: (1) the "credentials" of the person or agency issuing the warning; (2) the relationship of the organizations to other "credible" organizations; and (3) the past history of job performance. Trust and credibility are valuable assets—difficult to obtain and once lost, difficult to regain. Prior to a volcanic crisis, agencies which may have to issue warnings or at least have a role in their dissemination can

take a proactive step toward enhancing their credibility. Agencies working in a coordinated and collaborative way with other agencies can improve their own credibility. Having a senior or publicly recognized person issuing or associated with the issuing of a warning notice and issuing warnings in association with other "lead" agencies will enhance credibility.

### C. Examples of Crisis Responses

#### *1. Mount Pinatubo, 1991: Learning Lessons*

Thousands of lives were saved during the eruption of Mount Pinatubo in the Phillipine Islands following a cooperative effort between the Phillipine Institute of Volcanology and Seismology (PHIVOLCS) and the USGS. The primary reason for successful evacuation of inhabitants was the cooperative effort between volcanologists and government officials. Through the use of a straightforward and readily comprehensible alert level scheme (ranging from 1 = low-level unrest to 5 = eruption in progress; see Table I) and the presentation of a nonjargonistic video to public officials on the dangers of volcanoes (pyroclastic flows, lahars, etc.), both public

officials and citizens became aware of the potential need for evacuation. As the alert level was progressively raised, so too was the radius of evacuation around Mount Pinatubo. By the time the eruptions of June 15, 1991, had begun, 58,000 people were evacuated. A major point to be taken from the Mount Pinatubo eruption and response is the role that volcanologists play in helping initiate a sequence of crisis response activities. That is, government officials may, as described in the next example, be reluctant to act for a variety of reasons. However, if scientists can describe volcanic processes and hazards in simply understood language and combine that with a message of the need for action in certain circumstances, this can set in motion the necessary events to save people's lives.

#### *2. Nevado del Ruiz, 1985: A Failure*

The eruption of Nevado del Ruiz volcano in Colombia on November 13, 1985, was about one-tenth the size of the 1980 Mount St. Helen's eruption. However, over 20,000 people died as a result of volcanic mudflows (lahars) whereas less than 100 died in the Mount St. Helens eruption as a consequence of a directed volcanic blast. Though the town of Armero, 72 km from the

TABLE I Alert Levels for Mount Pinatubo, May 13, 1991<sup>a</sup>

Alert level	Criteria	Interpretation
No alert	Background; quiet	No eruption in foreseeable future
1	Low-level seismicity; other unrest	Magmatic, tectonic, or hydrothermal disturbance; no eruption imminent
2	Moderate level of seismicity, other unrest, with positive evidence for involvement of magma	Probable magmatic intrusion; could eventually lead to an eruption
3	Relatively high and increasing unrest including numerous b-type earthquakes, accelerating ground deformation, increased vigor of fumeroles, gas emissions	If trend of increasing unrest continues, eruption possible within 2 weeks
4	Intense unrest, including harmonic tremor and (or) many "long-period" (low-frequency) earthquakes	Eruption possible within 24 hours
5	Eruption in progress	Eruption in progress

#### Stand-down procedures:

In order to protect against "Lull before the storm" phenomena, alert levels will be maintained for the following periods after activity decreases to the next lower level:

- from Alert level 4 to 3—Wait 1 week
- from Alert level 3 to 2—Wait 72 hours

<sup>a</sup> Slightly different schemes have been developed for other volcanoes worldwide. Some volcano observatories use a numbering system whereas others use a color scale.

Source: Newhall, C. G., and Punongbayan, R. S., eds. (1996). Page 90 in "Fire and Mud: Eruptions and Lahars of Mount Pinatubo, Philippines." Philippine Institute of Volcanology and Seismology and Univ. of Washington Press.

volcano, was identified by geological studies as being at risk from lahar inundation—it was directly in the flow path of lahars resulting from pyroclastic flows melting the snow on Nevado del Ruiz—an assortment of human errors contributed to a lack of warning.

After the eruption began, and even though the Armero police were notified, there was no or very little response. This was probably linked to the fact that the eruption happened 2 days before an emergency management plan was to have been reviewed. Thus, despite the scientific knowledge, various human factors precipitated this disaster. At the time of the eruption police may not have known how to translate the warning into public protective activity. In addition, there was a lack of risk education and information about volcanic hazards available to the public. These included no pre-event public education programs and the lack of a warning system and evacuation plan established, tested, and in place. From a human factors perspective, the element of fear in government officials was great—the most common human reaction to uncertainty about the environment is fear and anxiety. The prediction of volcanic eruptions brings with it uncertainty and the fear of false alarms. We know from psychological research that the most common behavior associated with fear and uncertainty is avoidance of action. Thus, an issue worth bearing in mind is the necessity of appropriately trained personnel being in charge of pre-event planning, education programs, warning systems, and risk mitigation—not only those who have the intimate knowledge of what needs to be done but also those who have the courage to counter fear, avoidance, and inactivity and be willing to initiate warning systems and evacuation plans when necessary despite protests from official quarters.

## D. Postevent Interventions

### 1. *Rationale*

Postevent education and intervention need to focus on both physical needs and social factors. Of course, there is a close relationship between these factors following a major disaster. Generally, people affected by a major disaster not only have physical needs to be met, including physical safety, they also have to cope with the distress, fear, and grief that can be associated with such events. Often, people will lose a sense of control and feel very uncertain about the future. As we have discussed, what usually accompanies uncertainty and a lack of control is a decreased ability to enact adaptive behaviors. In the first instance, these behaviors need to focus

on physical survival; however, people who are very distressed or in shock often lack the necessary psychological resources to initiate recovery-based activities. Thus, while issues related to safety and physical needs take necessary precedence as seen in the case examples of Nevado del Ruiz and Pinatubo, social factors are obviously implicated in risk and recovery-related communication. Responding agencies have an obligation to build in information speaking to these factors. For example, part of planning for warning systems includes having in place guidelines for informing people when eruption and warning levels are declining, and what people should be doing to keep themselves and their families safe and to meet their physical needs. An issue of critical importance related to both physical needs and social factors is the absolute necessity of pre-event planning and coordination across all responding agencies. As we pointed out earlier in discussing pre-event education programs, the critical issue of consistent messages being sent out by multiple agencies through multiple channels is just as relevant following an event as it is in helping the public be prepared. When various agencies are not coordinated and are putting out inconsistent or even conflicting information, uncertainty will result. As we have pointed out, the most common emotion associated with uncertainty is anxiety and fear; the most common behavior is avoidance. Consistent themes presented by various agencies can help people not only reduce uncertainty, but also help them to gain an increased sense of control about what constitutes appropriate mitigation and recovery-based behaviors. Thus, the process of planning and coordination across agencies combined with the actual consistent content of messages will set the stage for helping people reduce uncertainty, feel more in control, and begin to take action.

Owing to the fact that enacting response and recovery-related behaviors following a disastrous event may be competing with distress and grief, all postevent education approaches need to be mindful of psychological factors. An initial way to include such factors was just discussed (i.e., planning and coordination across agencies and consistent messages to help people reduce uncertainty and reestablish a sense of control). Another way that we have found is to pursue collaborations between physical and social scientists. As we articulated earlier, given that the credibility of a communication source is an issue in this field, our own approach in New Zealand has increasingly emphasized such collaborations. For example, as we will expand upon in the case example section later, following the Ruapehu eruptions, misinformation about physical aspects of the eruptions (e.g., safety and effects of ash in water supplies) led to distress

in some children and adolescents (and some parents). Information provided by a volcanologist (senior author)—in consultation with a child clinical psychologist (second author)—helped reduce fears and distress and increase coping ability.

In terms of social and emotional factors, a necessary first step in any intervention is an awareness of the normative effects of hazards and disasters on communities and individuals. While a fairly sizable data base has focused on such factors, systematic research looking at the effectiveness of postevent interventions is sparse. One reason for this is that the topic of postdisaster research is in its infancy. The formal concept of post-traumatic stress disorder (PTSD) did not gain formal recognition in the psychology profession until the 1980s. Though some research has looked at the effectiveness of different approaches following other traumatic events (e.g., assault), very little has looked at these approaches following a natural disaster. However, this has not prevented numerous education and intervention approaches being developed for disaster victims. They range from those emphasizing predisaster readiness as discussed earlier to a range of approaches emphasizing postdisaster coping. Postevent approaches range from community-based early intervention (i.e., soon after the event) to longer term approaches for those who do not cope effectively.

We focus here on general issues identified as important following distressing events as a guide to developing specific programs following volcanic eruptions. The first includes a technique called “multiple gating,” followed by a discussion of elements included in education and intervention approaches.

## ***2. Multiple Gating***

Multiple gating is a model of intervention designed to capitalize on available resources when addressing the needs of large numbers of people both before and following an eruption. This approach is designed to use a parsimonious assessment methodology to help identify those at risk for increased distress. For example, self-report measures are available that can be filled out in a matter of minutes. For those identified at this initial “gate,” brief education programs can focus on providing relevant information (see next sections for the content of this information) in large group, community-based settings (e.g., at local schools). For those who do not respond to such efforts, later gates can become increasingly comprehensive in terms of both assessments used and intervention offered (e.g., small groups, family-based, individually focused). When large numbers of

people are impacted and when a dearth of resources are available for individual attention to each person’s needs, this approach can be ideal.

The first step in this model is primary prevention. As we discussed earlier, predisaster readiness has been identified as effective in helping people more readily adapt to the effects of a disaster. While some eruptions can be anticipated to a degree, others occur with less warning. In these cases, crisis response and other forms of early intervention are vital. Crisis response can assist people to cope with safety issues and physical needs while also serving as a first line of intervention to help with negative emotional arousal. Early intervention is designed to help victims establish a sense of control that can prevent future problems. These interventions can be planned and implemented first to assist at a community-wide level. For example, community-and school-based education programs can provide efficient information dissemination that includes specifics on safety, physical needs, what constitutes normal reactions to a disaster, coping skills, and information about how to access agencies and support. A brief education program presented by a volcanologist and child clinical psychologist reduced symptoms of PTSD and increased coping ability in 7- to 13-year-old schoolchildren following the 1995 Mount Ruapehu eruptions. These children continued to show reduced distress at follow-up 7 months after the initial disaster. We illustrate this program shortly.

For those who continue to have problems despite such initial efforts, the next gate would emphasize group- or individually focused interventions to provide additional help. The major point to be taken from this section is that the use of a gating methodology allows for efficient use of available resources. We now discuss features of education and intervention programs that we believe are important.

## ***3. Support and Information***

While support is often a given following a natural hazard, some focus on this factor is necessary owing to its importance. Victims of disasters need support. One vital part of support discussed above includes helping victims become aware of important information as soon as possible after the disaster. As discussed, victims can begin to regain control as they receive information that addresses safety factors, physical needs, normal psychological effects of natural hazards, and simple coping skills (e.g., simple problem-solving skills, how and where to access information and agency-based support, the rationale behind using social support networks). There may be loss associated with an eruption. Within supportive environ-

ments, victims can be provided with information that helps them understand issues related to the normal grieving process.

#### ***4. Specific Ingredients: Focus on Exposure and Related Techniques***

Despite differences across a variety of intervention approaches, most emphasize looking back at the event and dealing with the distressing thoughts and associated feelings.

The rationale behind the technique of exposure is that the distress associated with an event will diminish as a function of a habituation process (i.e., "extinction") associated with the willingness to look back at stimuli associated with that distressing event. An issue that underlies this technique is the time interval allowed for exposure to traumatic stimuli. Overly brief exposure intervals are not recommended. In fact, too brief an interval may actually increase distress. Generally, exposure intervals need to be sufficiently long enough that the person begins to experience reduced arousal and distress. Variation in application does, however, exist in terms of the level of arousal (low versus high) as well as the type of actual exposure (imaginal versus *in vivo*). For example, the variant "systematic desensitization" uses a hierarchy of fears ranked from least to most distressing and imaginal exposure. By contrast, *in vivo* flooding involves direct exposure to the actual setting associated with distress. The idea here is to induce a high level of anxiety that begins to reduce with prolonged exposure intervals. For example, intervention following volcanic eruptions most often cannot involve direct exposure to eruptive activity. However, exposure can nevertheless take place. For example, video excerpts of the 1995 Mount Ruapehu eruptions were used in an intervention with children and adolescents (see later case example).

Interventions that use exposure generally include other techniques. For example, relaxation (e.g., breathing relaxation, deep muscle relaxation) during exposure is designed as a competing response to excess arousal. Exposure-based approaches may also include the technique of modeling (i.e., watching another cope effectively) and practice (e.g., role play) of coping skills. Self-reward (the ability to "pat oneself on the back") is a skill designed to reinforce consistent attempts at mastery and coping. Homework is designed to help the victim practice skills learned in naturalistic settings.

In addition to these techniques, intervention often includes other components aimed at cognitive and affective processes (e.g., reducing uncertainty). For exam-

ple, in working with anxious children, including those who have experienced traumatic events, we use a FEAR acronym to help children remember problem-solving steps and increase their sense of control: identifying unwanted arousal as a signal to using relaxation techniques (*feeling upset?*), identifying fear-related thinking (*expecting bad things to happen?*), devising and carrying out coping plans (*attitudes and actions that can help*), and engaging in self-reward and coping with less than complete success (*results and rewards*). Once learned, this approach is then used to help the child cope during the second half, or exposure phase, of the intervention. Other techniques—modeling and role play, praise, concrete reinforcement, homework tasks, and assisting parents—are used to help the child (and family) use these skills. This kind of approach appears to have promise for children following volcanic eruptions. Similar problem-solving models have proved useful with adults and families.

#### **E. Case Study: Ruapehu Early Intervention**

In this section, we provide one example of an early intervention with children—that is, what would constitute the initial steps in a multiple gating intervention model. At the end of the case example, we provide ideas on multiple gating with adults (and families).

A study by the authors has assessed the effects of a brief, school-based intervention with children following the 1995 eruptions of Mount Ruapehu, New Zealand (Figure 5). One hundred twelve children, ages 7 to 13, from three separate schools all within an 11-km radius of the base of Mount Ruapehu participated in two preintervention assessments 1 and 3 months following the initial eruptions. The children were assessed on self-reported levels of (a) PTSD symptoms as well as (b) the ability to cope with stimuli related to the eruptions (e.g., thoughts about the eruptions). Of the children involved, 62% were identified as having mild or greater self-reported PTSD-related distress 1 month following the eruptions. It is also a common finding in working with distressed children that some who were deleteriously impacted very likely were not willing to admit distress on self-reports. Consequently, it is likely that there was another small subsample of distressed children not identified through our self-report methodology.

The intervention itself was administered 2 months after this first assessment. Children from each school were randomly assigned to one of two 1-hour intervention conditions: (1) video-based exposure combined with

FIGURE 5 Eruptive activity from Ruapehu on Monday, 25 September 1995. The 1995 eruptions lasted for 3 months and caused closure of three ski fields and had a major economic impact on surrounding communities. Further eruptions in 1996 amplified the effects from the previous year's eruptions. [Photo copyright Institute of Geological and Nuclear Sciences Ltd.]

expert information or (2) video-based exposure, expert information, and additional cognitive-behaviorally based intervention. The first condition included a 20-minute video of the initial eruptions and a presentation by a volcanologist on physical science. This presentation included issues related to general safety (e.g., ash was a nuisance rather than life threatening) following consultation between the volcanologist (first author) and a child clinical psychologist (second author). In this condition, the child clinical psychologist also presented information intended to help children understand that fears following such an event were normal (i.e., presented information related to normal psychological effects). The second condition included these components as well as additional techniques designed to help children actively cope with distressing reactions. The techniques—active problem solving, seeking social support, and modification of negative self-talk—were discussed and modeled by the child clinical psychologist.

The findings of the intervention indicated that both conditions were found to help distressed children significantly reduce PTSD-related distress. The cognitive-behavioral condition was found to be slightly superior to the exposure-only condition with regard to helping children significantly increase self-reported coping ability. At a follow-up assessment done 4 months after the intervention, positive changes were maintained for cop-

ing ability. Continuing, significant improvement was indicated for PTSD-related distress. Additionally, comparisons between treated children and a nontreated group at this gate found superior effects for the combination of time and intervention versus the effects of time alone on both coping ability and PTSD-related distress. In fact, the treated group's mean PTSD-related distress score was in the nondistressed range whereas the nontreated group's mean symptom score continued to be in the distressed range.

One issue worth highlighting here was the value of collaboration between a volcanologist and a clinical psychologist. Combining expertise areas may have potential implications in a wide range of applications, with this area being a fruitful one for more collaboration and research. Another issue is the fact that children who are not in communities vulnerable to products from an eruption may nevertheless experience distress. There were indications in our research that children 11 km from the base of Mount Ruapehu on the leeward side were as impacted initially as those children who lived at the base of the mountain on the windward side.

In our research, this precedence appears to have been emphasized more in the two communities at the base of the mountain than in the community 11 km from the base. Prior to our intervention, we found that a child's ability to cope improved over the 2-month inter-

val between our preintervention assessments in the two communities at the base whereas it was seen to deteriorate slightly in the children living 11 km away. The point here is that adults need to be sensitive to the fact that natural disasters like volcanoes can be upsetting for children in a wide range of locations both near and far from an actual impact area. Thus, simply because adults may not be experiencing any ill effects, this should not be taken as a gauge for children's reactions.

Another issue worth highlighting is how to deal with those who have continued distress despite early, group-based interventions. In following a multiple gating methodology, follow-up interventions would include those that were increasingly more comprehensive. For example, after large group interventions, smaller group interventions might represent the next step, particularly if larger numbers of people continue to show elevated levels of distress. Following that gate, for those who do not respond to small group applications, more intensive individual therapy may be recommended. For adults and families, this gating procedure would be similar to that used with children and adolescents though necessarily adjusted to meet particular needs of the target population. For example, for adults, larger group interventions might be held in a community-based setting and include developmentally appropriate versions of exposure, expert information, and cognitive-behavioral strategies combined with information on how to assist their children and other family members (e.g., normalizing fears for their children while demonstrating confidence and means by which a disaster can be coped with).

### III. SUMMARY

Northeast or quiescent times are the most common and afford the best opportunity to develop mitigation strategies and prepare society for an eruption. Public education programs should aim to improve a community's understanding of the nature of volcanic hazards. During a crisis period, risk education and effective interventions are critical in reducing the adverse effects of volcanism on society. It is contingent upon governments, emergency services, and other relevant organizations being able to understand the significance of information they receive and respond appropriately. Agencies issuing warnings must distinguish the function of sending out messages which direct an emergency response,

such as an evacuation, from that providing information about the emergency. Developing links with the media before a volcanic crisis will help response agencies better coordinate information during an event. During and after an eruption, hazard-relevant education programs can help reduce fears associated with uncertainty and increase the ability of affected populations to cope with the event.

## PART IX

---

# ECONOMIC BENEFITS AND CULTURAL ASPECTS OF VOLCANISM

Most people think of volcanoes either as objects of awe and fascination or as agents of destruction. Indeed, at times they can be both. However, volcanoes also contribute to commerce and culture in myriad ways. The seven chapters in this section explore a few of the ways in which volcanoes enrich our lives and sometimes our pocketbooks.

Modern life is highly dependent on energy to heat buildings, cook food, and run automobiles and machinery. In many volcanic regions geothermal resources are exploited either directly for heat or indirectly for the generation of electricity. Geothermal energy may be renewable, provided that it is withdrawn at a lower rate than the natural heating. It is also clean compared with the burning of fossil fuels. These issues and other aspects of geothermal energy are discussed in the opening chapter of this section, Exploitation of Geothermal Resources.

Volcanic ash and lava from eruptions often cover large expanses of ground and are detrimental to life, but over time these same materials weather to form soils. The resulting volcanic soils have unique physical and chemical features, which affect properties such as moisture retention. Some mountainous volcanic regions are noted for their production of coffee or wine, owing to volcanically derived soils. So, if you start your day with a cup of coffee and end it with a glass of wine, volcanoes may have been indirectly responsible. The following chapter, Volcanic Soils, details the properties, distribution, and formation of such soils.

Volcanic rocks are the most plentiful rocks in many areas and are often used as building materials for structures and road beds and in some types of cinder blocks, landscaping, and walls. The altered volcanic clay, bentonite, is commonly used in diverse products from drilling mud to cosmetics. The next chapter, Volcanic Materials in Commerce and Industry, describes many products derived from volcanoes.

Hot springs and fumaroles are often found in close association with volcanoes. This combination has led to the development of many spas and resorts at volcanoes. The attractive mountainous terrain of volcanic areas is also suitable for hiking, camping, and climbing as well as for viewing the various surface manifestations of volcanic activities. These and related topics are discussed in the following chapter, Volcanoes and Tourism.

Ironically, volcanic deposits are wonderful preservers of ancient buildings and artifacts, even though at the time of eruption they were undoubtedly viewed as destructive. Much of what we know of some ancient civilizations was instantly preserved by the devastating force of volcanic eruptions. Examples include the well-known Roman cities of Pompeii and Herculaneum and the Bronze Age Akrotiri in the Aegean. Other less well known sites near Ilopango in El Salvador, Arenal in Costa Rica, Sunset Crater in Arizona, Mount Rainier in Washington, Mount St. Helens in Washington, and sites in the Yukon Territory have yielded clues showing the widespread effects of eruptions on the life of early

peoples. The chapter Archaeology and Volcanism explores how archaeological sleuths have harvested information about early cultures and describes the origins of geomythology.

Volcanoes are often used as metaphors for power or unpredictability. Volcanoes are also frequently viewed as windows to the interior of the earth. These ideas show up repeatedly in popular culture and often make their way into books, movies, cartoons, and other forms of expression. Two famous examples that began as books and were later made into films are the novel *The Last Days of Pompeii* by George Bulwer-Lytton (1834) and the science fiction work *Journey to the Center of the Earth* by Jules Verne (1864). This section of the encyclopedia, and the entire text, concludes with the chapter Volcanoes in Literature and Film. This chapter provides brief descriptions and synopses of many volcano books and movies.

Readers may be surprised by the far-reaching benefits of volcanoes outlined in this section and their broad impact on our lives. Although we tend to think about volcanoes primarily while they are erupting, their products and images are found in many places in both ancient and modern life. A world without volcanoes would be a duller, less economically viable, and certainly less interesting place.

## GLOSSARY

- geothermal exploration well** A well drilled for the purpose of locating a potentially exploitable geothermal reservoir.
- geothermal field (area)** An area with finite surface boundaries, often defined by the distribution of hot springs and/or fumaroles, overlying a potential geothermal energy resource.
- geothermal fluid** Hot water and/or steam hosted in a geothermal system. Geothermal fluids contain both dissolved gases and solids. Occasionally geothermal fluids are highly mineralized containing as much as 30% dissolved salts, such as at Salton Sea, California. Such salty fluids are typically high in many metals and probably represent ore-forming fluids.

**geothermal reservoir** A body of hot rock containing geothermal fluid that is economically exploitable.

**geothermal system** A body of hot rock and hot fluid in a particular rock-hydrological situation.

**injection well** A well used for disposing of waste geothermal fluid from production wells/power plants.

**production well** A well that produces steam/hot water that can be economically exploited.

**permeability** The property of a rock which allows the passage of fluids without impairment of its structure or displacement of its parts. A rock is said to be permeable, if it permits an appreciable quantity of fluid to pass through it in a given time, and impermeable, if the passage is negligible.

**porosity** The proportion of pore space occupied by the rock as a whole.

---

## I. INTRODUCTION

The ultimate source of all energy exploited by mankind is the Sun, except for nuclear energy and geothermal energy. The heat within the Earth, which constitutes geothermal energy, comes from the decay of radioactive

elements, particularly uranium, thorium, and potassium, and the Earth's gravity field.

The amount of heat stored within the Earth is enormous. However, use of this energy has only proved to be economical where geological, hydrological, and geophysical conditions are favorable for the formation of geothermal systems. Basically, a geothermal system represents groundwater that circulates to a depth of a few kilometers where the water gains heat by contact with hot rock. Hot water is less dense than cold and, therefore, tends to ascend by buoyancy. Groundwater convection (circulation of groundwater) may be driven by hydrostatic head or by the density difference between colder water in the downflow limb of the convection cell and hotter water in the upflow limb. For the same groundwater level, within and adjacent to a geothermal field, the pressure at any depth will be higher in the descending cold water than in the ascending hot water. Provided this difference and rock permeability are sufficiently high, groundwater convection will be sustained.

Geothermal systems typically form in active volcanic regions where geothermal gradients and rock permeabilities are high. However, economic geothermal reservoirs have also been discovered in sedimentary strata, including oil-bearing strata, and in fractured volcanic rocks outside areas of recent volcanism. The exploitation of geothermal resources has had a relatively insignificant environmental effect. With respect to atmospheric pollution, it is superior to the use of fossil fuel.

Extraction of heat from impermeable rock has been attempted in a few areas. It involves the drilling of injection and production wells, hydrofracturing of the rock to create permeability, pumping of cold water into the injection well, and extraction of this water from the production well. As the water flows through the artificial fractures between the two holes, it gains heat from the rock. So far, extraction of heat from impermeable rock (hot dry rock) has not proved to be economical, although it is technically achievable.

Modern usage of geothermal energy started at Larderello in Italy. On July 4, 1904, the first electric power exploiting natural steam discharges was generated in the area. In 1912, the first turbine generator unit powered by underground steam was installed at Larderello. By 1944, the installed electric generating capacity at Larderello was 127 MW. In the 1920s geothermal power investigations were carried out in California and Japan, but there were no significant power developments there at that time. Many countries have been actively involved in developing their geothermal resources since the 1960s, both for various types of direct use and electric power generation (Fig. 1). During this period, the ex-

ploitation of geothermal resources has been increasing rapidly. As an example, the installed capacity for electric power generation increased by 40% in the period 1990–1998.

The present world use of geothermal energy is summarized in Table I. As may be deduced from this table, in some countries (e.g., Indonesia, Italy, Mexico, Philippines, and the United States), exploitation of geothermal resources has emphasized their use for electric power generation. Many other countries (e.g., China, Hungary, Iceland, Japan, and the United States) use geothermal water directly on a large scale, particularly for space heating.

Geothermal energy accounts for only a small fraction of the world's energy consumption. In that sense it is not an important energy resource. However, in some countries, particularly many third world countries, geothermal reservoirs constitute an important energy resource in terms of their total energy consumption. Iceland is unique for the extent and economic importance of its use of geothermal energy. Geothermal resources account for a little more than 50% of the country's annual energy consumption. In the United States, geothermal resources account for about 0.4% of the annual energy usage. For the world, it is a little less than 0.3%.

Geothermal fluids have been utilized on a small scale as a source of various chemicals. At Larderello, boron was extracted from the steam before electric power generation started. In Japan, cesium was extracted from hot spring waters, and mercury was extracted from hot spring deposits at Sulphur Bank in California. Extraction of various base metals from the geothermal brine in the Salton Sea area in California has been considered. In New Zealand, a technique was developed to extract silica from the waste brine of the Wairakei geothermal power plant by coprecipitating it with lime to form a useful calcium-silicate for the building industry. This technique was not economical.

---

## II. THE POTENTIAL USE OF EARTH'S HEAT AS AN ENERGY RESOURCE

The principal features that determine the potential use and economics of geothermal resources include the geothermal reservoir temperature, rock permeability, volume of the reservoir, and amount and chemical composition of its fluid. Of these, temperature is the most important. The location of the resource is also of much importance, at least, when using hot water or steam

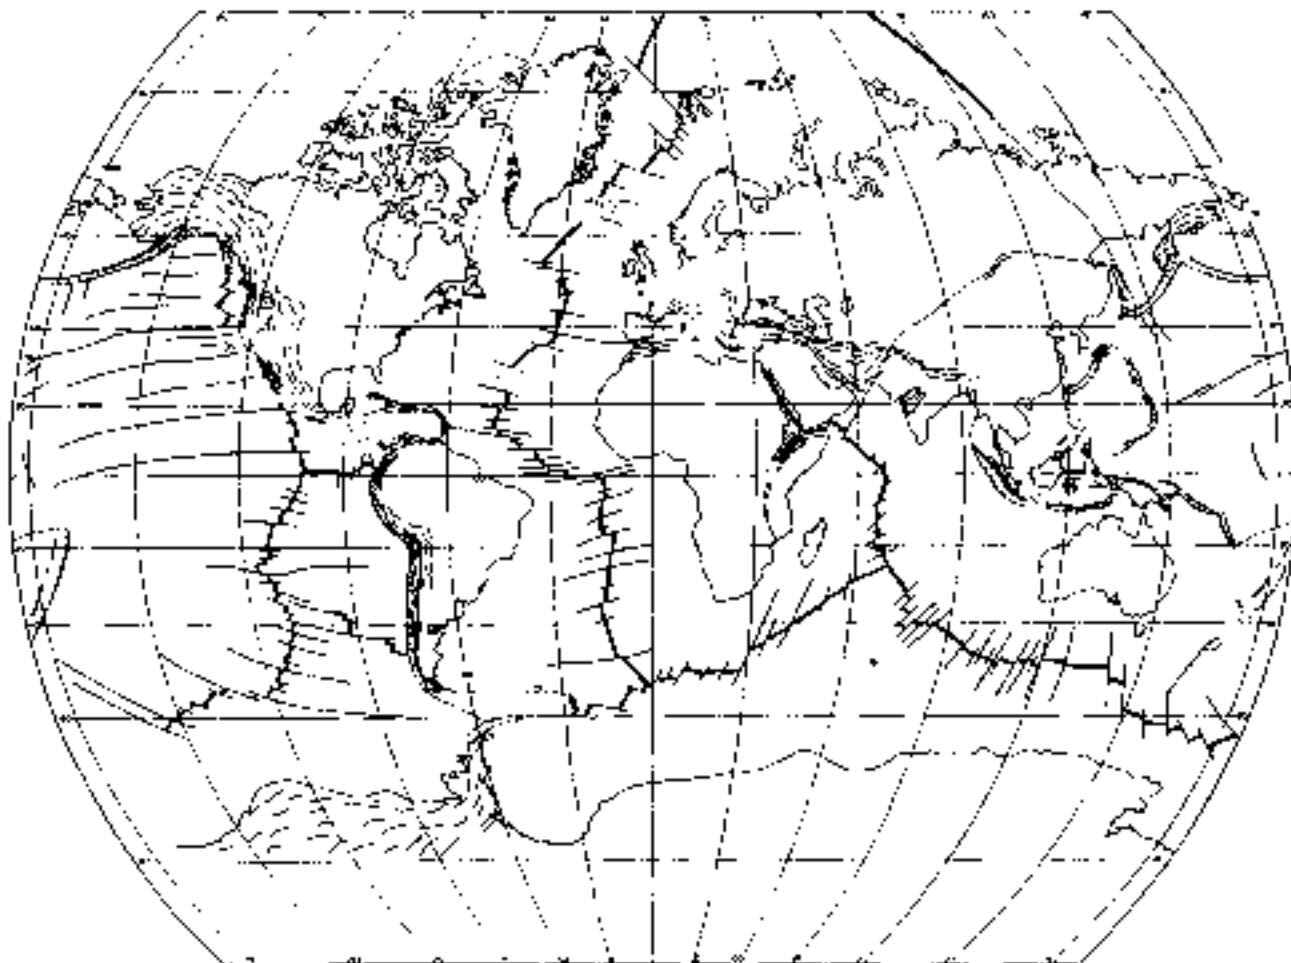

FIGURE 1 World map showing countries where geothermal energy is harnessed. Dark shading: power production. Light shading: direct use.

directly. For cost and technical reasons, transport of heat over long distances is not possible. In this respect the value of geothermal energy is inferior to fossil fuel and nuclear energy.

Baldur Líndal, an Icelandic chemical engineer, assessed the potential use of geothermal water and steam in relation to their temperature (Fig. 2). From this figure it is clear that thermal water with temperatures as low as 20–30°C constitutes a useful energy resource.

Some geothermal fields (e.g., Larderello in Italy and the geysers in California) are vapor-dominated, but most drilled fields are liquid-dominated. In liquid-dominated fields, water forms a continuous fluid phase in fractures, but vapour is the continuous phase in vapor-dominated fields.

The boiling point of water is pressure and salinity dependent, the temperature of boiling rising with increasing pressure. In the geothermal industry, the boil-

ing point of water is frequently related to depth (Fig. 3). The depth is calculated on the assumption that the pressure exerted at each depth is that of a water column, which is at the boiling point at all depths. Rising water in a geothermal reservoir, or in a producing well, boils in response to pressure drop. At the same time, the water cools, and some of it is transformed into steam. The amount of steam that forms depends on the initial temperature of the reservoir water and the magnitude of the pressure drop. For example, 41% of 300°C water is converted into steam by allowing the pressure to drop to atmospheric. At the same time, the water-steam mixture cools to 100°C. Thus, steam is produced not only from vapor-dominated fields but also from liquid-dominated ones.

When water boils in the aquifer of producing wells as a result of pressure drop, the temperature of the flowing fluid becomes lower than that of the enclosing rock. As a

result, heat tends to flow from the rock to the fluid, which enhances steam formation in excess of that caused by the pressure drop. Due to their different flowing properties, the water and steam may segregate in the aquifer, the steam flowing preferentially to the well. Both processes cause the steam-to-water ratio in the well discharge to be higher than that caused by pressure drop alone. It is, in fact, not uncommon that wells drilled into liquid-dominated reservoirs yield steam only. Such wells occur, for example, in the liquid-dominated fields of Olkaria in Kenya and Krafla in Iceland.

Geothermal steam is used in much the same way to generate electric power as is steam formed in boilers using fossil fuel or nuclear energy as the energy resource. There is, however, one major difference. In the case of fossil fuel or nuclear energy, the steam inlet pressure for the turbines can be chosen as desired. For geothermal steam, the characteristics of the reservoir determine, at least to an extent, what the optimum turbine inlet pressure should be. Long-term well tests are required to determine the optimum inlet pressure.

## The Linal Diagram

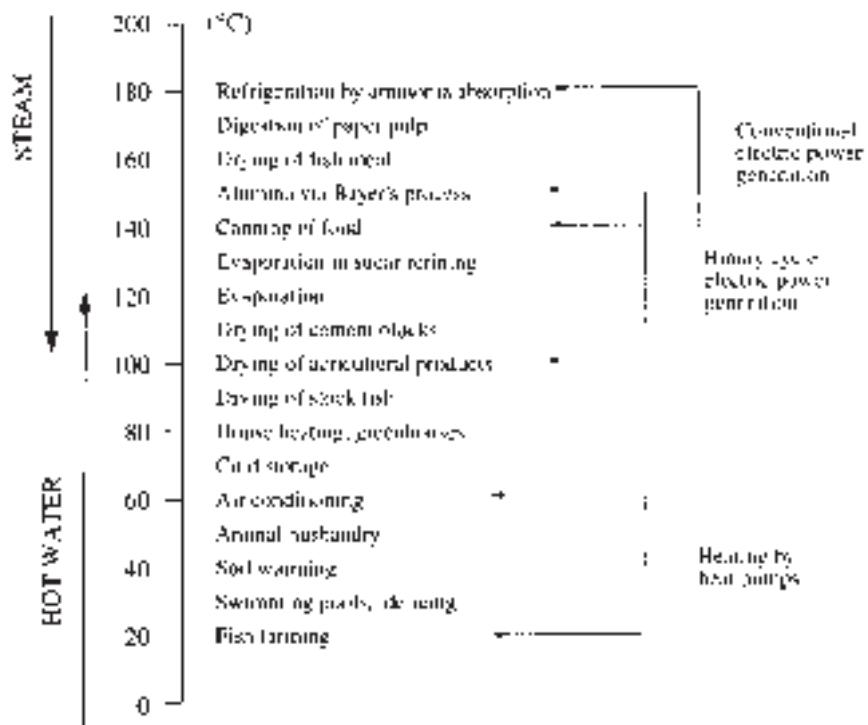

FIGURE 2 The Líndal diagram.

The efficiency of conventional use of geothermal steam for electric power generation is poor. Only some 10% of the heat discharged from drillholes is converted into electric energy, the exact number depending on the reservoir temperature and the well-discharge enthalpy. As an example, consider a reservoir at 200°C with a wellhead steam separation pressure of 6 bars abs. (this is equal to a temperature of 159°C for steam-saturated water). Boiling by pressure drop from 200 to 159°C will cause 8.7% of the reservoir water to be converted into steam. Only this 8.7% will be utilized to generate power; the remaining 91.3% of the discharged mass goes to waste. For a reservoir temperature of 300°C and the same turbine inlet pressure, 67.6% of the discharged fluid would go to waste. About 2 kg/s of steam are required to generate 1 MW of electricity.

Direct use of geothermal heat is much more efficient. For space heating, heat can easily be extracted from water by cooling it down to 35°C. Taking the initial temperature to be 80°C and defining useful heat as that in excess of 20°C gives an efficiency factor of 0.75 (75%).

The poor utilization of geothermal energy by conventional electric power production has led to improved

exploitation technology and more versatile use of the resource. Two methods have largely been practiced. One involves the so-called binary cycle, and the other, combined utilization (Fig. 4). The binary cycle improves

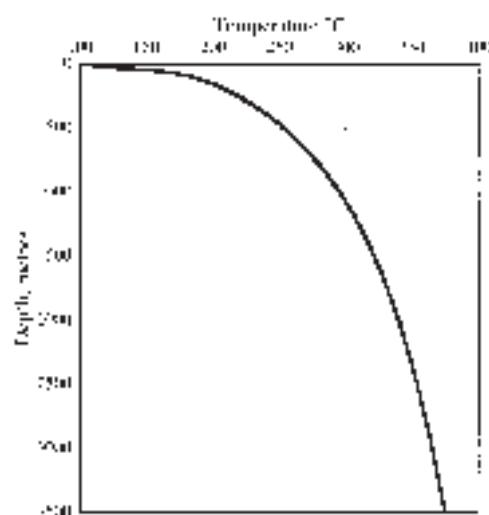

FIGURE 3 The boiling point curve of pure water with depth.

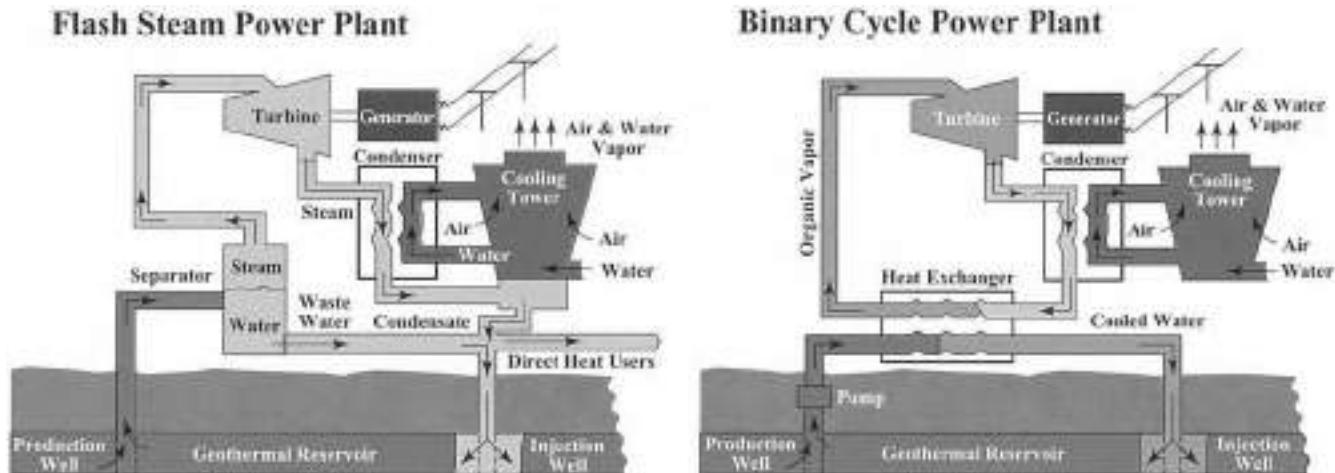

FIGURE 4 A schematic layout of conventional flash steam and binary cycle geothermal power plants.

use of the resource for electric power generation. It involves heating a low-boiling point fluid in a closed loop of a heat exchanger. That fluid is then used to drive a low-pressure turbine. Combined utilization commonly involves electric power generation as well as direct use. Back pressure turbines are generally used in this case. Low-pressure steam emerging from the turbine is conveyed through a heat exchanger to heat up fresh water that is in turn used directly for space heating or other purposes. In this way, the geothermal resource can be more effectively utilized.

The possibilities of combined utilization schemes depend on the local market. Two examples of such schemes include the Svartsengi and Nesjavellir power plants (Fig. 5), both in Iceland. In these operations, high-pressure steam is utilized to generate electric power, and the hot water is conveyed through heat exchangers to heat up fresh water that is in turn used for space heating. It is not possible to use the geothermal water directly because of its chemical composition. As combined schemes improve the efficiency of the exploitation of the resource, they effectively extend the life of any geothermal reservoir. They also reduce the environmental impact of the exploitation. Because of all this, combined utilization should become more widely applied in the future.

Some problems are associated with efficient use of high-temperature geothermal fluids. This usage requires much cooling of the fluid which can induce scaling (formation of chemical deposits) in wells and surface equipment, particularly of amorphous silica. Such scaling can hinder smooth operation of a geothermal installation.

### III. DRILLING FOR GEOTHERMAL WATER AND STEAM

Only a very minor part of exploited geothermal water comes from natural springs. All geothermal steam and practically all geothermal water are recovered from subterranean geothermal reservoirs by wells. Geothermal wells are commonly 1000–2500 m deep. The deepest ones at present reach about 4 km. Many wells drilled for direct use of hot water may, however, be much shallower, in some cases only about 100 m.

The purpose of geothermal drilling is to (1) locate a potential geothermal reservoir, (2) characterize this reservoir, and (3) ultimately recover steam and/or water from it cost-effectively.

Geothermal drilling technology is mainly obtained from the oil industry. However, some modifications are required, mostly because geothermal systems are largely hosted in fractured volcanic rocks, whereas drilling for oil and gas is primarily into sediments and sedimentary rocks. Rotary drilling is used for geothermal wells. The rotary drillbit is connected to the engine of a drill rig via a string of hollow drillrods. Rotation of the rods causes the bit to rotate at the bottom of the hole. The lowest part of the drillrods, called collars, is massive and heavy and gives the required load on the drillbit to squeeze its teeth into the rock at the bottom of the hole, whereas the rest of the drillrods are suspended in the mast of the rig. As the teeth push into the rock at the bottom of the hole, they break loose chips of rock.

A drilling fluid, typically water, is pumped down the drillrods and out through the holes in the drillbit. The fluid ascends through the annulus between the rods and the walls of the hole bringing with it to the surface the rock chips. Occasionally detergent foam is used if the water level in the geothermal reservoir is very low and, in the case of vapor-dominated fields, air has been used. During drilling, it is feasible not to build up much higher pressure in the well than in the surrounding formation. This may cause movement of the drilling fluid with the

rock chips it carries, into adjacent horizons, deteriorating their permeability. Loss of drilling fluid is also undesirable for drilling technological reasons. It may cause the drill chips to cumulate in the hole causing the drill-rods to become stuck.

A complicated casing programme is required for geothermal wells, especially when temperatures are high (Fig. 6). After drilling through soil and any loose sediments, a surface casing is lowered into the well and cemented in place by pouring concrete into the annulus

FIGURE 5 Photo taken in midwinter of the Nesjavellir power plant, Iceland. High pressure steam is used to generate 60 MW of electric power. Water and steam is passed through heat exchangers to heat up 1100 liter of fresh water to 85°C (equivalent to 200 MW thermal) which is piped for 27 km to Reykjavík and used for space heating. The pipe to Reykjavík runs up the hill on the right-hand side of the photograph. Steam separator station is behind the power station next to chimneys discharging excess steam from the wells into the atmosphere. Photo Emil Thor Sigurdsson.

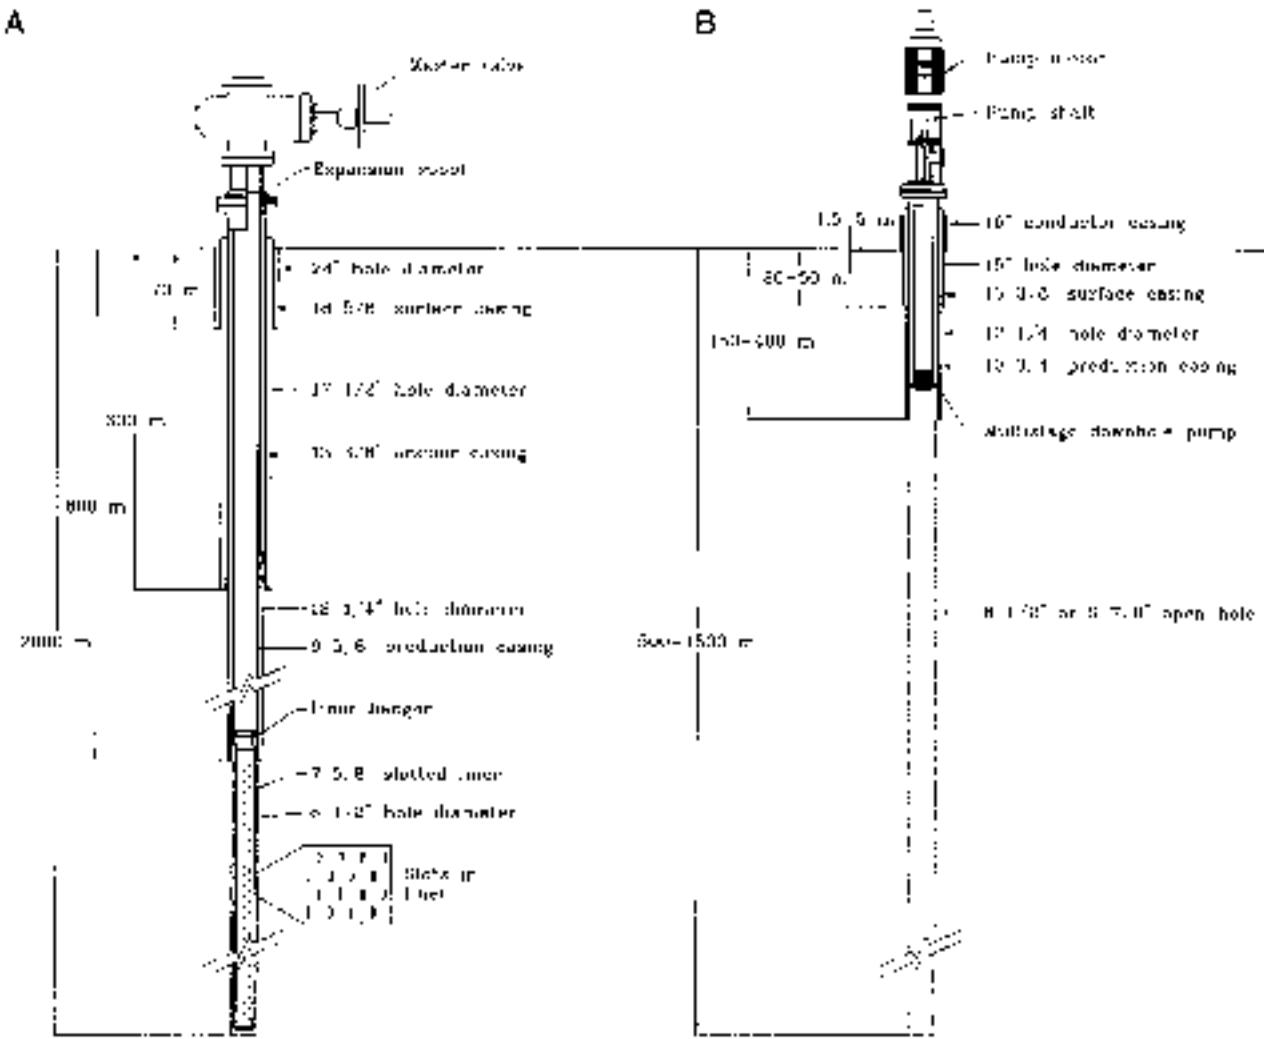

FIGURE 6 Schematic layout of wells drilled into (A) high- and (B) low-temperature geothermal fields.

from above. The purpose of this casing is to prevent collapse of the loose top layer into the hole when deepened. After the surface casing has been cemented, drilling for anchor casing starts. It is termed anchor because the wellhead equipment is welded to this casing. If the final well depth is projected to be about 2000 m, this casing is frequently set at about 300 m. The anchor casing is cemented in place by pumping cement sludge down through the drillrods so that it ascends through the annulus between the casing and the wall of the hole. It is important to cement this casing well. The next casing is the production casing. For a 2000-m deep well, it is often set at about 800 m depth and cemented similarly to the anchor casing. Like the anchor casing, the production casing reaches the surface. Finally, the

well is drilled to the target depth. A liner, or perforated casing, is set below the production casing to prevent the walls of the well from collapsing during production. The total length of casing, including the liner, in a 2000-m deep well is about 2400 m. The casing programme requires the diameter of the drilled well to be largest at the top and successively narrower for each casing. The surface casing is typically 14 in. in diameter and the liner is 8 in. A typical geothermal well drilled into a high-temperature volcanic system costs about U.S. \$1.5 million and takes 1.5–3 months to complete. As much as half of the drilling cost goes into the casing material.

The casing program depends not only on intended drilling depth but also on stratigraphy and the spatial

distribution of temperature in the reservoir. Anchor and production casings may be set at deeper levels than in the example given in order to case off either loose strata or relatively cold aquifers or both.

Casing programs for low-temperature fields are simpler than for high-temperature ones (Fig. 6). Both the production casing and the liner are, as a rule, omitted. The depths of the surface and anchor casings are determined by stratigraphy and reservoir temperature distribution. Further, the depth at which the anchor casing is set depends on the anticipated maximum drawdown of water level, at least if submerged pumps will be used. For safety reasons, such pumps must not be lowered below the lower end of the casing. Rock debris falling from the uncased walls of the well onto the pump could make it impossible to pull it out for maintenance.

---

#### IV. STRATEGY IN GEOTHERMAL EXPLORATION, DEVELOPMENT, AND PRODUCTION

##### A. General

The presence of geothermal reservoirs is generally manifested by hot springs and/or fumaroles at the surface and, in some cases, by hydrothermal alteration and sinter deposits. Exploration has, however, revealed hidden reservoirs with no surface manifestations. There is sometimes little relationship between the distribution and intensity of surface geothermal activity in an area and the lateral extent and productivity of the underlying geothermal reservoir.

As with exploitation of Earth's mineral resources, uncertainty is always involved with the success and economy of exploration and development of geothermal resources. At the onset of geothermal exploration, it is uncertain if it will result in economically, technically, and environmentally feasible exploitation of the resource. The cause of the uncertainty lies in the limited information available about the characteristics and size of the anticipated resource. Geothermal exploration and development, therefore, invariably requires risk capital. Sometimes the exploration and development work yields negative results in the sense that the characteristics of the resource are not favorable for economic exploitation.

Due to the uncertainty in geothermal exploration and development, it has become common practice to divide

exploration and development into phases (Fig. 7). For each phase, costs are minimized and information is maximized. At the end of each phase, a decision is whether to continue or terminate the project. The phases are:

1. Surface exploration to obtain indirect information about the extent of the geothermal reservoir, subsurface temperatures, and other features such as permeability control for fluid flow
2. Exploration drilling to obtain the first direct information on reservoir temperature, pressure, permeability, and the like
3. Appraisal drilling (also called production drilling) to evaluate the characteristics of a prospective well field
4. Feasibility study and preliminary power plant design, the purpose of which is to analyze the economy of the project and to decide on erecting the plant
5. Final design, financing, additional production drilling, preparation of tender documents, bidding, and construction

##### B. Surface Exploration

Surface exploration is used to locate both favorable geothermal areas for development and sites within them for drilling. It includes geological studies and geochemical and geophysical surveys.

Geological studies focus on mapping the distribution of geological formations and the distribution and types of thermal manifestations. An attempt is always made to relate the distribution of the thermal manifestations with local structures, such as faults. Frequently, the overall distribution of the geothermal activity can also be linked with some regional geological structures such as calderas, in which case favorable drilling targets might be confined to that caldera. Calderas, which form in response to rapid emptying of a magma chamber during a major volcanic eruption, define approximately the areal extent of the underlying magma chamber, which in turn constitutes the heat source for the overlying geothermal system.

The principal purpose of geochemical surveys is to predict temperatures in the underlying geothermal system based on the chemical compositions of hot spring waters and fumarole steam. They also provide information on the origin of the geothermal fluid and subsurface flow directions. Studies in many drilled geothermal fields have shown that the chemical and isotopic compositions of well discharges are controlled by equilibrium

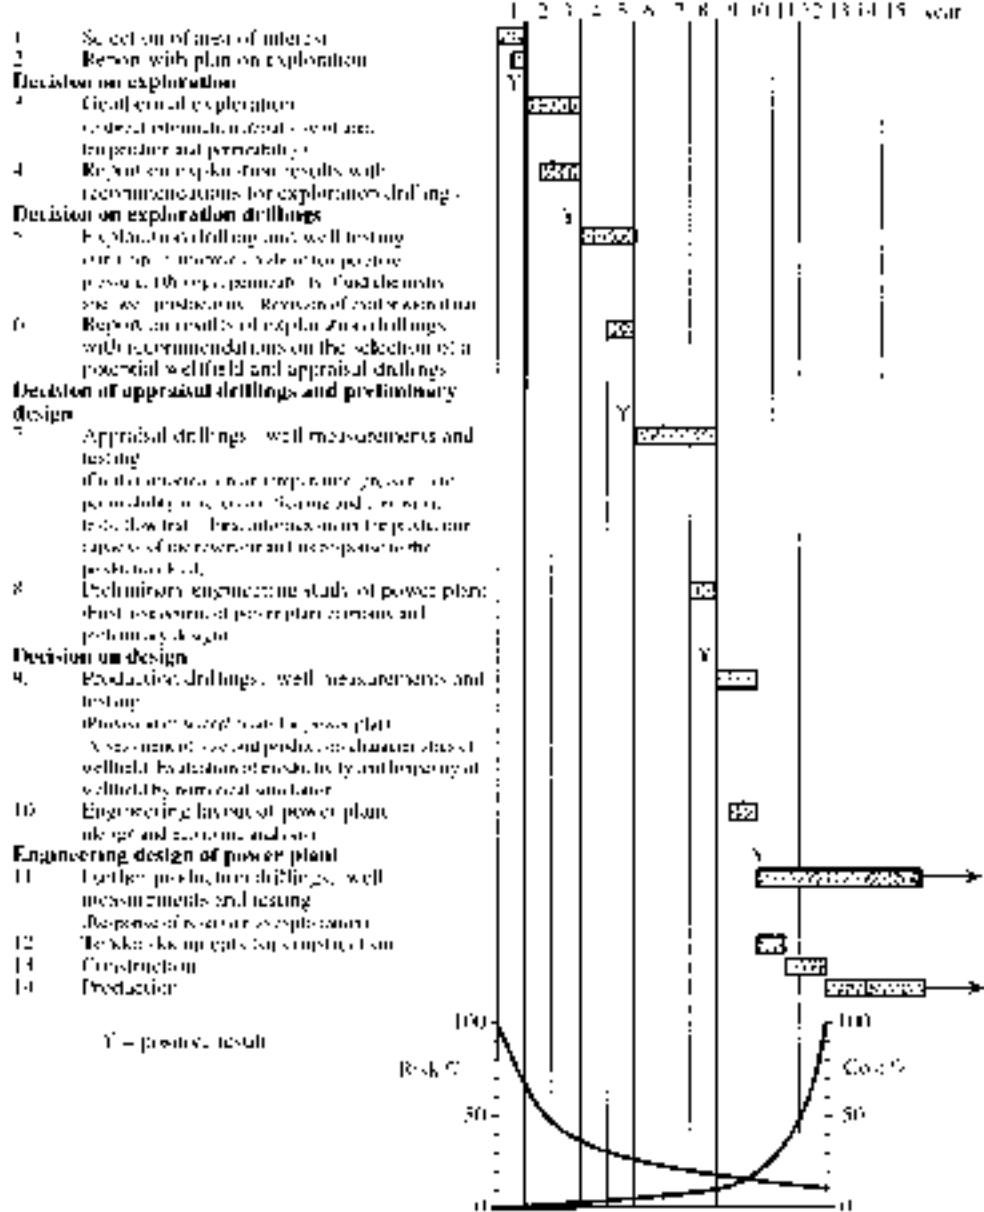

FIGURE 7 Strategy in geothermal exploration and development.

reactions with minerals in the reservoir rock. Equilibria between solution and minerals are generally temperature dependent in such a way that concentrations, or concentration ratios, of aqueous components change with temperature. In upflow zones of geothermal systems, the rising fluid often cools, by conductive heat loss, boiling, or both. However, reequilibration may be limited, partly because of the short residence time in the upflow and partly because reaction rates decrease with decreasing temperatures. As a result, the chemical

and isotopic compositions of the fluid discharged at the surface can, and often do, reflect temperature conditions in the geothermal system below the zone of cooling in the upflow. Several mathematical equations have been developed to describe the relationships between specific aqueous concentrations, or concentration ratios, and temperature.

Geophysical surveys have been classified into two groups: one that provides information on geological structures, and another that supplies temperature data.

The most widely used geophysical exploration tool maps electrical resistivity of bedrock. The resistivity of bedrock to induced electric current is inversely related to temperature, hydrothermal alteration, rock porosity, and water salinity. Intense rock alteration is typically associated with geothermal systems, and geothermal waters contain more dissolved salts than nonthermal groundwaters. Therefore, geothermal systems characteristically show up as resistivity lows. Resistivity surveying has proved useful to map the lateral extent of geothermal reservoirs, which is important because one of the features that affects the generating capacity of a particular geothermal reservoir is its size. Magnetic and gravity surveys are sometimes useful in locating faults and intrusive bodies which tend to have higher density than volcanic strata.

Drilling of shallow gradient holes (few tens to a few hundreds of meters deep) has also been used in geothermal exploration. Ascending hot water produces anomalously steep thermal gradient near the surface, and the drilling of the gradient holes aims at locating such anomalies.

The results of exploration surveys are synthesized as a conceptual model of the reservoir, which shows predicted subsurface temperatures, structural control of groundwater flow, the lateral extent of the area and possibly some other geological features such as caldera structure. If the outcome of the exploration survey is favorable, the report describing the results will include proposed sites for exploration drillholes.

### C. Exploration Drilling

Exploration drilling provides the first direct information on the geothermal reservoir. It is much more expensive than the surface exploration. The most important data obtained from exploration drilling include temperature, permeability, fluid chemical composition, and well-discharge rates. Successful results from exploration drilling lead to the selection of a potential production well field within a particular geothermal area.

In a geothermal field that is tens of square kilometers in size, it is common to drill about four exploration holes initially. These holes are drilled at prospective production well fields according to the results of the surface exploration surveys.

The main purpose of any exploration drilling is to locate a promising production well field. However, some exploration wells might be drilled near the anticipated margins of the geothermal area to verify its boundaries,

especially when exploring a small field, in which case its size and capacity are of concern for the intended utilization. New information from the exploration drilling and later drilling and well-testing require updating the conceptual reservoir model.

### D. Appraisal Drilling

Having located a promising production field within a geothermal area through exploration drilling, the next phase often involves the drilling of step-out wells to appraise the production characteristics of the site and the size of the prospective production field. Step-out wells are drilled at a radius of about 1 km away from the successful exploration hole.

Further drilling around a successful exploration well, called appraisal drilling, aims at quantifying the characteristics of the geothermal reservoir. Appraisal drilling provides the necessary information for design and economic analysis of the project and last but not least recovery of water/steam for the intended utilization. For this reason, appraisal drilling is often termed production drilling. Having delineated a production well field, additional production wells are drilled between the appraisal wells to recover steam/water for the intended exploitation.

### E. Feasibility and Design of Power Plant

There are no rules as to how much steam (water) should be proved before a decision is made to construct a power plant. In a new area, the amount of steam to be proved may be as much as 80% of the total required. However, if a new production field is being developed within a geothermal area that has been under exploitation for some time, the number may be considerably lower (50%) because understanding of the characteristics of the area is probably high based on information and experience gained from previous development.

It is common practice to discharge all wells drilled in a particular well field simultaneously for several months to test interference and measure decline in output with time. Through numerical simulation the flow-test results are used to predict the generating capacity and the longevity of the production well field.

In detail the strategy of geothermal exploration and development depends on the size of the plant to be constructed. The scheme described earlier was drawn

up with a 50- to 100-MW electric plant in mind, which is a common size for such plants.

The generating capacity per unit area of a geothermal field depends on many factors such as temperature, permeability, and porosity. A useful working rule, when information is limited, is to assume a capacity of 15 MW electric/km<sup>2</sup>. Thus, a well field of 4 km<sup>2</sup> would be required for a 60-MW plant, plus some reserve for the drilling of additional wells to replace the anticipated decline in output from the initial production wells.

Geothermal wells are never bonanzas like oil and gas wells. Oil wells produce a commodity measured in dollars, whereas geothermal wells produce a commodity measured only in cents. For this reason, geothermal exploration and development demands a high ratio of successful wells for any geothermal project. To generate electric power in a particular area from geothermal steam that would be very attractive economically, the average yield of every drilled geothermal well needs to be about 10 kg/s of steam (equivalent to 5 MW electric) over a period of 10 years or proportionally longer if the yield is lower. The average yield per drilled steam well in the world is 4–5 MW. The best wells drilled so far have capacities of about 25 MW electric. The poorest average yield of wells drilled into exploited geothermal reservoirs is a little less than 2 MW.

at the Geysers in California, which is a vapor-dominated field. One of the reasons for the rapid pressure drawdown at the Geysers is the low porosity of the reservoir rock and correspondingly low quantity of reservoir fluid. To counteract the pressure decline, water has been injected into the reservoir at the Geysers.

Today, monitoring of the response of a geothermal reservoir to the production load has become the general practice worldwide. Data on the long-term response of a geothermal reservoir to production are necessary for specifying how the reservoir should be best exploited both economically and environmentally. Data to be collected are both physical and chemical. Essentially they involve regular measurement of flow rates and discharge enthalpy of wells and regular sampling and analysis of the well fluid. Pressures are also frequently monitored at depth in nonproducing wells. The chemical data are useful in assessing any changes in scaling tendencies and whether the discharged steam forms only by pressure drop or whether heat flow from rock also contributes to the steam formation.

Monitoring data are also valuable for both the timing and siting of new wells that need to be drilled to make up for the decline in flow from initial production wells. The data are further used to update the reservoir production model and to improve predictions about the longevity of the reservoir.

---

## V. MONITORING OF GEOTHERMAL RESERVOIRS

During the early days of geothermal exploitation, it was generally considered sufficient to prove the required flow rate of steam to water for the intended use by drilling and short-term testing (6–12 months, maybe less) of the wells, and extrapolation of the results into the future. Experience has, however, shown that pressure declines in exploited geothermal reservoirs, which results in decreased yield of wells and sometimes incursion of cold groundwater into the reservoir. This problem has necessitated monitoring of the response of geothermal reservoirs to the production load. Therefore, as earlier considered, geoscientific work is not complete at the onset of production.

Overexploitation of geothermal reservoirs is not uncommon. It leads to rapid drawdown of reservoir pressure and a corresponding decline in well output and power generation. For example, this has been the case

---

## VI. IS GEOTHERMAL ENERGY A RENEWABLE RESOURCE?

Geothermal energy is commonly considered to be a renewable resource. Technically this is not correct. First, each geothermal system has a given lifetime, which typically lies between 10<sup>5</sup> and 10<sup>6</sup> years. Second, heat extraction from a drilled geothermal reservoir generally outpaces the reservoir's ability to replenish the extracted heat. It is, therefore, reasonable to regard geothermal reservoirs as mines of heat. The quantity of heat stored in a given volume of rock is positively related to temperature, porosity, and the steam-to-water ratio. Water has about five times higher heat capacity than rock, which explains why porosity influences the amount of heat storage. For a rock porosity of 17%, close to half of the heat is in the water, whereas the other half is in the rock. Furthermore, there is a lot more heat stored in a specific volume of water than in the same volume of

steam. Consequently, other things being equal, the quantity of heat stored in boiling geothermal reservoirs decreases with increasing steam-to-water ratios.

The heat stored in the rock cannot be extracted and exploited in a sustained way in subboiling systems unless cooler water is drawn into the reservoir. In boiling systems, on the other hand, this is not the case. Extensive boiling caused by pressure drop in producing aquifers leads to cooling of the geothermal fluid, thus favoring flow of heat from the rock to that fluid. Theoretically, heat can be extracted from the reservoir rock until its temperature approaches that of the fluid entering wells. The fluid inflow temperature will be somewhat higher than the wellhead temperature depending on the pressure drop of the fluid in the well. The wellhead temperature is related to the wellhead pressure and is equal to that of steam-saturated liquid water. During operation, the pressure on each wellhead is set to satisfy the design turbine-inlet pressure.

Deep drilling in Iceland indicates that nonvolcanic geothermal systems are transient rather than steady-state features. Such systems are typically associated with recent subvertical tectonic fractures in which groundwater circulates to a depth of a few kilometers. An example is provided by the Laugarnes geothermal field within the city of Reykjavík. At deep levels, the temperature in the Laugarnes geothermal reservoir is lower than outside it. At shallow levels, on the other hand, temperatures within the reservoir are higher than in the surrounding rocks (Fig. 8). One explanation for this tem-

perature distribution is that relatively cold groundwater flows to deep levels where it gains heat by contact with hot rock. At the same time, the rock cools. Due to buoyancy, the hot water rises and heats the rock at shallow levels. This density-driven circulation of the groundwater will cease when the convecting water has cooled the rock at deep levels to a certain degree. At this time, the geothermal system becomes extinct. The quantity of heat transported to shallow levels at Laugarnes by the convecting groundwater is much larger than the terrestrial conduction heat. Therefore, a non-volcanic geothermal system, like Laugarnes, is clearly transient in nature and is appropriately viewed as a mine of heat rather than a renewable energy resource. The same applies to volcanic geothermal systems except those that receive continuous or episodic supplies of new magma into the roots of the system, either into chambers or as small intrusions.

Because geothermal reservoirs are viewed as mines of heat, they should be efficiently exploited, considering not only the economics of depreciation and return of investment capital but also environmental aspects and conservation of natural resources for future generations.

## VII. ENVIRONMENTAL ASPECTS

### A. Atmospheric Pollution

Geothermal energy is a relatively clean resource in comparison with fossil fuel. Geothermal steam always contains carbon dioxide together with some other gases. However, the emission of carbon dioxide into the atmosphere associated with exploitation of geothermal steam for electric power generation is much less than that from burning coal, oil, or gas. It is frequently around 10% of the carbon dioxide emission from fossil fuel-fired electric power plants and much less, if the gas is injected with the waste fluid back into the reservoir through special wells drilled for this purpose. Exploitation of water from low-temperature geothermal reservoirs for direct use is often not associated with any emission of carbon dioxide into the atmosphere. The water is low in this gas and has no tendency to degas when exposed to the atmosphere because its carbon dioxide partial pressure is less than atmospheric. In Iceland, hot water usage from low-temperature geothermal reservoirs low in carbon dioxide amounts annually to over 5000 GWh, which is equivalent to 570 MW thermal for 100% load

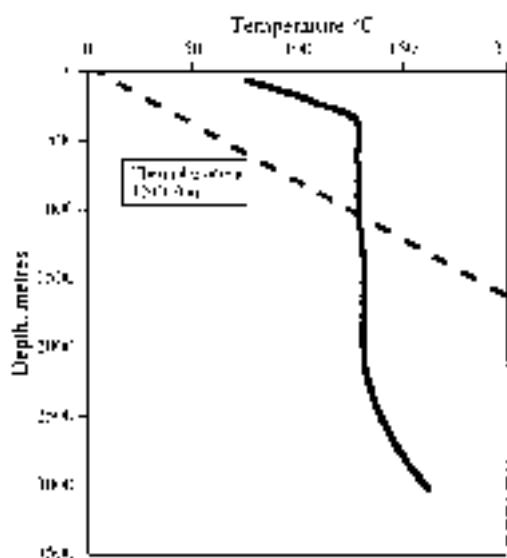

FIGURE 8 Temperature profile in a deep well in the Laugarnes geothermal field within the city of Reykjavík, Iceland.

factor. This use is very substantial considering that the country's population is only 270,000. In Hungary and China, which both use geothermal water extensively for space heating (Table 1), the situation is not as favorable because the water contains substantial amounts of carbon dioxide.

### B. Other Pollution

Although geothermal energy is a relatively clean resource, its exploitation has considerable environmental impact. The pollution associated with harnessing geothermal resources is: (1) visual, (2) thermal, and (3) chemical. Additional effects are local land erosion and soil disturbance as well as noise pollution.

Thermal fields often occur in areas of scenic beauty, which are highly valued and of economic importance for tourism. Power plants, steam supply systems, and roads to individual wells can degrade the scenery, particularly in areas of rugged terrain. However, in some areas, like the Geysers in California, both power plants and pipelines have been tastefully camouflaged. The power plants are inconspicuous, and the pipelines are painted in colors that blend with the normal background. In other areas of the world, care has not been taken to reduce visual pollution as far as possible.

It is necessary to build a road to every drill site for transportation of the drill rig and for maintenance after the well has been completed. For the same reason, roads are also required along pipelines. This leads to much disturbance of the land surface, particularly on steep slopes. The combination of heavy rains and steep slopes of incompetent rock in such areas can also cause landslides and high soil erosion rates.

Direct use of hot water generally has much less effect on the environment than exploitation of steam for power generation. This is partly because low-temperature or nonvolcanic geothermal fields tend to occur in areas of lower relief than high-temperature or volcanic geothermal fields. Hot water pipelines require less maintenance and can, therefore, be subsurface. Also, the hot water is generally pumped from the wells, and the quantity pumped is in harmony with the usage so no water is wasted. For example, in the hot water fields exploited by the Reykjavík Heating Service in Iceland, there is practically no visual pollution except for small shelters that cover each wellhead.

The withdrawal of large quantities of water from a geothermal reservoir may lead to substantial ground

subsidence depending on the strength of the rock. Subsidence can cause tilting and stressing of pipelines and surface structures, change stream beds, and lead to flooding. At Wairakei in New Zealand, maximum ground subsidence presently exceeds 10 m. It is also a problem in the Broadlands field, near Wairakei.

Geothermal steam always contains some hydrogen sulfide. This noxious gas is lethal if in sufficient quantity, and it may have adverse effects on crops and aquatic life. Hydrogen sulphide, and other gases, escape into the environment from condenser gas ejectors discharge, with warm air and surplus condensate from cooling towers, and in solution in waste water. Escape of hydrogen sulfide into the atmosphere may cause some acid rain as a result of its oxidation into sulfuric acid. It is now common to scrub this gas from the geothermal steam and oxidize it to sulfate by passing the steam through an alkaline solution containing hydrogen peroxide.

Geothermal waters have, as a rule, much higher salt content than nonthermal groundwaters. Many elements can occur in concentrations higher than acceptable for domestic use and for irrigation and stock watering. This is particularly the case for boron, arsenic, hydrogen sulfide, and overall salt concentration. Furthermore, the concentrations of some trace metals, especially in saline waters, may be unacceptably high. These include elements such as mercury, lead, manganese, and zinc, among others. On the Greek islands of Milos and Nisyros, drillholes tap waters from over 300°C geothermal reservoirs, which have about three times seawater salinity. Development of the respective reservoirs has been postponed for the time being because of concern for possible groundwater and seawater pollution by the geothermal fluid.

### C. Directional Drilling

Directional drilling has received increased attention in recent years to reduce the environmental impact of geothermal exploitation. Such drilling involves drilling of several wells from the same platform. First, every well is drilled vertically, but below the production casing each is deviated from the vertical, the deviation increasing with depth. By directional drilling, roads and drill rig platforms are reduced in number. The success of directional drilling depends on the level of producing aquifers. If permeable aquifers are abundant in the reservoir just below the production casing, the directionally

drilled wells will be closely spaced at the level of these aquifers, and interference between them is likely. The success of directional drilling is best when productive aquifers occur at deep levels in the reservoir.

#### D. Injection of Waste Fluids

During the early years of geothermal utilization, the waste fluid was generally disposed of by the least-expensive method available. This most often involved surface disposal into the nearest stream or into ponds constructed for this purpose. To minimize the environmental impact of geothermal exploitation, injection of the waste fluid into wells has been adopted in many fields during the last 10–20 years.

Injection may require the drilling of special wells, either within the geothermal reservoir or outside it. Alternatively, production wells that turn out to be non-productive or very poor may be used for injection. At any rate, if injection is intended, this has to be taken into account during phase 3 (Fig. 7) in the development procedure for a geothermal resource.

Injection of used geothermal fluids was seriously discussed for the first time at the UN Conference on Geothermal Energy held in Pisa, Italy, in 1970. There are two basic reasons for the interest in injecting used geothermal fluid (water and condensed steam). One is that injection helps maintain reservoir pressure and in this way reduces decline in flow from wells with time, thus increasing the operational life of the well field. The second reason is to reduce the environmental impact caused by surface disposal of water with high concentrations of undesirable elements.

The waste fluid may be injected into shallow or deep wells. Ideally injection into the reservoir is preferred. Caution is advised on such injection, however, because of the risk of thermal breakthrough (i.e., the relatively cool injected water may flow rapidly into the aquifer of producing wells and cause their performance to deteriorate). Because permeability within a reservoir is generally so variable and anisotropic, it is not possible to predict with confidence how an injection well will perform, with respect to either its capacity or which way the injected fluid will flow once in the reservoir.

Another problem associated with injection is deposition of minerals from the fluid. The mineral generally of primary concern is amorphous silica, but also at times calcite and anhydrite. Deposition is mostly affected by

boiling of the geothermal water and changes in temperature. If deposition occurs, it may block the injection well and/or damage formation permeability in the vicinity of the well. It is now possible to predict with reasonable confidence the conditions under which deposition tends to occur and, thus, specify desired injection conditions.

## GLOSSARY

**A horizon** A dark mineral soil horizon that formed at the surface or below an organic horizon and has humus accumulation.

**B horizon** A mineral soil horizon that formed below an A or organic horizon and shows evidence of chemical weathering or alteration.

**C horizon** A mineral horizon underlying the B horizon that shows very little alteration from its parent rock materials.

**E horizon** A mineral soil horizon formed below the organic horizon but above the B horizon. The main feature is the loss of silicate clay, iron, aluminum, or some combination of these leaving a concentration of sand and silt.

**Alfisols** One of the 12 soil orders in the U.S. soil classification system. These are soils with subsurface silicate clay

accumulation by illuviation. They form in cool and humid regions but sometimes in semiarid regions.

**alophane** A poorly crystallized aluminosilicate mineral usually formed from weathered volcanic ash, commonly referred to as an amorphous mineral.

**Andisols** One of the 12 soil orders in the U.S. soil classification system. These soils form in volcanic deposits that show evidence of weathering.

**Andosols** One of the soil great groups in the World Reference Base (WRB) used to classify volcanic ash-derived soils.

**Aridisols** One of the 12 soil orders in the U.S. soil classification system. These soils form in dry conditions such that there is redistribution of soluble materials, but there is not enough water to leach salts out of the soil profile.

**clay** There are two definitions: (1) A particle size grade, mineral particle with diameter  $<0.002$  mm; (2) clay sized secondary minerals, mainly layered silicates.

**Entisols** One of the 12 soil orders in the U.S. soil classification system. These are the recently formed soils with little if any profile development.

**Gelisols** One of the 12 soil orders in the U.S. soil classification system. These soils commonly have permafrost within 1 m.

**glass** Short for volcanic glass. Glass is a supercooled silicate commonly used for window glass. Volcanic ash has chemical and physical properties similar to glass.

**Histosols** One of the 12 soil orders in the U.S. soil classification system. These soils form in organic matter.

**humus** The portion of soil organic matter that largely consists of an amorphous and colloidal mixture of complex organic substances no longer identifiable as plant tissue.

**Inceptisols** One of the 12 soil orders in the U.S. soil classification system. These soils have few diagnostic features, except a pale brown horizon or mottled or gleyed B horizons.

**liquid limit** Soil water content at which the soil starts to form puddles.

**Mollisols** One of the 12 soil orders in the U.S. soil classification system. These soils have high accumulations of calcium-rich organic matter, largely from the root systems of grasses in the A horizon.

**noncrystalline** Clay minerals that lack a three-dimensional crystal structure, yet the arrangement of atoms is not entirely random. Atoms behave as spheres with definite radii and have their own coordination tendency.

**ochric epipedon** A surface horizon of mineral soil that is too light in color, too high in chromium, too low in organic carbon, or too thin to be any other diagnostic soil horizon and that is hard and massive when dry.

**Oxisols** One of the 12 soil orders in the U.S. soil classification system. These are the most highly weathered soils with B horizons which are very high in clay-size particles dominated by hydrous oxides of iron and aluminum. Most silica has been leached out.

**paracrystalline** In crystals, atoms are packed in a three-dimensional pattern and are called crystalline (long-range order), whereas in amorphous (without form) materials, they are not arranged in such a regular manner. Instead, they form a two-dimensional crystallite.

**plastic limit** Soil water content at which soils material becomes plastic, or capable of flowing.

**permanant charge** The negative charges on clay surfaces due to isomorphous substitution in the tetrahedral and octahedral layers of aluminosilicate clays.

**sand** Soil mineral particles with diameters ranging from 0.05 to 2.0 mm.

**silt** Soil mineral particles with diameters ranging from 0.002 to 0.05 mm.

**Spodosols** One of the 12 soil orders in the U.S. soil classification system. These soils are characterized by an albic (E) horizon overlying a spodic (B) horizon that had illuviated organic matter alone or in complex association with aluminum and iron.

**Ultisols** One of the 12 soil orders in the U.S. soil classification system. These soils are leached Alfisols. They lost most of their calcium and magnesium on the exchange sites of clays, thus they are more acidic.

**Vertisols** One of the 12 soils orders in the U.S. soil classification system. These soils form in parent materials rich in expanding clays such as smectite. They

swell when wet and shrink when dry, thus creating deep cracks during the dry season and hummocky microtopography.

**variable charge** It is also called pH-dependent charge, which is due to the broken O bonds and edge hydroxyls. The charge changes with pH; net negative charge develops when soil solution pH is higher than zero point charge and net positive charge develops when solution pH is lower than zero point charge.

**S** OIL IS A natural body composed of solids (minerals made up of sand, silt, and clay size particles and organic matter), liquids, and gases that form on the land surface, occupy space, and are characterized by one or both of the following: horizons, or layers, that are distinguishable from the initial material as a result of additions, losses, transfers, and transformations of energy and matter or the ability to support rooted plants in a natural environment (Fig. 1). Most soils derived from volcanic ash and pumice show distinctive properties that are not found in soils derived from other parent materials under the same vegetation and climate. Volcanic soils have several important properties in common. The amorphous clays have a low permanent charge and a high pH-dependent charge, and phosphorus fixation and water retention are high relative to most other soils with comparable textures. Carbon contents are high relative to other mineral soils due to low bulk densities. Volcanic ash soils pose unique engineering problems due to the fragile nature of ash and pumice and also, because it is not uncommon for the liquid limit to be reached before the plastic limit. This chapter details the geographic distribution of volcanic soils and their unique chemical, mineralogical, morphological, and physical properties; the soil formation processes; and the importance in agriculture.

## I. DEFINITIONS

Volcanic ash soils are often synonymous with the Andisols order which is the 11th soil order in Soil Taxonomy—the official U.S. soil classification system. The name *Ando soils* was introduced by U.S. soil scientists in 1947 during reconnaissance soils surveys in Japan. The name was connotative of soils formed in volcanic ash which had thick, dark surface horizons and were acid in reaction. In Japan, they are called Ando soils, whereas the name Andosol is used for

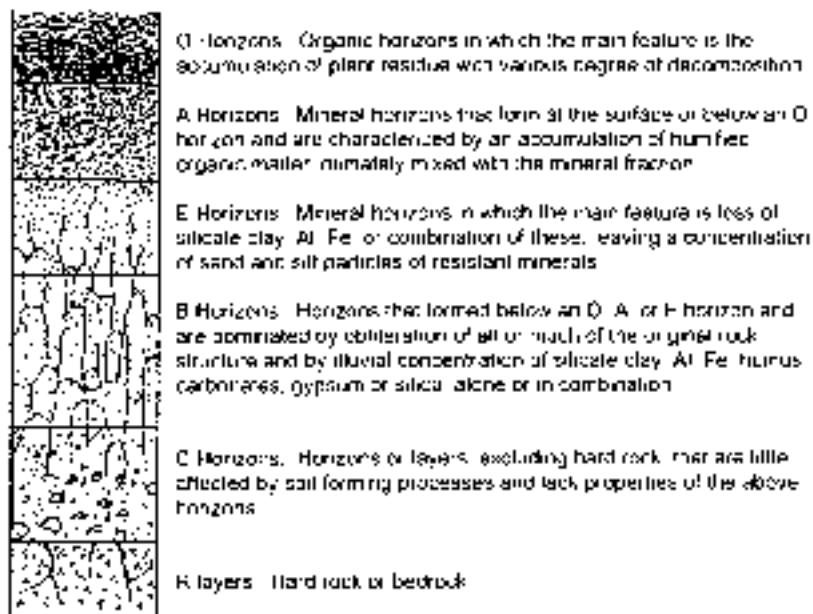

FIGURE 1 Hypothetical mineral soil profile showing the major horizons that may be present in a well-drained soil in temperate humid region. Any particular profile may have some of these horizons, and the relative depths vary.

volcanic soils in the World Reference Base (WRB) soil classification system.

Although often interchangeable with volcanic soils, the definition for Andisol is more rigorous. The central concept of Andisols is a soil that develops in volcanic ash, pumice, cinders, and other volcanic ejecta and/or volcaniclastic materials, with an exchange complex that is dominated by X-ray amorphous compounds of aluminum (Al), silicon (Si), and humus or by a matrix dominated by glass, having one or more diagnostic horizons other than an ochric epipedon. Bulk densities are low in most horizons, although the absolute values vary with the degree of weathering, the humidity of the soil climate, and in a few cases the degree of cementation by silica or other cements. Some Andisols are not derived from volcanic ash or volcanic ejecta but are formed in siliceous or tuffaceous materials. On the other hand, volcanic soils includes all soils derived in materials of volcanic origin with or without the previously mentioned unique properties.

These soils exist in a wide range of climate conditions from cold to hot and from dry to humid. Even though Andisols form from parent materials that have appreciable amounts of glass, other soil orders such as Spodosols, Mollisols, Ultisols, Alfisols, and Oxisols may form from volcanic materials if conditions are suitable. Entisols form in recent ash or older ash with very little weathering due to very dry conditions.

Thus, in this article *volcanic soil* refers to soils derived from volcanic ash that includes soil orders in addition to the Andisol order.

## II. GEOGRAPHIC DISTRIBUTION

Volcanic ash soils cover more than 1.5 million km<sup>2</sup> or about 1% of the Earth's land surface (Fig. 2). By far the most striking pattern in the distribution of volcanic ash soils follows the Circum-Pacific Ring of Fire, the concentration of active tectonic zones and volcanoes along the western coast of both North and South America, across the Aleutian Islands down the Kamchatka Peninsula and Kurile Islands of Russia, through Japan, the Philippine Islands and Indonesia, across Papua New Guinea, and Pacific islands to New Zealand. Another large area of volcanic ash soils exists along the Rift Valley in Africa through Yemen, Ethiopia, Kenya, Rwanda, and Burundi. Other areas of volcanic soils associated with active volcanism exist in the Cameroons, West Indies, southern Italy, the Canary Islands, and Iceland. In China, volcanic soils formed in Quaternary ash deposits are found in the northeastern and southern provinces, Inner Mongolia, Xinjiang, Hainan, and Taiwan.

In Alaska, volcanic ash deposits are widespread and

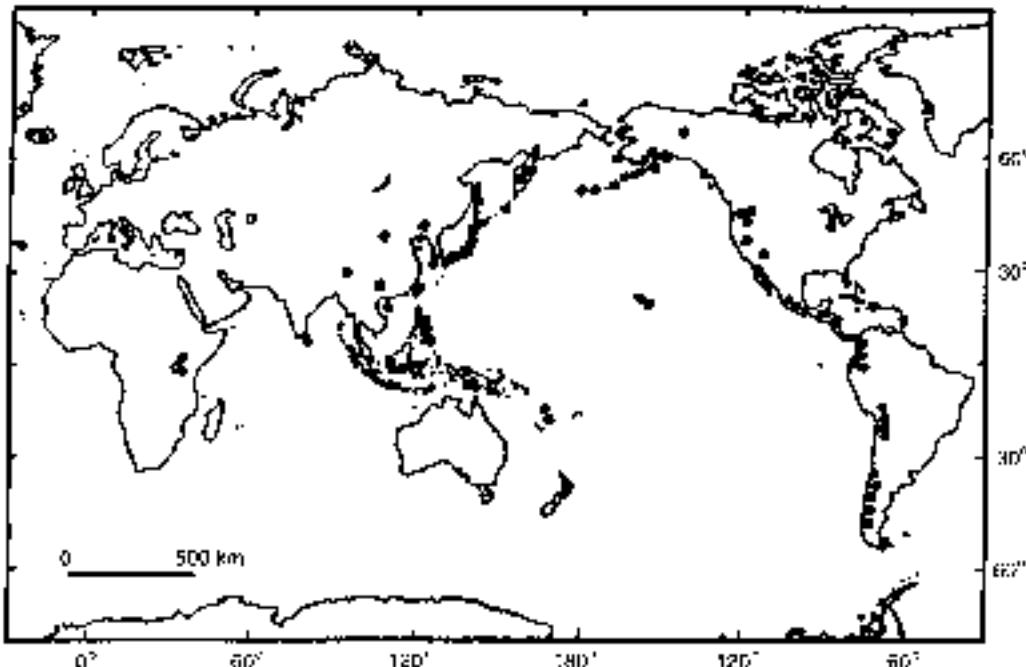

FIGURE 2 Distribution of volcanic soils in the world (indicated by black dots).

abundant in Quaternary sediments throughout the southern region; however, they are less abundant in the central region and are only found to a limited extent in the northeast region. In the Aleutian Islands, there are approximately 80 active volcanoes that produced about 120,000 km<sup>2</sup> of soils formed in volcanic ash and other pyroclastic materials. Volcanic ash soils also exist in Washington, Oregon, California, and Idaho, all of which are affected by the 17 active volcanoes in the Cascades Range. Volcanic soils form in Tertiary volcanic ash deposits in Arizona. Volcanic ash deposits are also found in permafrost regions of southern Yukon Territory, southern portions of British Columbia, and Alberta of Canada.

At present about 1500 volcanoes remain from the periods of intense activity of the Holocene, Pleistocene, and late Tertiary periods. These volcanoes have extruded thousands of cubic kilometers of lava and related volcanic material, and it is from this material that Andisols form.

Soil Taxonomy is the U.S. soil classification system, which is based on soil properties. There are 12 soil orders in Soil Taxonomy. The hierarchy of the U.S. soil classification system is order, suborder, great group, subgroup, and series. In this chapter only the suborders of Andisol will be introduced for discussion in the following sections. Details for each category can be found in the Keys to Soil Taxonomy.

The majority of volcanic soils are derived from volcanic ash and are classified in the Andisols order. Andisols are those soils that contain <25% organic carbon and have >35 cm within the top 60 cm of the mineral soil surface that meet the Andic soil properties, which differentiate them from the freshly deposited or unweathered ash or pumice. These properties are defined based on the presence of weathered products such as amorphous material and humus–metal complexes, bulk density <0.90 g/cm<sup>3</sup>, and high phosphate retention (>85%), or the presence of volcanic glass if the weathered products are low but measurable.

The seven suborders of Andisols are based on soil climate and drainage conditions. Aquands are Andisols with saturated and reducing conditions within the upper 25 cm. Cryands are those formed in areas with a mean annual soil temperature less than 8°C. Torrands are those with an aridic (dry) moisture regime. Xerands are those with a xeric moisture regime (moist and cool winter, warm and dry summer). Vitrands are those with high volcanic glass and thus lower water retention than

### III. CLASSIFICATION OF VOLCANIC SOILS

Soil classification is designed to group our knowledge on different soils for land-based technology transfer.

other suborders. Ustands are those with a ustic (subtropic) moisture regime. And Udands are those with a humid climate. In the next category, there are 29 great groups that are based on soil profile characteristics. The great groups are further divided into 196 subgroups based on deviations from the typical ones. The subgroups are differentiated into several thousands soil series based on soil horizon arrangement. In general, Andisols are formed in parent materials of volcanic origin, but this is not a requirement for an Andisols, as there are some Andisols formed in nonvolcanic materials. An example of the hierarchy is illustrated here:

Andisols	Order
Cryands	Suborder
Fulvicryands	Great group
Typic Fulvicryands	Subgroup

Fulvicryands are those Cryands that have more than 6% organic carbon but that have a light color.

However, not all volcanic ash soils fall into the Andisol order. For those in which the ash layers are too thin, they are classified into Andic subgroups of the other 10 orders except Histosols. Those in which the ash layer is deeper than 35 cm but that are too young or have little or no weathered product are classified as Entisols. When Andisols undergo further weathering, the amorphous minerals may transform into 1 : 1 and 2 : 1 layer silicates. Then bulk density increases, variable charges and P fixation decreases, and the soils become Inceptisols. Aridisols may form in volcanic deposits that may be old and thick but the dry climate limits the weathering to salt accumulation. Mollisols generally form in older and basic volcanic deposits under temperate and humid climatic conditions. The allophane and imogolite have transformed to halloysites and other 2 : 1 layer silicates; thus the variable charge decreases, bulk density increases, and layered clays are saturated with basic ions, mainly calcium (Ca) and magnesium (Mg). In Japan, some volcanic Mollisols developed in tephras older than 12,000 years. Under cool and humid environments, Andisols transform into Spodosols in a relative short time (i.e., several thousand years) due to strong leaching and the high susceptibility of volcanic glass to weathering. Alfisols and Ultisols form under subtropical environments, when the poorly crystalline minerals in Andisols transform to crystalline layer silicates such as kaolinite and vermiculite. Ultisols are more leached than Alfisols, thus they are more acidic. In the subtropic environment, Vertisols are formed when volcanic ash weathers to expanding 2 : 1 layer silicates, such as smectite. Oxisols form under the hot and humid conditions where volcanic deposits have undergone strong weathering and have lost most of the silica through leaching, and with residual

accumulation of hydrous iron and aluminum oxides. Gelisols may form from volcanic ash and pumice if the ash layer is underlain by or partially within permafrost.

#### IV. FORMATION OF ANDISOLS

##### A. Parent Material

The parent material of volcanic ash soils includes ash, pumice, cinders, and other volcanic ejecta. These soils are formed in volcanic materials from ultrafine dusts to a mixture of large boulders and volcanic bombs which are ejected by explosive volcanic eruptions. Many volcanic ash soils are multisequa (repeated A-B-horizon sequences) resulting from a series of eruptions laying down ash and then pumice or cinders. This interbedding results in unique soils that can be easily studied by dating the various layers present. The soil properties are affected by the chemical and mineralogical properties, texture, and deposition features of the volcanic ash. Volcanic ash can be divided into the light-colored and dark-colored groups. Felsic tephra is acidic and light-colored. The main rock types include rhyolite and dacite with a total  $\text{SiO}_2$  content >62%. Mafic tephra contain dark-colored material with the major rock type being basalt with a 45–54%  $\text{SiO}_2$  content. Rock types of the intermediate group are andesite and basaltic andesite with  $\text{SiO}_2$  contents ranging from 54 to 62%. The mafic rock types contain more of the minerals plagioclase and pyroxene. Opaque minerals are present in all three groups. The rate of chemical weathering is much faster in soils derived from dark-colored glass-rich tephras (basaltic tephras) than from light-colored glass-rich dacite tephra. In Alaska, light-colored tephras exist in south-central Alaska and dark-colored tephra exist in the Aleutian Islands and southeastern Alaska. Thus the volcanic ash soils in southcentral Alaska are more acidic than those from the Aleutian Islands, and those in the Aleutians are more fully developed.

##### B. Climate

Climate plays an important part in Andisol formation, and it is the key to differentiating the Andisol order into suborders with the exception of Aquands and Vitrands. The Torrands (Latin *torridus*, hot and dry) are Andisols formed in hot and dry climates and are least weathered, thus there is calcite accumulation in the soil profile.

The Ustands (Latin *ustus*, burnt; implying dryness) are Andisols formed in semiarid climates and experience some degree of leaching. The silica is leached from the upper to lower profile and, in some cases, forms a hardpan. The Xerands (Greek *xeros*, dry) are Andisols formed in Mediterranean climates with dry, hot summers and cool, moist winters. Organic matter started to accumulate in the Xerands. The Udands (Latin *udus*, humid) formed under humid or very humid climates. These soils are highly leached, thus very acidic, and have a high organic matter content. Cryands (Greek *kryos*, coldness) are Andisols that form in climates with cool summers and mean annual soil temperatures that are less than 8°C. Most Cryands are found in Alaska, the Kamchatka Peninsula, and the high mountains of East Africa, Iceland, the Cascades Range, and the Andes Mountains. The suborder, Vitrands are Andisols with soil materials dominated by only weakly weathered volcanic glass. Aquands are Andisols with an aquic (wet) condition.

The “classic” Andisol of Japan and other areas along the Ring of Fire forms in humid environments which also tend to be fairly cool. These are deep, organic-rich soils. This suggests the optimum climate for rapid formation is one of cool temperatures and high rainfall. Even within the tropics, the better expressed Andisols are found at higher elevations with cooler temperatures. In the warm areas, the transformation to Ultisols and Oxisols is even more rapid.

### C. Topography

Andisols tend to be in mountainous to hilly areas because that is where volcanoes are found, but fine ash can be carried over long distances and deposited on a variety of landscapes. Also water can rework ash such that extensive flat areas of Andisols are found in intermountain valleys. Large lava flows may likewise result in fairly flat areas for the formation of Andisols. Aquands are Andisols that form in topographic positions with restricted drainage. They tend to be dark-colored because of the accumulation of organic matter due to the anaerobic conditions. Because of the mode of ash deposition there is no single dominant topographic area where Andisols are expected.

### D. Vegetation

The natural vegetation associated with Andisols varies but has a major influence on the type of Andisol formed.

Many areas in the Pacific Northwest and Alaska are under forests. Udands generally are formed under forest vegetation, but in south central Alaska and Japan, some Udands form under dense grass. Cryands generally form under conifer forest, but the Cryands in the Aleutians form under tundra vegetation. Vitrands and Xerands have a mixed vegetation of grass and forest, such as those found in northern California, central Washington, and Oregon. Torrands have shrubby or grass vegetation. In general the soils are moderately acid so that any vegetation associated with acidic materials will predominate.

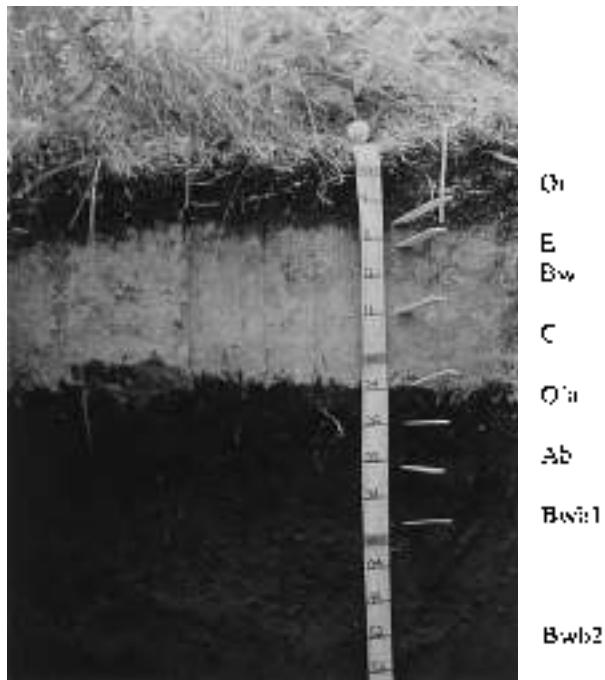

### E. Time

As with all soils, time is a major factor in the formation of Andisols. Andisols generally are found on young parent materials in humid climates. By their very nature, the older and more stable the landscape, the more weathering will have taken place, and either Ultisols or Oxisols will be found. The drier and/or cooler the environment, the longer it takes for an Andisol to form. For example, there are volcanic materials in extremely dry areas that have not weathered at all and are still Entisols. An A horizon can form on newly deposited ash in several hundred years, whereas an A-B sequence can take several thousand years. In Japan, most Andisols are 4000–7000 years old. In southeastern Alaska, a highly developed Cryand has a C-14 date of 12,000 years old. Yet, in a Haplocryand from northeast Kodiak Island, Alaska, an incipient profile including a dark A horizon, weak E horizon, and an iron-stained B horizon have already formed in the 1912 Mount Katmai ash (Fig. 3).

---

### V. SOIL-FORMING PROCESSES IN ANDISOLS

Soil formation is the combined effects of five soil forming factors: parent material, climate, topography, vegetation, and time. The genetic concept of an Andisol is that of a soil that forms in a humid environment from volcanic ash. There needs to be a minimum amount of weathering to produce Andic Soil Properties as defined in the Keys to Soil Taxonomy. Because most Andisols are formed in humid environments, weathering is quite rapid in volcanic ash. In surface (A) horizons, most of the active aluminum and iron released from volcanic

**FIGURE 3** A volcanic soil formed in the 1912 Mount Katmai ash over a buried, well-developed Andisol in northeast Kodiak Island, Alaska. The photo was taken in 1986, and a dark O horizon, a thin E horizon, and an incipient B horizon have already formed in the younger ash under the cool and humid environment. The dark color of the upper buried horizon is due to high humus content. (Explanation of subscripts in the B horizons: w, weathering; b, buried and in O horizons; i, least decomposed; a, highly decomposed).

ash forms complexes with humus. In the subsurface (B) horizons, aluminum and silicon oxides precipitate together to form allophane and imogolite. Allophane and imogolite are the early weathering products of volcanic glass and can be extracted with acid-oxalate. If there is more extensive weathering, halloysite and other crystalline minerals may be formed.

Because Andisols form under many different environments, there is an extensive range in properties. Properties common to most volcanic soils including Andisols are: low bulk densities, high levels of carbon to depth, and a high level of phosphorus fixation; it is these properties that are used to define Andic soil material. The overall processes are ones which lead to the formation of stable complexes of aluminium, iron (Fe), silicon and organic matter. If the weathering process continues, other types of soils are formed when more crystalline minerals develop (e.g., Ultisols, Oxisols, Inceptisols, and Alfisols).

## VI. PROPERTIES OF VOLCANIC ASH SOILS

### A. Morphological Properties

Most volcanic ash soils have striking morphological features. They usually have multiple sequences of horizons (Fig. 3) as a result of intermittent volcanic fallout. In the field, it is easy to identify the dark surface horizons (A) overlying a reddish brown or dark yellowish brown subsurface horizons (B). The A-B sequence generally represents one deposition (eruption) event and multiple sequences are common, which reflect the intermittent nature of volcanic ash deposits. Such stratification is an important tool for dating volcanic activities and geological events. Often a thin gray or whitish layer of recent ash fall may be found at or near the surface. Because of the nature of the ash fall, the horizons are generally flat, and the transition from one horizon to another is distinct. In the field, when excavated, volcanic ash soils give a feeling of "puffiness" due to the low density. On grassland, the soils generally have a granular structure in the A horizons due to the disturbances of roots and soil fauna. The structures in the B horizons are generally subangular blocky. Udzands that formed in high rainfall areas have a high clay content and are subjected to wet/dry cycles that result in columnar structures. Soils that are high in allophane are sticky in moist field conditions. Andisols generally have deep rooting zones due to the low bulk density.

### B. Mineralogical Properties

The mineralogical properties of volcanic ash soils are what give rise to the unique chemical and physical properties of these soils. The primary minerals in tephra are commonly divided into light (specific gravity <2.96) and heavy (specific gravity >2.96) minerals. The light minerals include volcanic glass, phenocrysts, feldspar, and silica minerals (mainly quartz). The heavy minerals include dark-colored volcanic glass and all the iron- and magnesium-rich minerals including pyroxines, ferromagnetic minerals, amphiboles, biotite, and olivine. The major secondary minerals in volcanic ash soils are allophane, allophane-like materials, imogolite, zeolite, non-crystalline and crystalline silicate clays.

Volcanic ash consists mainly of volcanic glass, which contains noncrystalline silica and aluminum with minor inclusions of ferromagnesium minerals. On weathering,

the glass releases aluminum and iron into solution, which forms a stable complex with humus resulting from plant material decomposition in surface soil horizons. These Al, Fe–humus complexes are immobilized and accumulate at the surface to form a dark A horizon. The Al– or Fe–humus complexes are dominant components of the colloidal fraction of the A horizon. With the dissolved Al being tied up with humus, the soil solution accumulates an excess amount of dissolved silica (Si). A secondary Si mineral forms in this Si-saturated solution, called laminar silica, which is commonly circular or elliptical in shape and extremely thin with diameters ranging from 0.2 to 0.5  $\mu\text{m}$ . Opaline silica is found in the surface horizons of soils from the Aleutian Islands and the Kenai Peninsula. It is easily identified with an electron microscope (Fig. 4). In humid environment, it takes few hundred years for opaline silica to form.

As depth increases in the B horizons, the supply of

organic matter or humus becomes limited. The dissolved Al and Si from all kinds of volcanic ash can form noncrystalline and paracrystalline substances, mainly allophane and imogolite. In the early 1940s, allophane was considered synonymous with amorphous clay because it is nearly X-ray amorphous, although under an electron microscope, it appears as hollow spheres 3.5–5.0 nm in diameter. Chemically, allophane has a formula of  $1.0\text{--}2.0 \text{ SiO}_2 \cdot \text{Al}_2\text{O}_3 \cdot 2.5\text{--}3.0 \cdot \text{H}_2\text{O}$ . Imogolite was first described in 1962 by Japanese researchers in a soil derived from glassy volcanic ash known as imogo. Imogolite is paracrystalline, gives a characteristic X-ray diffraction pattern, and infrared and differential thermal curves. In the 1970s, the introduction of high-resolution electron microscope in clay minerals research provide us an insight view of the internal structures and morphology of allophane and imogolite. Under an electron microscope, it appears as smooth, curved threads or tubes with inter-

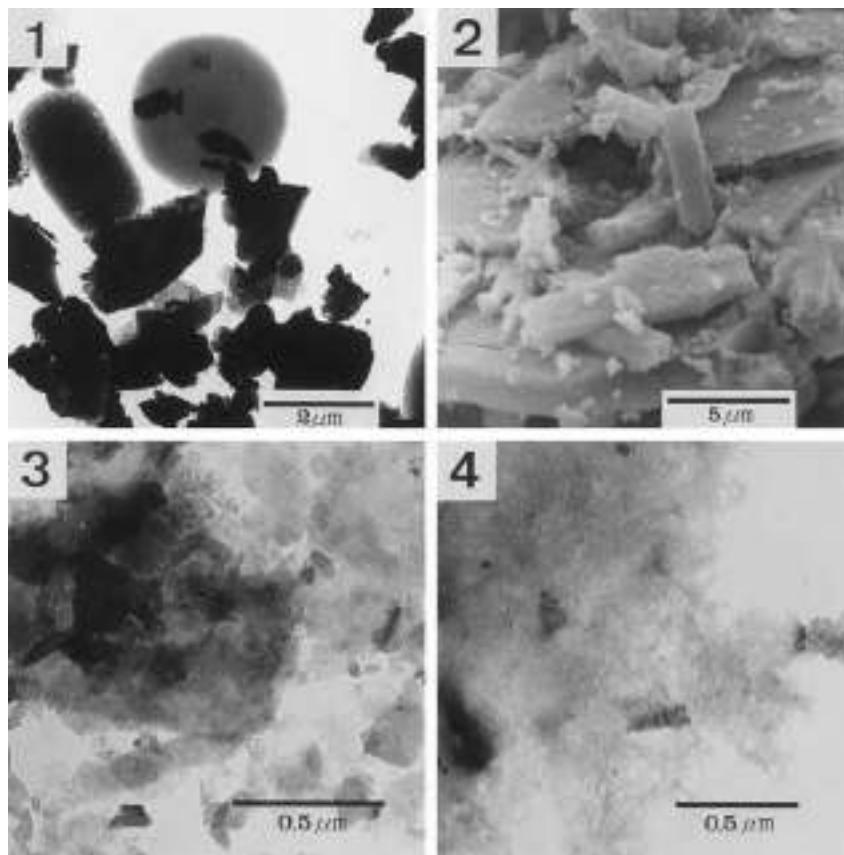

FIGURE 4 Electron micrographs of clay minerals in from some Haplolyands from Aleutian Islands, Alaska: (1) Laminar opaline silica (OS) and volcanic glass (VG) in the A horizon. (2) Zeolite (clinoptilolite) (CL) in a buried B horizon. (3) Humus (dark color) and volcanic glass (light color) in the A horizon of another profile. (4) Allophane in the buried B horizon. [Adapted from Ping *et al.*, 1988; copyright Soil Science Society of America, with permission.]

nal and external diameters of 1.0 and 2.0 nm, respectively. Chemically it has a formula of  $\text{SiO}_2 \cdot \text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$ . The Al:Si atomic ratio of allophane and imogolite are 1.0–2.0 and 2.0, respectively. Imogolite formed from transformation of allophane through removal of silica. Both allophane and imogolite are found in B horizons 5000–10,000 years old. Generally, it takes more than 1000 years for allophane to form and more than 2000 years for imogolite to form in a humid environment. The allophane content in a soil increases with depth, usually in the B horizon and buried horizons. It increases with the age of the volcanic deposit and the amount of annual precipitation. Allophane and imogolite can be dissolved in acid-oxalate solution, and the dissolved Si can be used to quantitatively measure their contents in soils. In south central Alaska, allophane in the B horizons ranges from 2 to 12%, in the Aleutians it ranges from 4 to 14%, and on Baranof Island it ranges from 10 to >20%.

Ferrihydrite is another amorphous mineral found in volcanic ash soils formed in areas of high rainfall (e.g., southeastern Alaska) or in soils with restricted drainage. It is a widespread and characteristic component of young iron-oxide accumulations precipitated from iron-rich soil solutions. It has a bulk form of  $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$ . Ferrihydrite can be quantified by the difference between dithionite citrate-extractable and oxalate-extractable Fe. In the B horizons, allophane, with or without ferrihydrite, dominates the colloids with Al- and Fe-humus complexes being minor components. The lower B and C horizons are also rich in allophane and ferrihydrite but contain few Al- and Fe-humus complexes. In addition to ferrihydrite, iron-hydroxides also exist in other noncrystalline or poorly crystalline forms. Most Al released from weathered volcanic materials is in complex with humus. But the mineral gibbsite is found in B horizons formed in old or buried volcanic ash or pumice.

Halloysite is a fast-forming member of the kaolinite (clay) subgroup primarily in porous volcanic glass deposits. Thus it has poor crystallinity. The spheroidal or tubular morphology is characteristic of halloysite, and platy halloysite is rare. Most halloysites are formed in weathered volcanic deposit or igneous rocks under semiarid to humid environments. In New Zealand some halloysites formed from fine-grained rhyolitic tephra in places with annual rainfall of 1200 mm. In Japan and the Aleutian Islands of Alaska, halloysites were found in old and buried ash or pumice deposits, which indicates that their formation is governed by the availability of silica from percolating soil solutions. Halloysites were found in B horizons more than 7000 years old.

Layer silicate minerals of structure 1:1, 2:1, and

2:1:1 and their Al interlayers are also common in Andisols. They are either the pedochemical products resulting from transformation of amorphous minerals (allophane) or the weathering product of mafic minerals (e.g., pyroxenes, amphiboles, and micas in parent ash). Zeolite minerals are found in some Andisols from the Aleutian Islands (Fig. 4). The existence of zeolite indicates that the parent material of the soil contains hydrothermally formed material.

The dominant components in the silt and sand fraction of Andisols are volcanic glass and other primary minerals. Normally, volcanic glass particles are like shattered glass, with sharp angles and edges; thus they are very abrasive. However, in soils, the glass particles are usually coated with allophane, Al- and Fe-oxides, and their humus complexes. These coatings on volcanic glass or other mineral particles can be easily removed with a oxalate solution, thus the freed mineral particles can be used for mineralogical analysis.

### C. Chemical Properties

The chemical properties of volcanic soils are dominated by humus and certain unique minerals. Some general chemical characteristics of these soils show that they have pHs ranging from 5 to 7 (weak acid range). This is in contrast to Spodosols which have similar minerals present but generally have pHs less than 5. The Al-humus complexes and the short-range-order colloids have Al-dominated exchange sites. In humid environments, the basic cations (Ca and Mg) are leached out. Therefore, most volcanic ash soils have high exchangeable Al and thus high Al saturation, generally over 40%. Base saturation is low (generally less than 10% in Alaskan soils). The Al on the Al-humus complex is the major source of acidity. Soils with high Al-humus can have a pH lower than 5.0. Volcanic ash soils, especially Andisols and Andic subgroups in other soil orders, have high phosphorus (P) retention capacity due to the high content of active Al and Fe compounds. Thus P retention was adopted as one of the criteria of Andisol classification.

Weathered volcanic soils have two distinct colloidal compositions dominating the chemical properties of the soil. The humus-rich allophanic Andisols generally have a mixture of variable-charge colloids (allophane and humus), whereas the humus-rich nonallophanic Andisols generally have a mixture of variable and permanent-charge colloids (layered silicates and humus). The permanent charges are from isomorphic exchange in lay-

ered aluminosilicates, whereas the variable charge is created in allophanic minerals and humus when the pH increases. Anion exchange capacity exists in allophanic Andisol but not in nonallophanic Andisol. These soils also have very large surface areas as high as  $600 \text{ m}^2 \text{ g}^{-1}$  and give rise to very large number of exchange sites. Thus for an allophanic A horizons, the effective cation exchange capacity is more than twice that of a nonallophanic soils with same amount of organic matter.

## D. Physical Properties

Soil physical properties are dominated by clay fractions and humus which are the exchange complexes of a soil system responsible for nutrient retention and exchange, water retention, shrink-swell potential, aggregate and structure formation, and many other properties. In well-developed volcanic ash soils such as Andisols and the Andic Spodosols, the exchange complexes are dominated by Al- and Fe-humus complexes, ferrihydrite, allophane/imogolite, and a small fraction of crystalline clay minerals. These colloidal components give these soils their unique properties.

### 1. Low Bulk Density

Soils derived from volcanic ash usually have a bulk density of  $<0.9 \text{ g cm}^{-3}$ . Organic matter, amorphous material, porous glass, and pumice all contribute to the low bulk density. Thus, the well-developed volcanic soils have higher organic carbon and allophane contents resulting in bulk density as low as  $0.5\text{--}0.9 \text{ g cm}^{-3}$ . Most Andisols are a good growth medium for plants because they are very permeable due to their low bulk density and high porosity.

### 2. Thixotropy and High Water Retention

Most well-developed volcanic ash soils in moist field conditions have a smearable feeling when rubbed between one's fingers. The soil appears barely moist, but after prolonged rubbing, the soil becomes greasy and wet. Once the pressure is relieved, the excess water is reabsorbed into the soil. Such a unique property is called thixotropy, which develops the unusually high water retention of allophanic soils. Allophane has a large specific surface area of approximately  $1000 \text{ m}^2 \text{ g}^{-1}$ , which is responsible for such a high water retention. Weathered volcanic ash soils may retain 40–90% water in humid regions and more than 100% in the highly weathered soils which exist in high rainfall ( $>2000 \text{ mm}$ ) regions

such as southeastern Alaska, the Cascades Range of the Pacific Northwest, and New Zealand. Thixotropy and low bulk density contribute to the low bearing capacity and poor traction of volcanic ash soils.

### 3. Irreversible Drying and Plasticity

Allophane is generally electrically neutral with its natural pH value close to 5.2. Thus, once dried, the allophane particles will go through dehydration and form closely packed aggregates of silt or sand size. These aggregates do not disperse on rewetting. Thus, a crust may form on ground surfaces without vegetative cover during hot, dry summers. The irreversible drying also results in unreliable particle size determinations if the samples are air-dried or even oven-dried before rewetting and dispersion. Thus, the traditional method of particle size distribution tends to underestimate the clay content of soils containing amorphous minerals. Newly formed volcanic ash soils do not have this problem because they do not contain allophanic minerals.

Plasticity is one of the physical properties distinguishing soils containing allophane from those containing crystalline clay minerals. Generally, moderately to well developed volcanic ash soils in their field-moist state have high liquid and high plastic limits. Field-moist samples from south central Alaska have a liquid limits ranging from 60 to over 100%, whereas those from south eastern Alaska have liquid limits ranging from 100 to 250%. In the field conditions, some highly weathered volcanic soils may reach their liquid limits before the plastic limits. Soils containing allophane and imogolite exhibit irreversible drying, thus after a loamy soil is air-dried, it forms strong aggregates, shows very little plasticity, and behaves like sandy soils.

---

## VII. VOLCANIC SOILS AND AGRICULTURE

Although volcanic ash soils cover slightly less than 1% of the total Earth's land surface, their importance to civilization is great as they support more than 10% of the total world population. The Rift Valley in East Africa nourished the earliest known human race. The fertile volcanic soils of Central and South America have long supported the Mayan and Inca civilizations by providing them with fiber and food and grazing ranges. Today, the volcanic ash soils support the most important cash crop for this region: coffee. In addition, these soils also

produce large quantities of tropical fruits and hardwood forests and, in recent years, support the beef industry. In Japan, Indonesia, and the Philippines, both native crop and rice fields were cultivated in volcanic ash soils for more than 10 centuries. In the South Pacific, from Hawaii to New Zealand, as well as in the Philippines and Indonesia, volcanic ash soils support various crops including sugar cane and tropical fruits and provide productive grazing ground for animals.

For centuries, vineyards have flourished in volcanic ash soils in southern Italy and nourished the Mediterranean culture. In southern Alaska and along the coastal regions of the Pacific Northwest of the United States, volcanic ash soils support the most productive conifer forests, providing an important economic base for the region. In the semiarid regions of California, Oregon, and Washington, some of the most productive vineyards and orchards of apples, peaches, cherries and apricots grow in volcanic ash soils. In this region, most volcanic ash soils are formed in Pleistocene and Holocene volcanic deposits, whereas in Napa Valley, most of the volcanic soils formed in Tertiary pyroclastic deposits.

The vineyards and orchards favor the Mediterranean climate of these regions, rather than volcanic soils alone. However, the volcanic soils developed under this climate share similar properties; they are less weathered and retain most of the bases which are essential for the crops. Thus most of those soils are Vitrands, Xerands, Andic Inceptisols, and Mollisols, and some Aridisols with irrigation.

Acidic Andisols exist extensively in subhumid and humid regions. The high Al saturation limits crop selection to acid-tolerant crops unless lime is applied. Thus, phosphorus fertilizer efficiency and Al-toxicity are major concerns in Andisols and associated Spodosols.

#### VIII. SUMMARY AND FUTURE NEEDS

Soils formed in volcanic ash have unique morphological, chemical, and physical properties. The importance of volcanic ash soils is demonstrated by the fact that they account for only 1% of the Earth's land surface, yet they support more than 10% of the world's population. These soils have nourished many ancient civilizations. The moderately and well-developed volcanic ash soils are fertile and provide the economic basis for some regions. Yet, changing land-use patterns over past decades due to economic growth have resulted in land and

soil quality deterioration. Sustained agriculture practices become more critical to maintain the social and economic structure. Volcanic soils formed in humid environments are highly leached and have developed strong acidity and aluminum toxicity; these soils deserve special management practices. More research is needed in soil fertility, especially phosphorus fertilizer efficiency, and acid-tolerant crops deserve more attention. The bountiful gift of these soils given by Nature cannot be taken for granted. The recent calamity resulting from volcanic eruption in Central America is a reminder of the hazard associated with the soils and the region. The prosperity of the people in the volcanically active regions can be guaranteed only with adequate tectonic monitoring and efficient infrastructure.

## GLOSSARY

**absorbent** A material that takes up, assimilates, or incorporates liquids through pores or interstices.

**aggregate** Mineral material composed of a mixture of different sizes that is separable by mechanical means. Aggregate is passed through sieves and other sorters to grade its size. Graded aggregates are mixed with cement or bituminous material to form mortar or concrete.

**basalt** A fine-grained, sometimes glassy igneous rock. Basalts have low  $\text{SiO}_2$  contents of 45–50%. They are usually found in lava flows which may be of variable size. They are frequently erupted from fissures and less often from central vents.

**bentonite** A special assemblage of clay minerals often

formed from weathering of volcanic ash. Typically, it is composed of nonrefractory clays rich in montmorillonite and is off-white in color. When the principal ion in the clay is sodium, bentonite is highly absorbent and subject to large volume changes.

**cinder block** A type of brick made from compressed aggregate material, often volcanic.

**drilling mud** A mud mixture of clays and water with a high density, viscosity, and strength. Acts as a lubricant, coolant, and sealant and floats drill cuttings up and out of the hole.

**montmorillonite** A clay mineral common as a weathering product of volcanic material.

**obsidian** A black, wholly glassy rock which displays conchoidal fracture. Most obsidians are of rhyolitic composition. Because glass is thermodynamically unstable, most obsidians undergo a process of devitrification and form crystal structures.

**perlite** A glassy and devitrified rock of rhyolitic composition which contains many curved or spherical cracks caused during cooling and contraction. These may be so well developed that the rock easily breaks into irregular pieces. Contained spherical pieces of unaltered obsidian are known as “Apache’s tears.” Perlite is used as an absorbent and insulator.

**pumice** A highly vesicular pyroclastic rock produced during explosive eruptions. It tends to accumulate as rounded lumps and also as abraded fragments called shards. Den-

sities are typically less than  $1.0 \text{ g/cm}^3$ , so pumice often floats on water.

**refractory** A material which does not significantly deform or change chemically at high temperatures. Bricks of such material in various shapes are used to line furnaces.

**tephra** All fragmental volcanic ejecta which are produced during explosive volcanism, including ash, cinders, lapilli, scoriae, pumice, bombs, etc.

**trap rock** An older term for compact, fine-grained igneous rocks such as lava flows, which have been broken into roughly uniform fragments. Often used for road beds, running tracks, and the like.

**tuff** A general name for consolidated ash or tephra, usually with largest clasts less than 2 cm. The material is erupted and is still hot when it hits the ground, resulting in consolidation and partial welding. Tuffs may be crystal rich (crystal tuffs), lithic rich (lithic tuffs), glass rich (vitric tuffs), or lapilli rich (lapilli tuffs).

**T**HE PRODUCTS OF volcanic eruptions have provided useful raw materials for man throughout history. In many regions of the world volcanic rock is ubiquitous, and the inhabitants of these regions have developed ingenious uses for this natural resource. Ranging from early weapons and implements to building materials, volcanic rocks have been sought out because of their physical properties for use in manufacturing processes, or as insulators, absorbents, or abrasives. Volcanic materials play an important role in our lives, regardless of whether we live near volcanoes or not, although most of us do not realize their wide variety of applications.

## I. INTRODUCTION

The use of volcanic materials most certainly sprang from necessity, but it was quickly learned that many volcanic materials are ideal for a variety of uses. They have a unique set of physical properties, and their natural occurrence makes them relatively inexpensive and thus ideal for construction and manufacturing. For example, pumice has a relatively high strength, yet in some cases a low enough density to float on water, and provides excellent insulation and absorption characteristics. Most explosive eruptions produce pumice and spread it over a large area. Volcanic rocks are present almost everywhere in the world and annually  $6-8 \text{ km}^3$  of new volcanic

material is erupted, nearly  $2 \text{ km}^3$  subaerially, and about 80% of this is particulate material from pyroclastic flows, debris avalanches, and ash falls. This is enough to cover 1600 football or soccer fields a kilometer deep in ash.

Before the industrial age, volcanic rocks were used for a wide range of purposes and provided a tradable commodity and a basis for local economies. Volcanic soils are fertile, and to this day many countries use volcanic ash as a soil supplement in agriculture (see "Volcanic Soils"). The use of volcanic materials has increased as additional applications have been found, strengthening the practical and economic relationship between mankind and volcanoes. Few data exist on the amount of volcanic material used or the "size" of the affected industries. To help get an idea of the number of volcano-related products available, Fig. 1 shows a histogram of the number of pages in the *Thomas Register of American Manufacturers: Products and Services Section* devoted to several volcano-related topics. We then added several familiar everyday examples to provide a basis for comparison. We found that one page or less was devoted to sulfur, monuments and memorials, pumice, bentonite, and additives; however, each of these volcano-related products had more entries than surfboards. Abrasives, on the other hand, is a substantially larger industry than air conditioners. Absorbents, polishers, and refractories, of which volcanic materials are components, offer a moderate number of products, slightly smaller than refrigerators. All the examples given have fewer manufacturers than batteries. Although crude, these estimates give a sense of the significant positive impact volcanic materials have on our everyday lives.

## II. TYPES OF MATERIALS

Volcanic products can be divided into several categories based on their use and chemical composition. These materials are summarized in Table I. The density and strength of each type of material depends on its chemistry and eruptive style, and in turn determines the ideal use for each product.

As a result of the eruption process, explosive volcanic products tend to be in the form of aggregates and have lower densities. In addition, they are often vesicular, giving them excellent insulating qualities. Many industrial processes, for example the manufacture of perlite, are designed to enhance these characteristics.

Volcanic materials often have very high strengths relative to their density, particularly for massive deposits,

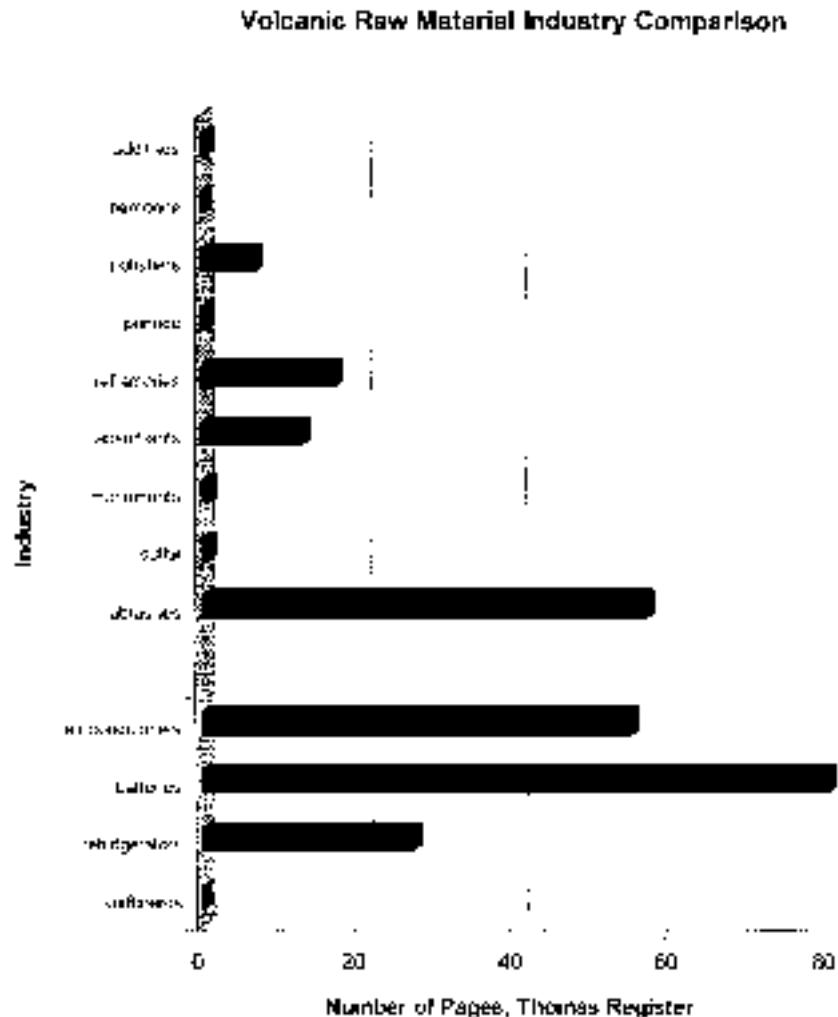

FIGURE 1 A histogram showing the number of pages of the *Thomas Register of American Manufacturers: Products and Services Section* devoted to various volcano-related topics. Several familiar everyday examples of other products are shown in the lower part of the chart to provide a basis for comparison.

such as lava flows or welded ignimbrites. This makes them cost-effective building materials. In the case of aggregate material, the irregular angular shapes allow particles to stick together, yielding very high angles of internal friction. This makes these aggregates ideal for use in constructing road beds or in laying railroad tracks. Because volcanic glass fragments are made of silica, a very hard substance, and the shards are often in the form of bubble-wall junctions, or small sharp tetrahedra, ash fall deposits are a good source of abrasives.

Volcanic rocks are not readily soluble in water nor do they take on water and increase in volume (with the exception of volcanic clays, see following discussion). This makes them more resistant to weathering than limestone or sandstone. Volcanic glass is resistant to

corrosion and forms the ground mass of most volcanic rocks. Most volcanic rocks have very small coefficients of thermal expansion (on the order of  $1 \times 10^{-7}$  cm deformation/cm distance/ $^{\circ}\text{C}$  or less), and thus will not change in size or shape even under very large changes in temperature. This makes them very good refractories.

Concrete fabricated from volcanic cinders is a better insulator by a factor of 3 to 4 than normal concrete (thermal conductivities of 0.35–1.5 kcal/m hour deg). This is because of the high vesicularity of the cinders used in its manufacture. The small vesicles resist the transfer of heat, making it more difficult for thermal energy to move through the block.

Igneous rocks (e.g., granite) are also used in construction and have similar strengths compared to volcanic

TABLE I Physical Properties of Useful Volcanic Materials: Color, Typical Grain Size in a Volcanic Occurrence, Density, Strength (Compressive), Thermal Conductivity, Heat Capacity, and Common Uses<sup>a</sup>

Volcanic product	Color	Typical grain-size	Density (g/cm <sup>3</sup> )	Strength (kbar)	Thermal conductivity (kcal/m hr deg)	Common uses
<b>Raw products</b>						
Basaltic scoria	Black to red	Coarse aggregate < 3 cm	1.2–2.5	0.6–1.6	<1.0	Road construction, use in cinder blocks, moderate insulator
Basaltic lava	Black/gray	Massive	2.4–3.1	<2	2.0–3.0	Construction, decorative purposes, moderate insulator
Rhyolite ash	Light gray/brown	Fine aggregate < 2 mm	1.5–2	<0.1	<1.0	Abrasives, creation of perlite, a good refractory, insulator
Pumice	Light gray/brown	Aggregate 0.2–10 cm	0.5–1.5	<0.5	<0.75	Absorbent, abrasives, good insulator
Silicic ignimbrite	Light to dark brown	Massive	2.1–2.8	<1	2.0–3.0	Decorative uses, construction, poor to moderate insulator
Rhyolite lava	Brown to gray black	Massive	2.1–2.8	<25	2.0–3.0	Decorative uses, construction, poor to moderate insulator
Obsidian	Clear black	Small lenses or tears (cm)	2.0–2.5	<11	2.7–3.5	Decorative uses, cutting implements, poor insulator
Native sulfur	Yellow	Microcrystalline	1.95–2.1	<0.1	0.13	Chemical additive, component needed to “vulcanize” rubber
Bentonite clays	Light brown	<0.005 mm	1.8–2.6	<0.1	Varies widely	Additive to drilling muds, good insulator and sealant
<b>Man-made products</b>						
Perlite	White to light gray	Coarse aggregate < 3 cm	0.3–1.2	<0.1	<1.0	Absorbent, insulator, lightweight concrete
Cinder concrete	Gray	Blocks (man-made)	2.0	<0.5	3.0–4.5	Construction, insulation

<sup>a</sup> Where appropriate, a range of values has been given. The values given are typical for the materials shown but there can be considerable variance. For example, basaltic scoria has been observed up to meters in size, though these are typically not used for raw materials. The thermal character of the materials is greatly dependent on physical factors, such as vesicularity, or for aggregates their grain size and spatial relationship to one another.

materials, but have higher thermal conductivity and thus do not insulate as well. Because these rocks were typically created at some depth, and thus pressure, the crystals are tightly pressed to one another, giving very good heat conduction across these boundaries. These materials often have larger crystals, making them useful for aesthetically pleasing facades. This chapter will not go into depth on the use of igneous materials, although in many ways they parallel similar volcanic products.

### III. PREHISTORIC USES

Volcanic glass has been used for early cutting implements, as have microcrystalline volcanic rocks, such as fine-grained basalts or andesites. Arrowheads, scrapers, and knives made from volcanic products are common finds at prehistoric sites near volcanic regions (Fig. 2). How our ancestors used volcanic rocks is nearly as varied as how we use them today. Pumice can be used as a float in fishing, and as an excellent abrasive, like sandpaper, to fashion other tools. Nonvesicular volcanic rocks are also ideal for crushing and have been used to grind wheat, by hand and in more carefully fashioned millstones.

Blocks of tuff are good refractories, reflecting and holding in heat, thus ideal for the construction of oven walls, chimneys, and kilns. The clays produced by the weathering of volcanic ash are ideally suited for making pottery (Fig. 3). A culture which had a good source of volcanic rocks nearby was not just threatened by possible eruption but also had a strong economic base. In Mexico, the early empire of Teotihuacan (pre ninth century) was founded on the manufacture and export of obsidian blades.

Volcanic rocks have also made good building materials, not only for stand-alone structures but for caves and tunnels as well. Large ignimbrites have been excavated by the local inhabitants in Japan, Italy, and Turkey for living space, storage, and emergency shelter. During the second world war, the Japanese military dug over 300 miles of tunnels in ignimbrites in Rabaul, Papua New Guinea (Fig. 4). These were used for shelter, to hide weapons and to provide bomb-proof storage for ammunition.

Because of the sharp color contrasts of volcanic rocks (e.g., basalt to sandstone or limestone), volcanic rocks have also been used for decorative purposes. Monuments, temples, and churches throughout Asia and Europe have used volcanic rock for sculpture and decoration.

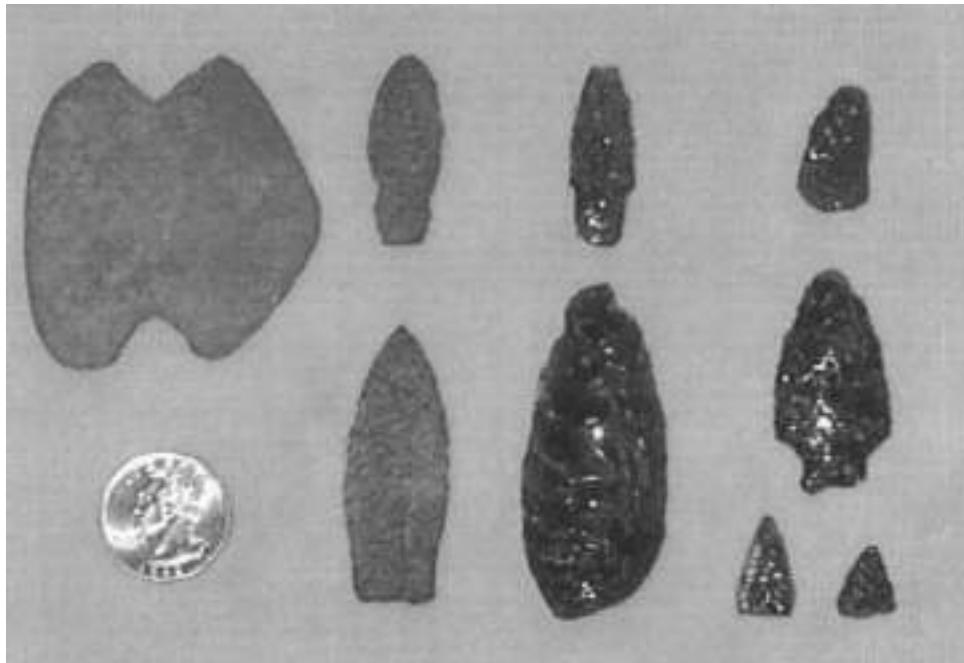

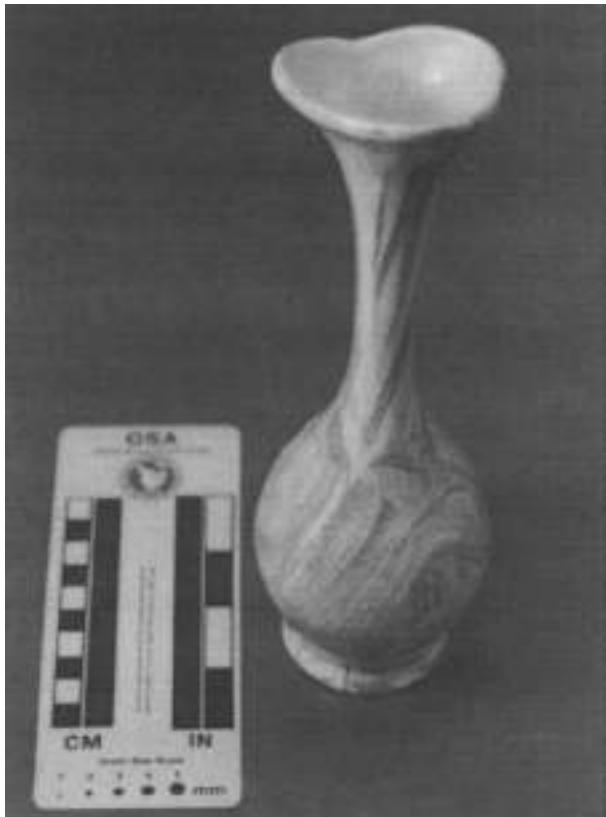

FIGURE 2 Implements have often been created using volcanic materials. The arrowheads are made of obsidian and the hammer of basalt. Such weapons maintained a keen edge after several uses and are easily as sharp as modern implements. These artifacts are from St. Lawrence Island, courtesy of the University of Alaska Fairbanks Museum.

**FIGURE 3** A vase decorated with volcanic ash from the 1980 eruption of Mount St. Helens. The ash, which occurs in different colors ranging from tan to gray to black to red, is used to add color and texture to pottery. Here the potter's clay is white, and brown ash is added to the exterior to make the swirl pattern.

#### IV. MODERN USES

Since the time when these early tools were used, because of the growth in world population and modern industry, more sophisticated uses for volcanic materials have been developed. These uses range from the mining of volcanogenic minerals to manufacturing aids, lubricants, and abrasives to construction materials. Volcanic products have also been used for artistic purposes (e.g., in gardens or as monuments). Often the applications are local, although certain types of volcanic minerals and rocks have become important exports for many countries.

#### V. ADDITIVES

Additives covers an extremely wide range of products, and we review several of the main volcanic contributors here. Volcanic ash and clays are common additives to many industrial materials. Whereas pumice and ash are excellent abrasives, volcanic clays can be used as lubricants and additives.

##### A. Bentonite

Bentonite is an off-white montmorillonite clay formed from altered volcanic ash. It has a sheet-silicate structure and is especially notable for the way in which it absorbs and loses water and for its base exchange properties.

**FIGURE 4** Right: Entrance to a tunnel cut into volcanic tuff from Rabaul caldera, Papua New Guinea. Hundreds of miles of tunnels were dug by the Japanese military during World War II. Left: Inside view of one of the larger tunnels. This one was used to store boats and barges to protect them from Allied bombing raids. The boats were moved using winches, sometimes with trolleys and rail tracks. This tunnel is about 100 m from the water's edge.

Sodic bentonite can absorb up to 10 times its own weight in water and can swell to 18 times its dry volume. Thus, it can be applied where its colloidal properties can be exploited. Bentonite has a wide variety of uses including foundry, animal feed, drilling mud, absorbent, industrial, and specialty uses.

About 70% of the world's known supply of western or sodium-type bentonite occurs in the state of Wyoming (notably in the Mowry Formation), with additional significant deposits elsewhere in the western United States. Volcanoes of the Yellowstone area of Wyoming were active for long periods in the early Cretaceous (ca. 100 million years) and deposited ash layers of a few centimeters up to 15 m thick into nearby shallow seas. The ash weathered with time, forming the bentonite.

Early uses of bentonite in the 1800s included lubricant for wagon wheels, sealant for log cabin roofs, and soap. Modern uses are highly variable. In foundry or metal casting, bentonite is mixed with sand to make the molds. The bentonite forms a pliable bond with the sand grains, so the mixture holds its shape well. Molten metal is then poured into the impression to make the casting. When complete, the bentonite and sand mold can then be broken away from the casting and reused. Bentonite is used as a binder for food pellets for animals and poultry and as a carrier for food supplements. Bentonite also absorbs excess moisture and oils, helping to prevent malodor, lumping, and caking of the pellets. Some recent research has shown that the base exchange properties of bentonite allow it to help remove certain toxins and ammonia. It also reduces feed flow through the intestines so that nutrient uptake is improved, indirectly aiding such factors as milk production, wool growth, and the quality and production of eggs.

Bentonite is widely used as drilling mud. It is mixed with water to form a slurry that is pumped through the drill string and out through the drillbit. The drilling mud helps to cool and lubricate the drillbit, and due to its high viscosity and yield strength, it extracts drill cuttings, carrying them to the surface, and helps to seal the drillhole and to prevent wall cave-ins. Bentonite is used to fill and seal abandoned drillholes. Similarly, bentonite has been used for sealing other waterways such as ponds, irrigation ditches, reservoirs, and industrial lagoons and has sometimes been used as a grout.

Because of its ability to absorb water and odors, bentonite has become a major component of the new "clumping" types of cat litters. (Nonclumping or regular cat litter is made from Georgia clay and other similar nonmontmorillonite clays.) The bentonite clumps are easy to handle, and the rest of the unused material remains intact, so the litter lasts longer between changes. With 54 million domestic cats in the United States

alone, this could be a significant impact! Materials very similar to cat litter, both clumping and nonclumping, are used in industry to clean up liquid spills.

Bentonite has been used as a binder for taconite, a low-grade iron ore. The taconite is ground finely, mixed with bentonite to make pellets or balls, and then briefly sintered in kilns to give the pellets a hard surface. The pellets can then be easily handled and shipped to steel mills.

Bentonite additives have been used to emulsify oils in asphalt and detergents; to improve strengths of ceramics and bricks; to retain microparticles in papermaking; to clarify water, wine, and juice; to treat wastewater, de-ink paper, and control airborne stack emissions; and to gel cosmetics and pharmaceuticals. It has also been used as an ingredient in cleansers, polishes, and sprays of various types. For obvious reasons, bentonite has been called the product of 1000 uses. The uses are dependent on its absorption characteristics, which are in turn dependent on the chemical composition of the clay.

## B. Pumice

Pumice is a porous, bubble-rich volcanic glass with low density. It is easily handled because of its low density and, when broken into finer particles, is widely used as an abrasive. The presence of the many bubbles means that the small pieces produced upon breaking are sharp and irregular. The particles are typically graded by size and backed with paper or other materials to produce sandpaper, grinding wheels, and other tools. Some pumice also had a highly specialized abrasive use until recently. Pumice that floats on water may be used in large washing machines to gently abrade cloth such as "stone-washed jeans." Eventually the pumice became waterlogged and sank, but it could be dried and used again.

Pumice is included in small amounts in certain soaps (e.g. "Lava" hand soap among others, Fig. 5) to provide a mildly abrasive action to aid in cleaning. Thus it adds a mechanical component to the cleaner that enhances the soap's chemical action.

---

## VI. AGGREGATES

Aggregates are broken pieces of rocks which range in size from fine sand to several centimeters in diameter. Volcanic aggregates, cinders, or scoria have been used for road construction, and the production of building

**FIGURE 5** Soap made using volcanic ash. Most of the soap is made from standard materials, but small amounts of fine-grained volcanic ash were added to provide a mild abrasive action in addition to the chemical action. This particular soap was sold in tourist shops soon after the famous Mount St. Helens eruption of May 18, 1980.

materials (e.g., concrete and cinder blocks). In addition, they have widespread use as ballast, and as a component in plaster and related materials. In general, the use of aggregates falls into three categories; loose aggregates, refractories, and absorbents.

Both perlite and pumice are used as aggregates, especially in applications in which low weight is desired, such as lightweight precast masonry or concrete floors. The main cost of aggregate is its transportation, so pumice is widely used wherever it is the closest available source of aggregate. Many countries, however, export pumice, taking advantage of its low density to minimize shipping costs. Both perlite and pumice are also used in certain types of insulation and acoustic tiles.

#### A. Perlite

Perlite is a highly hydrated volcanic glass. The hydration occurs along conchoidal fractures which pervasively criss-cross the material, so that perlite breaks up easily into small pieces. Many of these have round surfaces and a waxy luster of typically light gray color, although greenish, brown, blue, and red also occur. The pieces resemble pearls, hence the name perlite.

Perlite is used generally as a lightweight aggregate but also has some specialty uses. It is a substitute for sand in lightweight wall plaster and is also used in ceramic products, fillers, and filters. In agriculture, perlite is

mixed with peat from 25 to 75% and used to grow many types of plants. Because of its high fracture density and high surface area, perlite is ideal for simultaneously holding water and air pockets. This dual ability of aeration and water retention is necessary for plant roots to function properly. Even when wet, a perlite–peat mixture weighs about four times less than wet sand, so the perlite is easier to handle and much less expensive to ship. Economic deposits of perlite are found in California, Nevada, and New Mexico in the United States as well as in Russia and Greece.

#### B. Cinder

Mining of cinder cones for loose aggregate is common in central Europe, the southeastern United States, and Japan. In the United States alone, ca. 1.5 tons of aggregate per person per year are used. Cinders are primarily used in the fabrication of concrete and cinder blocks. This was also one of earliest industrial uses of volcanic aggregates, developed by the Romans, who had convenient sources of many types of volcanic products from the nearby volcanoes (e.g., Colli Albani near Rome and Vesuvius near Naples).

Today, aggregates are still an important resource. It is inconceivable to think of modern construction without the use of concrete or pressed cinder blocks.

In the construction of roads, a flexible bed of high strength, with good insulating properties is important to build a long-lasting roadway. Volcanic cinders are ideal for this purpose. The irregular surface allows particles to stick together, providing high angles of internal friction (up to 45°). The insulating properties ensure that the ground beneath the roadway is protected from extreme temperatures, and the associated deformation. In Alaska road beds like these are sometimes used to minimize the effect of annual frost heave and permafrost on roads. In addition to the thermal insulation, cinders provide a sound insulation as well, and individual vesicles can act as tiny cushions, absorbing vibrations.

Cinder can also hold water in open vesicles, or in the pore space between aggregates. It is often used to hold water around plants. In addition, cinder sorted to specific sizes becomes an effective barrier for tunneling pests, such as termites. The material is too well anchored to be moved, and large enough that a termite cannot grasp or carry each particle. The cinders are too strong to be broken, are resistant to weathering, yet are small

enough and so closely packed that the termite cannot fit between individual particles.

### C. Refractories

Refractories are materials that are not deformed or damaged by high temperatures, thus they are used to make firebricks, crucibles, insulation, furnace linings, and furnaces themselves for metallurgy and glass making. Pumice and clays are sometimes ingredients of refractories, and bentonite is used as a binder during production. Ignimbrites or welded tuffs can be cut into bricks and are used directly as refractories.

---

## VII. CONSTRUCTION

Volcanic stone has been used worldwide due to its stability, strength, coloring, availability, and resistance to weathering. Its uses vary from simple garden walls to baroque cathedrals to modern skyscrapers.

### A. Massive Stones

Massive volcanic stone provides a good building material because lavas and ignimbrites have high strengths and good insulating qualities. Such stone has been used throughout Europe and Britain for monuments and churches. One of the best examples of this is the Cologne Cathedral (Fig. 6), which is composed of 12 different types of stone, over 300,000 tons, more than half of which are volcanic, derived from the nearby Eifel Volcanic Field in central Germany. As with aggregate, a significant cost of this building material is its transport, and thus local sources are often preferred over imported materials. Lavas tend to dominate the use of massive volcanic rocks in construction, though less resistant rocks have also been used. In the past, ignimbrites were much easier to cut and shape but are more susceptible to weathering. As the science of masonry has progressed, harder and more resistant stone could be just as easily shaped or fabricated. In the case of the Cologne Cathedral, many of the older stones were made of more malleable softer rock and are now being replaced with harder, more massive stone (e.g., basalt).

Volcanic material is also ideal for use in monuments, markers, or gravestones. This is the most common use

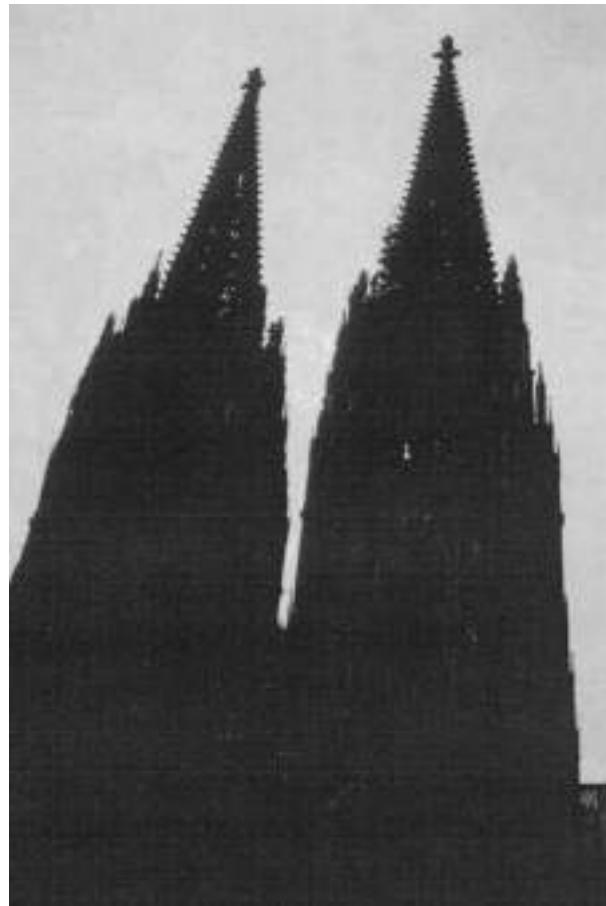

FIGURE 6 The imposing dark spires of the Cologne Cathedral. Over 100,000 tons of volcanic rock was used along with other materials in its construction, which lasted over 700 years. Most of the material was derived from the nearby Eifel Volcanic Field. Volcanic stone was often used during the Middle Ages, not only because it was local and easily acquired but also because it was resilient, and the dark colors were very imposing.

of volcanic rock throughout Asia. In Japan, one of the most volcanically active countries in the world, lanterns, sign posts, carved idols and icons are typically made from one of the many volcanic stones of the region (Fig. 7). Often the dark colors of volcanic rock provide a somber presentation, appropriate for many religious ceremonies.

Larger-scale construction projects in Japan are seldom made of stone because these buildings tend to fracture and collapse in this earthquake-prone region. Strict regulations are imposed to ensure that the supporting frame of a building is made of a more flexible material (e.g., wood or steel). Today, even with improved con-

**FIGURE 7** Lanterns at a temple in Kyoto, Japan. These were created using local andesite. Volcanic rocks are often used in monuments and idols.

struction techniques, the use of massive volcanic stone is limited to tiles, steps, sidewalks, and facades.

### B. Concrete and Cinder Blocks

Concrete is one of the oldest uses of volcanic products and was originally developed by the Romans as a non-water-soluble alternative to the gypsum-based mortar used by the Egyptians. Primarily developed to tile and seal the aqueducts, this strong new material was used in many of the classic Roman structures, a number of which are still standing today. The precise technique used by the Romans is still a mystery, and modern concrete has not yet achieved the durability shown by these early structures. Although concrete can be made from any aggregate material, volcanic aggregate provides enhanced strength and insulation, making it a preferred material.

Today pumice and cinders are used in creating concrete prefabricated parts for buildings. In addition to its strength and insulation characteristics, pumice concrete can withstand flexure better than its counterparts. Although it has limited flexibility, it has a small coefficient of thermal expansion, and when reinforced, it can withstand significant thermal shock, as in the case of a fire. For example, when heated to 1000°C, a temperature where a metal door or window frames would melt, and then suddenly quenched with cold water, pumice concrete shows little or no damage whereas concrete made of nonvolcanic material rapidly and severely fractures.

This difference is the result of the very small coefficient of thermal expansion of volcanic material. Buildings made of pumice concrete or cinder blocks are less likely to collapse when on fire than buildings made with limestone concrete or even steel.

This material also has the advantage of weighing less than normal aggregates or massive blocks. When shear strength is not the dominant factor in the design of a building, a lightweight concrete is a good low-cost alternative.

### C. Tunneling

Soft volcanic rocks, such as ignimbrites have often been used for tunneling, for storage, and for housing. Examples of this can be found in Japan, Ischia, Herculaneum, and New Guinea (Fig. 4). In Japan, the soft volcanic clastics, which were formed submarine and are now sub-aerial, are tunneled for roads, although there is often a danger of collapse because these rocks are porous and have low strengths, only a little stronger than loose aggregate material. In the winter, water trapped in the rock freezes and expands and can cause fatal tunnel collapses like the one in the Fall of 1995 on Japan's northern island Hokkaido.

### D. Mining

Sulfur is the ninth most abundant element in the universe and one of the four most basic chemical commodi-

ties. The chief sources of free sulfur are volcanoes, fumaroles, and certain sedimentary deposits. Sulfur occurs naturally in several forms, of which rhombic sulfur is the most common at volcanoes (often as flowers of sulfur).

Important compounds of sulfur include hydrogen sulfide ( $H_2S$ ), which has the familiar rotten egg smell, and is used extensively in chemical plants and laboratories as an analytical agent. Sulfur dioxide ( $SO_2$ ) is a precursor of sulfuric acid; it is also used as a bleach and as an industrial reducing agent. In small amounts, sulfur dioxide is used as a food preservative and to aid the ripening of fruits. Sulfur dichloride ( $S_2Cl_2$ ) is used in the manufacture of chemical products such as lubricants and mustard gas. Sulfur hexafluoride ( $SF_6$ ) is used as an insulator in many electrical devices. Sulfurous acid ( $H_2SO_3$ ) forms the salt sodium sulfite ( $Na_2SO_3$ ) which is used in the manufacture of paper pulp, in photography, and in removing oxygen from boiler feedwater. Sulfuric acid ( $H_2SO_4$ ) is used in the manufacture of explosives, detergents, dyes, drugs, pigments, fertilizers, and many inorganic compounds. Synthetic organic sulfur compounds are components of pharmaceuticals, insecticides, and solvents and are also used to help vulcanize rubber and to produce rayon.

The first recorded therapeutic use of sulfur was by Philippus Aureolus Theophrastus, Bombast of Hohenheim, in the late 15th century, not only as a bath additive but also in various compounds taken internally to relieve minor ailments.

### VIII. DECORATIVE USES

Volcanic rocks are often aesthetically pleasing and can take many forms. Minerals in the rocks can often reach sizes useful for decorative purposes and can even be used as precious or semiprecious stones. Volcanic products can supply the materials used to create works of art, such as decorative pottery (Fig. 3).

Polished banded rhyolites, or basalts, are commonly used as veneer for countertops, walkways, or stair steps and facades for buildings. In some cases, volcanic rocks are exported for this purpose from famous localities, such as the Clermont-Ferrand region of France.

Volcanic rocks often yield semiprecious stones. Olivines are common in basalts, as are pyroxenes. Even more exotic minerals can be found in lavas (e.g., hauyne, a rare pyroxene mineral, in the trachytes of central Germany and topaz in rhyolites of the southwestern United States and Mexico).

Over time, volcanic ash weathers into fine clays which

FIGURE 8 An ash tray made from lava at Mount Etna. In perhaps the most direct use of red hot lava, the still molten rock is scooped up and placed into a mold and squeezed immediately. The ash trays are then set aside to cool and are ready for sale a few hours later.

are preferred for delicate pottery in Japan. The fresh glass can be used as glaze due to its low melting temperature. Decorative uses of volcanic rocks can be more coarse; different colored cinders are often used in gardens or in more elaborate arrangements such as in Japanese rock gardens. Fresh lava is pliable, and local vendors in Italy gather the fresh lava and create souvenirs for tourists (Fig. 8). This is the most direct use of lava known to us.

### IX. CONCLUSIONS

Volcanic raw materials have been used by man throughout history. The oldest uses relied on the fact that volcanic rocks were plentiful locally and were easy to fashion into tools, such as the shaping of obsidian arrowheads. Modern uses include those for which volcanic rocks are a local source of aggregate, such as road beds, but also a variety of new specialty uses. For example, most uses of bentonite were developed in the last 100 years, and perlite has been exploited only since the 1950s. Volcanic rocks have some unusual properties, particularly density and thermal conductivity, so it is likely that new uses will continue to be found. These materials may have uses in combination with reinforced platinum, carbon fibers, or other new products to make unique composite materials for construction.

Volcanic eruptions occur at more or less steady rates on a global scale, thus there will always be replenishment

of volcanic raw materials from new eruptions. Therefore, in addition to the excitement, awe, and scientific value of eruptions, in a very substantial way volcanoes will continue to contribute raw materials to sustain the industrial needs of modern life.

## I. INTRODUCTION

Volcanic regions have increasingly become major destinations for tourism. People visit volcanoes for a variety of reasons, the major one probably being the fascination of being close to nature's power. When we discuss volcanoes as benefactors, we usually focus on their energy and mineral resources. However, another major economic resource that stems from volcanoes is tourism; it is in fact the largest resource in some volcanic areas and certainly one with the greatest economic potential worldwide.

Active volcanoes have long attracted visitors. In the 17th and 18th centuries, the northern European aristocracy visited Vesuvius and Etna as part of the Grand Tour. Today, people from all social classes visit volcanic regions for their scenery and for their educational, ecological, and adventurous aspects. Some of the world's most visited volcanoes highlight the reasons why people

choose them for tourism. The thrill of seeing a live volcanic eruption draws millions of people every year to Kilauea in Hawaii, Stromboli in Italy, and Arenal in Costa Rica. History and archeology, and the fascination always present in "lost cities," attract visitors to Vesuvius and Santorini. The educational aspects of volcanoes in terms of their role in nature and society are a major attraction of volcanoes in national parks, such as Mount St. Helens and Yellowstone. Interest in ecology brings millions to see Costa Rica's volcanoes in the rainforest, the Galapagos volcanic islands, and the Virunga Mountains in eastern Zaire. Some volcanoes are popular mainly for their magnificent scenery. Crater Lake is a prime example; others include the Lake Myvatn area in Iceland and the Canaries and Azores Islands. People also visit volcanoes simply because they are mountains to climb or ski. Rainier, Kilimanjaro, and Cotopaxi are among the world's favorite volcanoes to climb, and the slopes of Mauna Kea and Etna have become well-known ski areas. Volcanic hot springs and spas cash in on their supposedly medicinal aspects. In the 18th century, Sir William Hamilton used to ride from Naples to La Solfatara for baths, today the mudbaths in nearby Ischia and Vulcano in the Aeolian Islands fulfill the needs of those seeking cures and restoration.

The development of volcano tourism has mirrored that of general western tourism, which evolved from a minority activity of the Elite in the 18th century to the mass participation industry of today. This change has

been one of the most significant social phenomena of the past 200 years and of the postwar era in particular. Travel is now considered a basic human right—it makes the quality of life better—and the right to travel has become part of political freedom. A global tourism boom is one of the major characteristics of the economy of the last decade of the 20th century, and it is likely to continue into the next millennium. Spending on travel now accounts for 10% of the world's annual economic growth and is expected to increase in the next two decades. Today, the number of trips for tourism is estimated to be 6 billion per year, and the number of tourists is growing faster than the populations of many of the countries they visit or come from. International tourism arrivals, just one barometer of this phenomenon, have risen from just 25 million in 1950 to 287 million in 1979 and to 595 million in 1996. In 2020, this number is expected to be 1.6 billion. The increase has been made possible because of economic and social factors, as well as technological advances in modes of transportation. Long-haul flights on large-capacity airplanes are a major factor in the increase of far-away tourism. In recent years, the Internet has proved to be a tremendous boost to tourism, as more and more people browse home pages of foreign tourism authorities, electronic encyclopedias, and other information resources before they book their travel, often electronically.

One of the main manifestations of the increase in the number of tourists worldwide is their impact on local societies and cultures. Although tourism has considerably helped the economies of many countries, to the point of becoming the major industry in several, it has also been destructive, both to culture and environment. Despite—or perhaps because of—the fact that eco-tourism is now one of the fastest growing sectors of the travel industry, mass international tourism has been very damaging to natural settings, including some of the world's most beautiful volcanic regions. Fortunately, many nations are waking up to this fact in time to save their land and heritage.

Another manifestation of mass tourism has been an increase in the diversity of places visited, and the types of activity pursued by tourists. The last two decades of the 20th century have seen a trend toward adventure travel, eco-tourism, and far away destinations. The focus of global tourism destinations has recently shifted from Europe toward East Asia and the Pacific region. Although Vesuvius and Etna continue to draw visitors from all over the world, lesser known volcanoes everywhere are becoming increasingly popular.

## II. HISTORY OF TOURISM

The history of tourism is not well known, but the Romans, for example, besides extensive and well-documented military tourism, used island locations such as Ischia and Capri for leisure and recreation purposes. Some pilgrimages and crusades may also be considered a form of tourism, such as described in Chaucer's *The Canterbury Tales*. It was in Europe, particularly in Great Britain, that the tourist industry was invented, refined, and developed as the Grand Tour—a socially acceptable way of sowing wild oats, of letting off steam for the young, well educated, and wealthy. The Grand Tour had its origins among the British aristocracy in the 16th century but increased dramatically in the 1760s. It became so popular that in 1749 Thomas Nugent published *Grand Tour*, the first guidebook to European travel.

Italy was the heart of the Grand Tour. As Samuel Johnson stated, "A man who has not been in Italy, is always conscious of an inferiority, from his not having seen what it is expected a man should see." A "must" in Italy was Naples, with excursions to the archaeological excavations of Pompeii and Herculaneum, begun in 1755 and 1738, respectively. The more adventurous also climbed Vesuvius to see the fireworks up close. Many aristocrats, including the German poet-geologist Goethe, enjoyed the local hospitality of the near-legendary Sir William Hamilton, the British Ambassador in Naples (Fig. 1).

The Grand Tour was originally a selective, primarily aristocratic prerogative, providing a classical educational journey from Britain to France, Italy, Switzerland, Germany, and the Low Countries. The original conception of the Grand Tour and its related journeying to fashionable resorts and spas during the 18th century was very much an extension of the normal pattern of aristocratic living. This is reflected in the employment structure that existed at that time to support this form of travel. Essentially, the rich and well-bred traveled with all or part of their normal retinue of servants. The fundamental principle of social distance between tourists and those providing service was established through early tourist travel of this nature and then widely adopted in the mass expansion of international travel.

The origins of modern mass tourism can be traced to rather more recent European development. The popularization of travel came, not surprisingly, with industrialization and the growth of increasingly leisured middle classes. It also benefited greatly from enhanced

**FIGURE 1** Eighteenth century print of the excavation of the Roman city of Herculaneum, buried in volcanic ash by the A.D. 79 Vesuvius eruption. The excavations and the volcano were an important stop on the Grand Tour of the northern European aristocracy—marking the first step in volcano tourism (author's collection).

transportation, particularly the growth of the railways. Indeed, changes in the nature of travel, transportation, and, most importantly, those participating in travel meant that the average length of the Grand Tour fell from 40 months in the mid-17th century to just 4 months in 1830, the dawn of the railway era. By that time, some 150,000 Britons a year were visiting Europe. The great leap forward in European tourism was made by Thomas Cook, who started tours for the masses in England in 1841 and on the Continent in 1855, marking the beginning of public tourism (Whitey 1997). Cook was certainly aware of the attraction of volcanoes for tourists. The first Cook party to Pompeii and Vesuvius volcano arrived in 1864 and aroused the wrath of the British resident bourgeoisie, who resented this intrusion of strangers (Fig. 2).

Cook's strangest acquisition was the Vesuvius Railway. The railway took tourists up the volcano, but it presented serious competition to the local Italian men who had earned a living by carrying people to the top in sedan chairs and who saw the railway as a threat to their livelihood. Cook had to be firm with saboteurs when he took over the operation of the railway, but he made it safe enough for even King Edward VII to travel on (Fig. 3). The local men had demanded that every passenger carried on the railway should pay tax in compensation, and the original owners of the railway had

agreed to this. Cook refused to give way to what he considered extortionate blackmail. The Vesuvius porters then damaged the railway, throwing the carriages down the volcano and setting fire to the station. Cook then kept his customers away from the volcano until he succeeded in convincing the local brigands that if they allowed the railway to operate peacefully, they would profit in other ways from the tourists who traveled on it. The funicular railway was destroyed three times by lavas, and it was not rebuilt after the damage suffered from the eruption of 1944. In its place a chairlift was constructed to carry tourists up to the crater rim, but it is now no longer operating. Visitors today have no alternative but to walk to the crater rim.

At the turn of the last century, the consummate volcano tourist was the Englishman Tempest Anderson, an accomplished photographer and amateur volcanologist, who chose this activity of leisure because it "had the advantage of offering exercise in the open air, and in districts often remote and picturesque." For two decades he spent his holidays in exploring volcanic regions, including Vesuvius, Etna, Lipari Isles, Auvergne, Eifel, Canaries, and Iceland, as well as numerous volcanoes of the Cascades and Yellowstone. In May 1902, when the Soufriere of St. Vincent and Mont Pelee erupted in the Lesser Antilles, Anderson was quickly on the spot with his camera. He gave illustrated lectures about his jour-

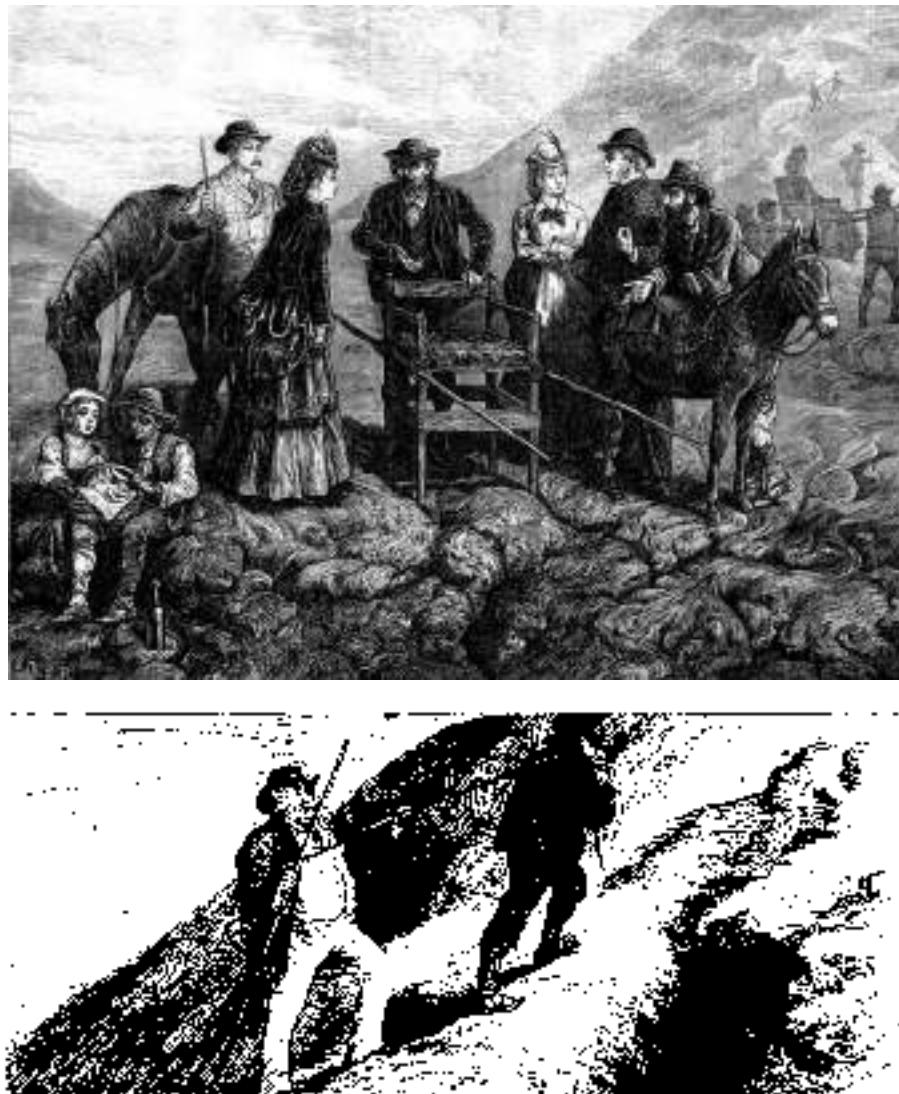

FIGURE 2 Nineteenth century tourists visiting Vesuvius had three choices. Either they could walk, be carried to the crater rim in a chair (top), or be dragged up on a rope by the Neapolitan porters (bottom). Woodcuts from *The Illustrated London News*, 1872.

neys at the British Association and the Royal Society; he also published his work, including an influential and widely admired volume with 105 full-page photographs of volcanic features (Anderson 1903).

### III. VOLCANOES AND NATIONAL PARKS

Many volcanic regions throughout the world have now been set aside or protected by their designation as na-

tional parks. Shortly after the spectacular geologic and natural wonders of the Yellowstone caldera had been described in the report of the Hayden expedition, the U.S. Congress passed a bill in 1872 that designated over 3000 square miles of land to establish the Yellowstone National Park, the first park of its type in the nation—and in the world (Fig. 4).

The unique qualities of the Cascades volcanic range were also recognized by Congress and four national parks were established. The first to be created was Crater Lake National Park, established in 1902, to preserve the spectacular caldera, its unique lake, and the surrounding environment. Crater Lake was discovered quite by acci-

**FIGURE 3** In 1880 the Thomas Cook company opened the Funicolare railway to the top of the Vesuvius cone. It was an event that transformed tourism to Vesuvius and put many of the volcano's guides out of work. But many felt that this application of industrial advance had "robbed the mountain of its poetry." The funicular was destroyed three times by lava flows; it was not rebuilt after the 1944 eruption.

dent by a prospector, John Wesley Hillman, in 1835. The creation of Crater Lake National Park happened largely due to the efforts of Judge William Gladstone Steel, who had read about the mysterious lake when he was a boy and vowed that he would find it one day. He finally did, in 1885, after 13 years of searching. Upon looking at the magnificent landscape for the first time, he decided that it must be protected and preserved. Judge Steel was appointed the Park's Superintendent in 1913, and it was he who first put fish into the lake—by hiking nearly 50 miles carrying minnows from the Rogue River.

Other national parks were established in the Cascades, including Lassen National Park in 1916, while the Mount Lassen volcano was still erupting. It includes vast hydrothermal areas and a dozen other smaller volcanoes such as Chaos Crags and Cinder Cone. The creation of Mount St. Helens National Monument was also prompted by an eruption, the cataclysmic event of 1980 that vastly changed the landscape. The desire to preserve a unique volcanic landscape was also behind the creation of Sunset Crater National Monument in Arizona. In 1928, a Hollywood film company planned to dynamite part of the crater to simulate an eruption. Angry protests

from local groups put a stop to this outrageous plan and eventually led President Hoover to declare Sunset Crater a national monument in 1930.

Although the United States still leads the world in the range and quality of national parks in volcanic areas, many other countries are following its example. Developed countries, in general, are careful to protect their more spectacular volcanic regions, and the last two decades have seen a significant increase in the number of national parks. Many developing countries have followed their example, despite their considerably more limited resources. In the Americas, Costa Rica is a leading example, with 25% of the country's land—including several of its volcanoes—now protected as national parks and forest reserves. Ecuador also preserves many of its fantastic volcanic regions as national parks, including the Galapagos Islands and Cotopaxi. Chile and Argentina have also established national parks to protect its Andean volcanoes such as Villarica, and Colombia's notorious Nevado del Ruiz is within Los Nevados National Park. Many volcanoes in Africa are now also protected as national parks, particularly those in the Great Rift Valley. Indonesia has a long tradition of wildlife reserves and preservation areas; the first reserve, in Sumatra, was

**FIGURE 4** A 19th century etching of Old Faithful erupting, the centerpiece of Yellowstone National Park, and a major lure for tourists (author's collection).

set up in A.D. 684 by the King of Srivijaya. More recently, in 1982, Bali hosted the third International Parks conference, during which the Indonesian government announced the creation of ten new national parks.

National parks fulfill one of the most important roles in volcano tourism—education. Learning about the world has always been one of the major factors driving tourism. Volcanoes are a fascinating topic to people of all ages and volcano national parks are ideal places to learn about how volcanoes work, particularly if there are well-laid out trails and displays in museums on site. Hawaii Volcano National Park, established in 1916, is undoubtedly one of the world's most educational national parks. The park preserves a large fraction of Mauna Loa and most of Kilauea, two of the world's most active volcanoes. Thanks largely to the existence of the park, Kilauea has become the world's most visited and most photographed volcano. The Thomas A. Jaggar Museum within the park has been open since 1987 and

attracts 3000 to 5000 visitors per day. Although small, it is a very informative museum, with displays that include a volcanologist's partly melted boots and a portable seismograph that visitors delight in jumping next to, producing their own earthquakes. The park's major contribution to education, however, is in the numerous well-laid out trails and stop-over viewpoints for those who prefer to drive. A large number of plaques with explanations about what the visitor is seeing are dotted at points of interest along the trails and roads. The spectacular scenery and frequent eruptions contribute to the public's enthusiasm about these volcanoes. Most other volcano national parks in the United States are highly educational, but parks in other countries, particularly in poorer areas, often lack the resources to educate visitors. However, the fact that a national park exists at all in many of these countries, protecting and preserving volcanic and other regions for the future, is truly commendable.

#### IV. WHAT VOLCANOES HAVE TO OFFER TO TOURISTS

##### A. Scenery

Some volcanoes are so visually spectacular that this alone makes them major tourism destinations. Perhaps the best known example is Crater Lake, which is thought to have one of the most beautiful blue colors of nature. Surrounded by forests and volcanic peaks, the lake lies inside the caldera of Mount Mazama. A cataclysmic eruption about 7700 years ago destroyed the top of the mountain and eventually water from rain and snow filled the caldera, forming the 6-mile wide lake. The lake's depth (1932 feet) makes it the deepest lake in the United States. Inside the lake is the small Wizard Island. The purity of the water and the great depth of the caldera are responsible for the startling indigo blue. Because it is a closed system, it is devoid of vegetation and until fish were introduced some 60 years ago, it was also free of aquatic life.

Haleakala in Hawaii is another leading example of spectacular volcanic scenery. The vast summit crater ( $49 \text{ km}^2$ ) is a breathtaking sight that many visitors compare to the Grand Canyon. Haleakala crater is indeed an impressive geologic wonder, with walls that plunge down up to a kilometer and enclose a barren but colorful landscape. The crater floor is covered with ash deposits in hues of gray, red, brown, and russet, broken up here

and there by steep cinder cones and dark lava flows. The crater, like the Grand Canyon, was enlarged by erosion.

The most spectacular sight offered by this volcano is sunrise. Haleakala means House of the Sun in Hawaiian and legends say that the island used to receive only a few hours of sunlight a day until the demi-god Maui snared the sun's rays with a lasso made of vines. To be released, La, the Sun, had to promise to travel very slowly across the sky. Many visitors today make the trip to the summit in darkness to watch the spectacular sunrise, when it seems that La is indeed keeping his word. Mark Twain described the sunrise over Haleakala as "the sublimest spectacle I ever witnessed, and I think the memory of it will remain with me always".

Other volcanic regions that attract tourists mainly because of their spectacular scenery include the Canary Islands, the Azores, the Lake Myvatn area in Iceland, and Soufriere volcano in St. Vincent.

## B. The Spectacle of Volcanic Activity

Volcanic eruptions are one of nature's most awesome spectacles. An active volcano can create a major economic boom for a region, or else it can destroy the local economy and infrastructure. From a tourism point of view, the best types of volcanic activity are long-lived Hawaiian or Strombolian eruptions. These types of eruptions allow tourists to see the activity at reasonably close range in relative safety. If the eruption lasts for months or years, the local economy can truly prosper from the sustained number of visitors. However, other factors—notably accessibility—are important for turning an active volcano into a major tourist destination. Stromboli, continuously active for over 2000 years, can be considered the world's top destination for those who want to see a live volcano, but its remote location makes it far less popular than many other volcanic regions around the world. Travel to Stromboli island is only possible by boat, and because rough winter weather can disrupt services, the bulk of the tourism is restricted to the summer months. Yasur in Vanuatu is another example of a volcano that sustains long-lived Strombolian activity, but it does not attract large number of visitors because of its remoteness.

Two of the most popular active volcanoes in the world today are Kilauea and Arenal. Kilauea has attracted tourists since the early 20th century, when a lava lake filled Halemaumau crater. A hotel, Volcano House, was built in 1846 on the edge of Kilauea caldera, with full view of Halemaumau, and counted Mark Twain and Robert

Louis Stevenson among its distinguished guests. Although Halemaumau is no longer active, Kilauea has continued to erupt often and spectacularly. The present Pu'u O'o-Kupaianaha eruption, which started in 1983, is the longest on record in Hawaii. The sustained activity has been a boom for local tourism and has spawned businesses ranging from new hotels to helicopter tours. Even when the eruption stops, Kilauea should continue to be one of the world's most popular volcanoes, because of its accessibility—one can drive right up to the edge of the caldera and to many other attractions—and because of the well-laid out trails within the national park.

Costa Rica's Arenal was not known to be an active volcano until its present eruption started in 1968. Before that, a few visitors came to climb to the main crater, which was home to thousands of finches. The current eruption has contributed to making Arenal and its surrounding area into one of the most popular destinations in the country. The volcano and its environs have recently become part of a national park. The Laguna Arenal, an artificial lake, has become a major recreation area, and new hotels and lodges with views of the volcano continue to be built. Although considerably more dangerous than Kilauea, Arenal's eruption can be watched in safety from a number of vantage points around the volcano, including the well-known Arenal Observatory Lodge. Many visitors stay up all night watching the red lava flows slowly come down the volcano's steep flanks. Only a few dare to make the dangerous climb to the summit, and at present only one guide is willing to make the journey.

Volcanic eruptions invariably change the tourism potential of a region. Although the mild current activity of Kilauea and Arenal attract visitors, violent eruptions can completely destroy the tourism infrastructure of a region. Often, however, the aftermath of a violent eruption will bring visitors back. Perhaps the best recent example is Mount St. Helens. Before the 1980 eruption, visitors were attracted to Spirit Lake and its magnificent setting. When the lake and its surrounding forests were destroyed, and the once alpine-looking landscape became bare and gray, it seemed that tourism in the area would not recover. Many people, however, wanted to come to see the eruption's effects and the new lunar-like landscape became a major attraction. In fact, the eruption has brought a steady stream of visitors and has made the area considerably more popular than it was before 1980. A landmark event was the creation of the Mount St. Helens National Monument in 1982. In 1993, the Coldwater Ridge was opened and during that year alone received about 1 million visitors. It offers exhibits and lectures about the volcano, its eruption, and the

gradual return of life to the devastated areas. Coldwater Ridge is still popular, but now it is only one of the four visitors' centers devoted to St. Helens. The boom in tourism is evident from facilities such as a local IMAX theater that shows movies about volcanoes and from the helicopter tours that are now available to visitors. The climb to the crater rim, from where one can see the impressive dome growing inside the gaping crater, has become one of the most popular in the Cascades.

### C. Hot Springs and Spas

Volcanic hot springs have long been thought to have health benefits. Long after the days of Sir William Hamilton's visits to La Solfatara, visitors still come to southern Italy to seek cures in the natural hot springs of Ischia and Vulcano. Ischia's spas are popular with day-trippers from Naples, while Vulcano, further away in the Aeolian Islands, is crowded every summer with about 10,000 visitors. Many of them visit the famous Laghetto di Fungi (the mudbaths) and afterwards take a dip in the ocean at the nearby Acqua Calda (hot water) beach. Hot springs bubble through the sand, making the seawater above feel like a natural jacuzzi.

Many other volcanic areas offer tourists the experience of volcanic hot springs and, sometimes, luxurious spas to take full advantage of the natural phenomenon. Hot springs in Japan are fully utilized by both locals and visitors for traditional communal bathing. Tourism from hot springs is the main source of income for the small city of Beppu, located on the Inland Sea. Beppu attracts some 12 million visitors every year from both Japan and abroad, thanks to its 4000 hot springs that were created by the A.D. 867 eruption of the now-dormant Mount Tsurumi.

In Iceland, an entire tourist and spa industry has built up around the hot springs in the town of Hveragerdi and a similar development is occurring at the Blue Lagoon, where the hot waters are reputed to have various therapeutic properties.

A particularly interesting area of volcanic hot springs is Tabacon near Arenal volcano in Costa Rica. The waters of the Tabacon River are heated by the active Arenal and, in the past few years, a lavish resort has been and has become very popular with visitors. The resort offers more than just hot springs: visitors can view Arenal's activity while wallowing in the pools and have the dubious pleasure of knowing that they are actually inside one of the most hazardous zones around the volcano devastated in the 1976 eruption.

### D. Climbing and Skiing on Volcanoes

High volcanoes are an irresistible lure for many climbers. Unlike the craggy peaks of the Himalayas or the Rockies, however, they normally only present two major difficulties—the altitude and the weather—apart from the occasional eruption. There are virtually hundreds of high, ice-covered volcanic peaks that present a challenge to the climber and will become increasingly more popular as targets for adventurous tourists in the future. Only a few of the more popular ones are discussed here.

Mountaineering on volcanoes began with the spectacular expedition of the English medical doctor Edward Whymper to Ecuador in 1880, where he climbed ten volcanic peaks, including the 6900 m high Chimborazo and the 6500 m Cotopaxi (Whymper 1987). He and his companions climbed Chimborazo from the southwest ridge, setting up several camps, but suffered from mountain sickness. As they approached the summit on the final assault, they became bogged down in exceedingly soft and thick snow, but managed to complete the ascent and return to camp in the dark after a 16-hour heroic effort. Whymper and his companions found, on the other hand, that the ascent of majestic Cotopaxi "was a walk," but when they crawled out to the very edge of the crater, they looked down into a deep and raging inferno of molten lava, steam, and volcanic gases (Fig. 5).

In Mexico there are several major ice-covered volcanoes that are popular targets for climbers. The lowest of these is Nevado de Colima in the west (4450 m), with a nearly continuously active crater of Volcan de Colima on its south flank. The highest volcano in Mexico is the 5700 m high El Pico de Orizaba (Citlaltepetl), at the eastern end of the range of volcanoes. In intermediate position are the famous volcanic peaks of Popocatepetl (5452 m) and Iztaccihuatl (5286 m), also known simply as Popo and Ixta. These volcanoes present a great attraction, as they allow climbers to experience high altitude with relatively modest expense, time, and equipment needs (other than ice ax, crampons, and rope) and with minimal technical difficulties. As pointed out by Secor (1981), the principal difficulties associated with these climbs may not be the ascent or descent, but rather the approach to the volcano. The remote roads are often in very poor condition and unmarked.

El Pico de Orizaba is Mexico's most majestic and highest volcano (5700 m). Located within about 100 km of the Gulf of Mexico coast, it is due west of the city of Veracruz. The usual approach to this volcano is from the village of Tlachichuca on the northwest side and then by four-wheel drive over a rough dirt road to the Piedra Grande rustic mountain hut at 4230 m on the

**FIGURE 5** Edward Whymper was the first mountaineer to scale volcanoes, including Cotopaxi and Chimborazo in the Andes of Ecuador. When he crawled to the very edge of the Cotopaxi crater in 1880, he looked down into a deep and raging inferno (Whymper 1987).

north flank. From here, the standard climbing route up the mountain is the Glaciar de Jamapa, typically a 6- to 9-hours ascent. However, some climbers set up a camp at the 4900 m level, before pushing on to the summit. From the edge of the Glaciar de Jamapa, the climb requires roping up, and the use of crampons and ice axes to the summit. The magnificent views include the Gulf of Mexico to the east and the volcanoes Popo and Ixta to the west. Climbing and hiking around Pico has the great advantage that the mountain is not surrounded by urban sprawl but is relatively remote. Many of the villages on its flanks can only be reached by footpaths.

The Popo-Ixta National Park contains two of the most famous volcanoes of Mexico. As it is within only 80 km of Mexico City, it is a very popular and busy area, but there is ample space here for climbers to strike out on spectacular trails and ascents (Secor 1981). Interest in Popocatepetl (5452 m) has of course been height-

ened greatly since the beginning of its current volcanic crisis, but access to the upper flanks has of necessity been restricted while the conditions remain hazardous. Meanwhile, Iztaccihuatl (5286 m) is accessible to all. The normal starting place for visitors to both volcanoes is the town of Amecameca to the west of the volcanoes, and from here good roads lead to Tlamacas mountain lodges on the north slope of Popo, and La Joya on the south slope of Ixta. The most popular route up Popo is Las Cruces, which has been done successfully even by burros and dogs—an ascent of five to eight hours. Above the Las Cruces hut (4480 m), ice axes and crampons are generally required for ascending the 30° slope to the crater rim above. The summit crater is the main attraction, with spectacular near-vertical walls, steaming fumaroles and nearly-suffocating sulfur fumes. Ixta, the seventh highest peak in North America, is generally approached from La Joya trailhead at 4000 m, on the south side of the volcano. The standard route is La Arista del Sol, with Popo to one's back and Pico to the east. It is a two-day climb for most people, and huts are available en route for spending the night. The ascent is about seven hours from the huts.

Nevado de Toluca (4704 m) is Mexico's fourth highest mountain, but is unique in that one can drive right into the crater of this extinct volcano, only about 30 km south of the city of Toluca. The ice-bound crater rim rises another 500 m above the crater lake, and ice axes, crampons, ropes and other suitable climbing gear is required for the final ascent.

The summit of the extinct Nevado de Colima can normally be approached by a dirt road north from the village of Atenquique, that leads to a microwave station at the 4000-m elevation; from here, the snow-clad summit at 4450 m is a mere scramble. Its smaller but very active neighbor Volcan de Colima is reached by a dirt road heading west from Atenquique, and this track will carry the climber most of the way to the slopes of the active crater, depending on weather. However, it is an active volcano, with frequent eruptions, and ascent up the loose pumice-covered slopes to the crater rim should not be attempted because of danger from explosions that can occur without warning.

One of the world's best known volcanoes among climbers is Kilimanjaro in Tanzania. Although located only 3° from the equator, this dormant volcano is capped by a glacier. It consists of three major peaks—Shira, Mawenzi and the most recently active Kibo (5895 m), the tallest point on the African continent. There are hundreds of small cinder cones on its slopes. Kilimanjaro is regarded as a 5-day climb.

The second most often climbed snowpeak in the

world—after Fuji—is the 3450 m high Mount Hood volcano in Oregon. It attracts thousands of skiers, climbers, and hikers every year, and they usually congregate in the famed Timberline Lodge. This huge and picturesque log cabin was constructed at the 1800-m level entirely of natural materials, as a public works project in the early part of the 20th century. The volcano can be viewed from many vantage points (e.g., Cloud Cap Saddle), but only experienced climbers should proceed to the summit.

Mount Adams is the second highest peak in the Pacific Northwest (3750 m), but it remains relatively unknown to tourists and little visited. The volcano has a relatively flat and broad summit plateau, and a large, ice-filled crater that is open to the west. Access is relatively difficult, and most climbers start hiking from Cold Springs on the south side of the volcano and then ascend the Suksdorf Ridge to the summit. This climb requires crampons and ice axes.

The earliest known ascent of Mount St. Helens volcano was in 1853 by Thomas J. Dryer, first editor of *The Oregonian*. This climb took place only about a decade after the 1842–1844 volcanic episode and before activity resumed on the north flank in 1857. Access to the volcano improved greatly after a wagon road was built to Spirit Lake in 1901, and climbing Mount St. Helens became a popular pastime in the Northwest. Outdoor clubs from Seattle (The Mountaineers) and Portland (The Mazamas) made regular excursions and climbs of the volcano throughout the 20th century—up to the cataclysmic 1980 eruption. This event reduced the mountain's height from 2950 to 2550 m. Access was restricted for a number of years, due to potential volcanic hazard to climbers. With the establishment of the Mount St. Helens National Monument, the volcano was re-opened to summit climbers in 1987, although they must obtain climbing permits from the U.S. Forest Service and use the south side route up to the crater rim.

The highest among the Cascades, the gleaming and ice-capped Mount Rainier towers at 4450 m above Puget Sound. This national park area is blessed with virgin forest and an unusual abundance of summer wildflowers that carpet its slopes. Because of the carving work of its glaciers, the volcano now has a complex shape. The Rainier National Park is readily accessible from all sides, and it is visited by hundreds of thousands of people every year. Climbing this volcano requires skill, experienced guides, and proper equipment. The fickle and rapidly changing weather is the climber's worst enemy, and sudden fierce storms are common around the summit.

Shasta volcano is attractive to mystics, skiers, and climbers. Skiers will normally drive to the Shasta Ski

Bowl, but at this location, neither the summit of Shasta nor Shastina are visible. Those wishing to climb to the summit will normally proceed to the Sierra Clubs Horse Camp on the volcano's southwest side, at an elevation of 2150 m. The trail leads up through Avalanche Gulch, to a 60m high bank of pumice named the Red Banks, and thence to the 4350 m high summit. Crampons and ropes are required for this climb.

### E. Ecology, Eco-tours, Nature, and Adventure Travel

Ideally, those tourists who explore the Earth do so without trampling down and defacing its fragile nature and practice eco-tourism. Inevitably, eco-tourists are attracted to and avidly seek out the most vulnerable regions, which are off the beaten track and have remained untouched by the regular tourist hordes. Thus the development of eco-tourism may defeat its very goals. In reality, eco-tourism has become a marketing tool, in order to attract visitors to new and hitherto undeveloped regions. Volcanoes are often set in remote, unspoiled locations that become major attractions for this emerging market. In such cases, tourists come mostly to see the flora and fauna, whereas the volcano often takes the role of a secondary attraction. The Galapagos islands, Costa Rica's volcanoes in the rain and cloud forests, and the volcanoes of the Virunga Mountains in Eastern Zaire are all popular with tourists largely because of their ecological appeal.

Many volcanic regions are the targets of modern eco-tourists, and Costa Rica is a prime example of a country where the concept of eco-tourism was proven. Rather than profit from the destruction of rainforests, Costa Ricans chose to use them as a magnet for the emerging eco-tourism market. About 25% of the land is now protected as national parks and forest reserves, some of which are private, bought with charitable donations from all over the world. Many tourists come to see the country's remarkable flora and fauna, which include over 1000 types of orchids and 850 species of birds, but the volcanoes are increasingly gaining in popularity. Volcan Arenal, active since 1968, has become one of Costa Rica's major attractions, and it is now used in the official logo of the country's Tourism Authority.

Although the major attraction of Arenal is its spectacular activity, and of Poas is its crater lake, most visitors take the nature trails which cut through the rainforests around the volcanoes. Toucans, hummingbirds, howler monkeys, and coatis are common sights, and the flora

along the trails include native orchids, ferns, and exotic plants such as bromeliads and *Gunnera insignis*, which the locals call poor man's umbrella because its leaves can be as large as two meters. Costa Rica's more remote volcanoes, notably Turrialba, are becoming more popular with tourists looking for unspoiled locations rich in wildlife.

The Galapagos islands have long been known for their unusual wildlife, which continue to be their main attraction for visitors. Tourism in the Galapagos has become a major source of income for Ecuador and helps to support the islands' conservation and research programs. Although the Galapagos have been protected since the unsettled areas of the islands were declared a national park in 1959, their popularity as a tourist destination has made restrictions necessary. The national park has designated vast areas to be off-limits to anyone except scientific researchers with a good cause. All tours to the islands are led by guides specially trained to follow a system of keeping interference with nature to the minimum possible. The number of visitors to the Galapagos increased from fewer than 10,000 in the 1960s to about 18,000 in the 1970s and is still on the rise.

Among the exotic creatures in the islands are spiky land and marine iguanas, four-eyed fish, flightless cormorants and albatross, and, most of all, the giant land tortoises that gave the islands their name (*Galapago* is Spanish for tortoise). All the Galapagos islands are volcanic in origin and geologically young. Eight of the volcanoes have erupted since the mid-18th century. Among these, Fernandina on the island of the same name, and Volcan Wolf, Sierra Negra, and Cerro Azul in Isabella island erupt frequently. Tourists climb some of the active volcanoes, in particular Alcedo and Cerro Negro in Isabella island, but Fernandina island is off-limits to all but researchers.

The remote volcanoes of Africa's Rift Valley, particularly those of the Virunga range in eastern Zaire, are emerging as a major eco-tourism destination. Most of the Virunga volcanoes are extinct, and their appeal is ecological—they are the natural habitat of the mountain gorillas, which live at altitudes of about 3500 m. The gorillas are naturally shy and elusive, and were discovered by westerners only at the beginning of the 20th century. Captain Oscar von Beringe, the first European to see these forest-dwelling apes, had no hesitation in shooting two of them and, presumably because of this, the apes were named *Gorilla gorilla beringei*. Years later, the animals gained worldwide appeal thanks largely to the movie *Gorillas in the Mist*, based on the story of Diane Fossey. The movie also helped to put the Virunga mountains in the itinerary of many adventure and eco-

tourism tours, even though spotting the gorillas is not easy. The high altitudes, difficult terrain, thick vegetation, and natural shyness of these animals can make the experience frustrating. Most tour groups, led by experience trackers, eventually manage to meet the gorillas, or at least hear their terrifyingly loud yells. The main destination for the gorilla-spotting tours are Karisimbi, which last erupted in the Holocene, and Mount Mikeno, now considered extinct. Other regions of Africa's Rift Valley that are notable for their ecological role include the Ethiopian highlands, habitat of the rare Simien fox, and the soda lakes, such as the much-photographed Lake Nakuru in Kenya, where vast numbers of flamingos come to feed. Close to Mount Lengai volcano is Lake Natron, where Great Flamingos breed, even though the water's high concentration of soda makes it lethal for most other creatures. Mount Kenya volcano, the second highest peak in Africa, is known for its African-Alpine environment, where unique giant lobelias flourish and are pollinated by the colorful scarlet-tufted malachite sunbird. Other volcanoes in the Rift Valley are beginning to attract ecologically oriented tourism, as Africa itself becomes a more popular destination.

Other volcanoes that are emerging as destinations for eco-tourism include Iceland, particularly the Lake Myvatn area, on the outskirts of the Krafla caldera. The lake, which was created when lava flows formed a natural dam in a large river, is the habitat for the largest number of species of ducks in the world, and offers a unique natural environment. This area combines more volcanological and ecological features per square kilometer than any other in the world, with numerous hot springs, fumaroles, eruptive fissures, cinder cones, pseudocraters, maars, calderas, domes, and virtually all imaginable volcanic landforms (Fig. 6).

#### F. Black and Green Sand Beaches

Volcanoes by the sea often offer exotic black sand beaches, though most tourists seeking beaches do not value pulverized volcanic materials as highly as finely powdered coral. The travel magazine *Conde Nast Traveler* described black sand as feeling "like a bed of hot coals—and irregularly shaped grains aren't particularly comfy." The magazine editors chose Ficogrande on the island of Stromboli as the world's best black sand beach. The beach is certainly popular, as most of the 2000 or so tourists that Stromboli hosts each summer spend time on the black sand. Other well-known and long-visited

FIGURE 6 An engraving of the Lake Myvatn area in Iceland, a paradise for tourists interested in both ecology and volcanology. In the background is Hverfjall, a recent maar explosion crater. The lake also has a unique duck population (author's collection).

black sand beaches are found on Santorini—Kamari and Perissa beaches are both made up of black sand and attract many thousands of tourists every year. Other volcanic islands with well-known black sand beaches include St. Vincent (Black Point Beach) and Grenada (Antoine Beach). However, most tourists who have a choice will head for these islands' white sand beaches instead.

Beaches near active volcanoes can prove to be ephemeral. This point was well demonstrated by the famous Kaimu Black Sand Beach on the southeastern shore of Kilauea. This much-photographed spot, a favorite of local surfers, was destroyed by the Pu'u O'o eruption, as was the nearby Kalapana Beach. The same eruption, however, created several replacements, including the half-kilometer long Kamoamoa that was formed between January and April 1988.

A more exotic type of volcanic beach is the green sand beach. These are considerably rarer, although the finely ground olivine feels no better than black sand—according to *Conde Nast Traveler*, the sand is “like finely ground Coke bottles.” However, tourists are attracted to the prime example of a green sand beach—Papakolea in Hawaii’s Big Island—because of its exotic looks. Located near South Point, the green sand is made up of olivine crystals weathered out of a cinder cone. The

original cone was formed about 7700 years ago by the Awawa Kahao eruption of Mauna Loa. Wave action eroded away about half the cone, leaving it open to the sea. Getting to this beach requires some work, as visitors either have to use a 4-wheel drive road or walk about 3 km from South Point. The road ends at an overlook, where most visitors stop. Climbing down onto the narrow beach is not recommended, not only for preservation reasons—this is an extremely rare type of beach—but also because the sea is rough and dangerous.

#### G. Archaeology and Volcanoes

The relationship between anthropology, archaeology and volcanoes reaches way back to the origin of the human race in the Great Rift Valley of Africa. All along the rift, from the Olduvai Gorge in Tanzania in the south, to Hadar in the Afar Triangle in the north, the remains of human ancestors and the earliest humans are intimately associated with volcanism and generally preserved in volcanic deposits. However, it is the excavation of entire cities, buried under volcanic ash in ancient times, that has captured the attention of the tourist and created a steady stream of visitors to Akrotiri, Pompeii, and Herculaneum.

The amazing discovery of Herculaneum and Pompeii on the slopes of Vesuvius in 1738 and 1748, respectively, created a new "must" destination on the Grand Tour of aristocratic northern Europeans. However, great secrecy surrounded the excavations initially, and only certain visitors, mainly through the assistance of Sir William Hamilton, were able to gain admission. Thus the excavations of the lost Roman cities did not become accessible to the general tourist until the late 19th century. Ever since, the tourist has remained amazed at the wonderful preservation of even the smallest and most fragile objects that were embedded in the volcanic ash of Vesuvius in A.D. 79 (Sigurdsson *et al.* 1985). The most sensational discovery was that of the Roman library in the Villa dei Papyri in Herculaneum, containing hundreds of papyrus rolls of ancient Greek texts.

There is no mirror of the past that offers us a more vivid reflection than Pompeii and Herculaneum. Here the visitor walks virtually into history and witnesses innumerable signs of long-arrested activity, with life and death on intimate terms. But they were by no means ordinary cities. The presence of so many fine sculptures, paintings, and mosaics is astonishing to the visitor, as is the grand scale of many of the homes and public buildings. The discovery of these art objects of classical antiquity had an immediate impact on taste and design in 18th-century Europe and, among others, inspired the pottery designs of Josiah Wedgwood in England. The visit of the German scholar Johann Joachim Winckelmann to the Herculaneum excavations in 1758 may be regarded as the birth of archaeology, and it certainly marks the beginning of the study of the history of ancient art. The early excavations of the Roman cities were conducted, under the direction of King Ferdinand IV, as a treasure hunt, with total emphasis on recovering valuable art objects from the ruins and no regard given to their context or history or the preservation of the buildings in which they were found. Winckelmann was shocked by these barbaric methods and published highly critical open letters in an attempt to save the cities from further destruction by the royal treasure hunters. His effort in Italy gradually placed excavations on a scientific basis and shaped the course of all later archaeological work. Practices were initiated, where objects were carefully recovered, identified, and catalogued; their location and position were documented; and the objects eventually exhibited for the benefit of later generations. As the first classical archaeologist, Winckelmann also brought intellectual discipline to excavations such as those in Pompeii and Herculaneum by analyzing the context of an object and assigning it to its proper place, not just within the temporal range in which it is found, but in

the cultural, artistic, economic and climatic conditions of the time. After his time, archaeologists did not just dig and collect, but they wrote of their findings.

The Pompeii of the Bronze Age is the city of Akrotiri, a major tourist attraction on the southern part of the Greek Santorini island in the Aegean Sea. When it was destroyed in ca. 1500 B.C. by the great eruption of Thera (Santorini) volcano, Akrotiri was a flourishing Minoan city. Like Vesuvius, Thera volcano is both a creator and a destroyer. It buried a treasure that has been brought back into the daylight for us to see, a wealth of information on the cultural and material civilization of the Bronze Age in the Aegean world of the Minoans.

In 1967 the Greek archaeologist Spyridon Marinatos began an excavation at a site called Akrotiri. It was just a hunch, based on some visible traces at the surface, such as pottery shards, and the fact that the soil here was very soft, even collapsing under the weight of a passing donkey. The excavations over the next few years revealed a magnificent city beneath a thick cover of pumice (Doumas 1983). Over 10,000 m<sup>3</sup> of the town have been excavated and are accessible to the tourist. Here the visitor can take in the atmosphere in a Minoan town, with carefully restored houses, pottery and magnificent frescoes, whose preservation to our day was made possible by their instantaneous burial in the pumice fallout and the pyroclastic surges during the Minoan eruption. Many of the finer works of art have been removed and are now exhibited in the Archaeological Museum in the town of Phira on Santorini and in the Archaeological Museum in Athens.

Marinatos and other scholars were aware of the sudden and mysterious destruction of the Minoan civilization on Crete in the Bronze Age, and in the 1930s Marinatos formulated a theory of a volcanic destruction of Minoan Crete, which he attributed to the Thera eruption. The causal relationship between this catastrophic eruption and the sudden demise of the Minoans in the Aegean region has been a topic of debate amongst archaeologists and volcanologists ever since.

A major natural disaster in Central America occurred in the third century A.D. The eruption of Ilopango volcano in what is now El Salvador disrupted agriculture and settlements in the southeast Maya area for a considerable time. Tephra from the eruption covered more than 10,000 km<sup>2</sup> with a deposit over 50 cm thick. It is estimated that tens of thousands of people were forced to migrate out of the region, and human occupation was only possible after several hundred years of weathering of the tephra deposit had taken place (Sheets 1983). In the sixth century, another major eruption buried farms and small villages in the region of Ceren, which have

been excavated to reveal house styles of the Maya, and agricultural and settlement patterns typical of Central America at this time. Just as Vesuvius has preserved for us the daily life of the Romans in Herculaneum and Pompeii, the on-going excavations in the volcanic regions of Central America are now revealing many fascinating details of the life of the Mayans. Tourists who are traditionally drawn to the magnificent stone temples of the Mayans will now be able to explore the new archaeological sites that are being unearthed from underneath thick blankets of tephra.

In North America, the best known volcanic archaeological site is at Sunset Crater in Arizona. When the area was inhabited by the Sinagua Indians, a series of eruptions began about A.D. 1064, creating a large cinder cone, lava flows, and several smaller cones. Tephra from the eruptions buried a number of circular and subsquare pit houses of the local tribe, as well as larger ceremonial pit houses. Artifacts found at these sites are now available for view by tourists visiting the Sunset Crater and Wupatki National Monument. The Wupatki (meaning tall house in Hopi) settlement was formed as a direct consequence of the eruption of Sunset Crater, as the Sinagua natives were forced to leave their farmlands near Sunset Crater. They settled on the Wupatki basin, where they were joined by two other tribes. The settlement thrived, partly because the thin ash layer deposited by the eruption contributed to the soil's fertility. For unknown reasons, the settlement was abandoned around A.D. 1225. Today, the Wupatki ruins are the best place for visitors to learn about the effects of the eruption of Sunset Crater on the local population.

#### H. Volcanoes and Religion

An ancient Chinese account of Japan states: "In the Empire of Wo there is a mountain called O-Su which unaccountably belches out fire as high as the heavens. This is truly a strange thing, and people go there to offer sacrifices." Virtually all cultures living with volcanoes have considered them as sacred abodes of gods, demons, or beneficent deities. Here we mention only four of the volcanoes that continue to inspire religious response.

Many Indonesians still believe that sacred volcanoes are the abodes of gods. Even today, during an annual ceremony, pieces of the hair and nails of the Sultan of Yogyarkarta (whose title is "Life-Giving Mountain") are placed on the crater rim of the dreaded Merapi volcano in central Java, as offerings to retain the Sultan's

FIGURE 7 Many Indonesians consider the Bromo crater in east Java as the abode of the gods and make frequent sacrifices here. A late 19th century photograph (author's collection).

spiritual power over a dragon that resides deep inside the mountain. The holy Mount Bromo, which lies inside the Tengger caldera of east Java, is the most worshipped volcano in Indonesia. The Tenggerese people who live on its slopes still retain a mixture of Hindu-Buddhist beliefs and are very sensitive to the changing moods of the volcano. Annually, on Buddha's birthday, the 14th day of the last Tenggerese month, they climb to the summit of Bromo's smoking cone to pray and to give offerings of money, vegetables, flowers, live chickens, goats, and, in the past, even humans. These sacrifices are probably stimulated by the story of Kiai Koesomo and his wife Njai. In return for Brahma's gift to them of fertility, they promised the god one of their sons. They soon forgot their duty and eventually Brahma demanded they return their 14th child, a son named Madin, who was swallowed up by the crater. As Madin departed, he asked the people to pray and make annual sacrifices in his memory. They continue to do so, praying for health and a rich harvest. Visitors to Bromo must arrive at dawn, usually by riding tiny Tenggerese ponies along the caldera rim and up the steep path to the base of the Bromo cone. Concrete steps now lead up to the crater rim.

The sacred Mount Fuji is Japan's most famous volcano. It is Japan's highest mountain (3776 m), perfectly symmetrical, and about 50 km in diameter at its base. Rising isolated from a plain, it totally dominates the landscape and can be seen from 13 of Japan's provinces. It approximates a symmetrical cone in shape, but it is the sweeping and graceful catenary curve of its slopes which has made it a token of all the scenic beauty of Japan and an object of veneration and even obsession. Fuji is in every way an uplifting sight. The ascent of the volcano is a pilgrimage that every Japanese wishes to make at least once in a lifetime. Mount Fuji is also known as Huchi, a word that may be derived from Fuchi, the Ainu goddess of fire. It is rightfully considered by many as the most beautiful mountain in the world. Fuji has erupted at least 14 times since the beginning of written records in the Heian era in the eighth century A.D. Its last eruption was in A.D. 1707 during the Hoei era, when explosive activity spread ash and pumice over vast areas of Japan, including the city of Tokyo. Already in the eighth century, Fuji was revered with superstitious awe, as shown for example in Manyoshu, one of the earliest poems of the Japanese language:

*No words may tell of it  
No name know I that is fit for it  
But a wondrous deity it surely is!  
It is the peace giver; it is the god, it is the treasure.  
On the peak of Fuji, in the land of the Suruga  
I never weary of gazing.*

Already in the earliest scrolls of Japanese painting from the 12th and 13th centuries, the isolated grandeur of Fuji is shown, drawn with reverence. In folk culture, it was one of the three lucky things to dream of—Fuji, falcon, and eggplant (a dream symbol of good fortune). As a symbol of good luck, it also figured prominently on surimono, the Japanese New Year's greeting cards, as well as a popular motif for decorating just about everything made in Japan.

Japanese legends of Fuji describe the formation of the mountain as an instantaneous event. Geologically, this is almost appropriate, as the volcano has a very high extrusion rate, and has been built up remarkably rapidly. One legend has it that many years ago, a poor woodman named Visu lived on the Suruga plain. One night he heard a great rumbling in the Earth, which terrified the woodsman so much that he gathered his children and ran out of the hut. Where there had been an empty plain, he now beheld a lofty mountain, which spewed forth fire and clouds of smoke. The next morning, when the peak was bathed in sunlight, it gleamed like opal, and Visu gave it the name the Eternal Mountain. In

another legend, a Japanese giant decided one day to fill up the Pacific Ocean, and spent the night carrying huge bags of earth to the sea. When morning came, he was disappointed to see the lack of progress made, and decided to abandon the project, dumping the last bagful of earth on the plain in a heap, which now is Fuji.

Another majestic volcano that has attracted religious worship is Mount Shasta in the Cascades range. Shasta stands more than 14,100 feet above sea level and is a truly impressive volcano. The native Indians once held that the volcano was the abode of the spirit chief Skell, who had descended from heaven to its summit, where his presence was marked by fire and smoke (Harris 1988). More recently, Shasta has attracted a variety of nontraditional religions, cults, and sects that have their headquarters in the small village of Mt. Shasta at the western base of the volcano. The diverse groups, who all believe that the volcano is a holy place and a magic mountain, include the Radiant School of the Seekers and Servers, the I AM Foundation, the Rosicrucians, the Association Sananda and Sanat Kemara, and the Knights of the White Rose. Shasta volcano is also alleged to be the home of the Lemurians, the refugees from the lost kingdom of Mu, now allegedly submerged beneath the Pacific Ocean. Few have claimed to see the Lemurians, who are said to inhabit tunnels within the volcano. Other lost tribes are also said inhabit the mountain, including the Atlanteans and the Secret Commonwealth (Fig. 8).

It is not clear what has brought Shasta such a wealth of mythology, but it is almost certainly due to the strong presence that this mountain projects, in its physical power and beauty, making it a credible gateway to mystical realms.

Kilauea is another volcano that has deep religious significance to the local people. Before Westerners came to Hawaii, natives worshipped Pele, the temperamental volcano goddess who made her home in Kilauea's fiery pit, Halemaumau. It is surprising how much the early Hawaiians understood about volcanic activity, as we can grasp from their stories about Pele. For example, Pele was thought to have made her first home in the northern islands of the Hawaiian chain, where the oldest volcanoes are. The stories of Pele's wanderings make it clear that the Hawaiians understood that the islands get progressively younger down the chain, toward the Big Island and Kilauea in particular.

The worship of Pele suffered a setback when Christianity was introduced by missionaries. The most serious blow to the old religion was dealt by the high chieftess Kapiolani in 1824. Kapiolani, who had become a Chris-

FIGURE 8 Mount Shasta in the Cascades volcanic range still has a unique attraction for various modern religious sects. An 1873 engraving (author's collection).

tian, knew that the worship of Pele was the most firmly entrenched in the hearths of Hawaiians and so the best way to earn converts to Christianity was to show that Pele did not exist. Kapiolani defied Pele by going down into the fiery pit of Halemaumau, throwing stones into the crater and eating ohelo berries that are consecrated to the goddess. When Kapiolani returned to the crater rim unharmed, the foundation of the old religion had been irreversibly shaken. However, the worship of Pele was never forgotten, and, in these days of religious tolerance, it has gained some popularity. Although few tourists come to Kilauea for religious reasons, local people still hold Pele and her volcano in great reverence and often throw offerings of flowers, money, and food into Halemaumau. Pele's High Priestess is well known to the volcanologists who work in the island, and she is respectfully allowed to offer prayers to the goddess when eruptions start.

#### V. CONCLUSIONS AND THE FUTURE

The most popular volcanoes in terms of tourism are probably in the United States, as the national parks attract many millions of visitors every year. Yellowstone,

Kilauea, Haleakala, Crater Lake, and Mount St. Helens are top attractions. In the Mediterranean, Vesuvius has retained its popularity, particularly because of the appeal of Pompeii and Herculaneum, but Santorini is increasingly attracting tourists. In the Caribbean, St. Vincent, St. Lucia, Guadeloupe, and Martinique are popular, although they are not among the most visited islands. In the Atlantic, the Canary Islands and the Azores are often the chosen destinations of British and other Europeans on vacation. New Zealand is very popular with Australians, but also European tourists, particularly British. In Asia, the Japanese volcanoes continue to attract the greatest number of tourists.

As interest in adventure and ecologically oriented travel increases, a number of other volcanoes are gaining considerably in popularity. Iceland is an example, particularly for European travelers. Americans are increasingly choosing Costa Rica and Alaska. Destinations such as Antarctica, the Andes, and Africa are becoming more affordable for the average tourist from all over the world.

Many of the world's most interesting volcanoes are not often visited because of the unstable political situation and the high crime rates of the countries they are in. Prime examples are the very active volcanoes of Guatemala and Nicaragua. Changes in the political system can completely transform a region's tourism industry.

A major recent example is Kamchatka. This region, and all its spectacular volcanoes, were completely off-limits to visits during the Soviet regime. Although few tourists yet travel to Kamchatka, this is very likely to change in the next decade.

Volcanic eruptions can attract tourists but also temporarily destroy the infrastructure needed to accommodate them. The recent volcanic activity in Montserrat has caused considerable disruption of local services, including the destruction of the capital and of the airport, and massive a exodus of the island's residents. Tourism used to be the island's main source of income, but the "Ireland of the Caribbean" can no longer accommodate visitors and, except for volcanologists, few people now want to visit the island. However, in a few years, it is very likely that the tourism industry will pick up again. Pinatubo, and the Philippines in general, are rising from the ashes of the 1991 eruption. When Pinatubo erupted in the Philippines in June 1991, the country was on the verge of a financial and economic disaster. The eruption forced the closing of American military facilities at both Subic Bay Naval Station and Clark Air Base, two important economic factors for the country. In recent years, however, an economic miracle has been happening in the Philippines, under a stable government. Visitor arrivals have doubled in 4 years, Clark Air Force Base is now an international airport, and a complex of luxury waterfront villas has been constructed at Subic Bay to house the tourists. The next big tourist draw that is planned for the Philippines are the crater lakes of Pinatubo. As happened at Mount St. Helens, a major eruption may be, in the long term, a boom for the local tourist industry.

## GLOSSARY

**archaeology** The scientific study of the physical remains of ancient human cultures and the art of interpreting their significance.

**Bronze Age** Period of human cultural development in Europe and the Near East characterized by the use of bronze tools and weapons that began between 4000 and 3000 years ago and ended with the Iron Age (about 1200 B.C.).

**etiology** From a Greek term meaning cause, origin, or source; in the study of ancient myth, it refers to oral traditions that attempt to explain the origins of natural or social phenomena.

**geomythology** The study of ancient oral traditions that pre-

serve memories of prehistoric geologic events, such as earthquakes or volcanic eruptions.

**lahar** An Indonesian term for a debris flow or mudflow originating on a volcano.

**Minoan culture** An ancient civilization centered on Crete and characterized by the building of large palace complexes, such as that at Knossos; it dominated the Aegean region from about 2000 to 1450 B.C.

**mudflow** A water-saturated mass of rock debris that moves downslope as a liquid under the pull of gravity; it can travel many tens of miles beyond its source.

**Neolithic** The New Stone Age; in Europe and the Mediterranean basin, it refers to prehistoric cultures using stone implements and characterized by settled agrarian pursuits.

**phreatic** Refers to a steam eruption that produces no fresh magma. A common precursor of eruptive activity, it is caused when groundwater, heated by a magmatic source, flashes into steam.

**Plinian eruption** Named for Pliny the Younger, a violently explosive eruption that ejects a large volume of tephra high into the stratosphere.

**pyroclastic** A Greek term meaning fire-broken; it refers to fragmental rock ejected during an eruption.

**pyroclastic flow** A dense, hot, dry mixture of gas and incandescent rock fragments that travels rapidly along the ground surface, typically at speeds of hundreds of feet per second.

**pyroclastic surge** A turbulent cloud of gas and fine rock

particles that flows over and above the ground surface at extremely high velocities. More dilute than pyroclastic flows, surges are not topographically constrained but sweep over ridges, hills, and other topographic obstacles.

**tephra** Rock fragments blown into the air above an erupting volcano; tephra ranges in size from fine ash to blocks many tens of feet in diameter.

**D**ESPITE THEIR REPUTATION as agents of destruction, explosive volcanoes have provided a major aid to archaeologists' study of ancient human remains. Large-volume eruptions of tephra can not only quickly and thoroughly bury entire settlements and other artifacts, effectively sealing them for posterity, but also typically lay down widespread layers of ash that, when dated, serve as valuable time markers. When the date of an extensive tephra layer is known, it enables researchers to establish the relative ages of objects found within, above, or below the deposit.

## I. VOLCANOES AS PRESERVERS OF ARCHAEOLOGICAL SITES

### A. The Science of Archaeology and Its Relation to Volcanism

Almost from its inception, archaeology has been intimately associated with volcanism. In many important ways, archaeology evolved as a scientific discipline in the laboratory provided by Herculaneum and Pompeii, Roman cities located on Italy's Bay of Naples that were buried in A.D. 79 by a catastrophic eruption of Mount Vesuvius. Rediscovered in the early 18th century, the two sites were first viewed as mere repositories of artistic plunder to furnish the private estates of European collectors. By the mid-19th century, however, under the leadership of such pioneering archaeologists as Giuseppe Fiorelli, excavators at Pompeii eventually established the systematic criteria for uncovering, cataloging, and conserving antiquities that characterize archaeology today.

An interdisciplinary science that utilizes the contributions of anthropology, geology, paleontology, ethnology, chemistry, and physics, modern archaeology involves studying and interpreting the material remains of ancient human cultures. Its objectives combine scientific and humanistic goals, including the identification and

analysis of artifacts to illuminate the long-forgotten cultural processes that created them. As a multidisciplinary enterprise, archaeology includes attempts to reconstruct the full spectrum of elements composing a vanished society, including such components as its economy, commerce, political organization, religious beliefs, and mythology.

Paradoxically, volcanoes, which are popularly regarded as mere destroyers, are perhaps nature's most effective preservers of ancient human structures and settlements. No other natural phenomenon can so quickly and thoroughly bury large areas, including evidence of human occupation, protecting artifacts from subsequent damage. Exposed sites gradually covered by slower geologic processes, such as sporadic flooding or sedimentation, are typically subject to severe erosion and destructive human activities, including war, vandalism, and the deliberate demolition of older edifices. By contrast, towns such as Pompeii, Herculaneum, and Akrotiri, a Bronze Age settlement on the island of Thera (Santorini), were rapidly engulfed in pyroclastic ejecta and survive relatively intact. Besides being spared the depredations inescapable in surface exposure, the buildings, artwork, and other artifacts buried by voluminous tephra falls or pyroclastic flows remain in their original context, their spatial and functional relationships largely undisturbed.

Volcanism's agency in preserving the human record extends to the earliest stages of human evolution. About 3.5 million years ago, at Laetoli in Tanzania, an adult hominid and one or two smaller companions, perhaps a female and/or child, walked upright across a newly deposited layer of ash. After a brief rainstorm splattered across the area, a second ash eruption covered the hominid footprints, effectively sealing one of the oldest surviving evidence of bipedalism until its discovery by 20th century investigators.

## II. HERCULANEUM AND POMPEII: CITIES OF THE EARLY ROMAN EMPIRE

### A. Historical Significance

Pompeii, in A.D. 79 a thriving commercial center of about 20,000 inhabitants, and Herculaneum (Figs. 1 and 2) a largely residential town of about 5000, are uniquely important. Frozen in time, they offer a superbly detailed picture of life in the early Roman Empire, encompassing

FIGURE 1 Whereas most buildings in Pompeii are roofless, crushed by the accumulation of tephra from Vesuvius, many of Herculaneum's structures, such as these small shops, retain their upper stories. An affluent resort town on the Bay of Naples, Herculaneum is perhaps the best-preserved urban site of the early Roman Empire. (Photo courtesy of Dr. James Straukamp.)

temples, theaters, shops, private houses, gardens, fountains, public baths, swimming pools, and a miraculously preserved library. Interred so swiftly that most residents had no time to save their possessions, the ruins contained a rich variety of rare items, including gold jewelry, silver dishes, the most complete known set of Roman surgical

instruments, and even wax tablets inscribed with bank records. Recovery of Greco-Roman statuary, paintings, and furniture influenced 18th and early 19th century art and architecture throughout Europe and America, where Thomas Jefferson modeled Monticello on classical styles.

FIGURE 2 Engulfed by pyroclastic flows during the A.D. 79 eruption of Mount Vesuvius, the Roman town of Herculaneum has been only partially excavated. Property owners of the modern town of Resina, built atop the site, effectively prevent further excavation. (Photo courtesy of Dr. James Straukamp.)

### B. Recent Discoveries at Herculaneum

Besides their historical role as a testing ground for new archaeological techniques and concepts of preservation, Pompeii and Herculaneum continue to yield invaluable information about the Roman world, including the physical attributes of the cities' former inhabitants. Until the early 1980s, when about 130 largely intact skeletons were exhumed along Herculaneum's former waterfront, it was assumed that most of Herculaneum's population had managed to escape the city alive. The discovery of so many well-preserved remains is particularly important because the Romans, who typically cremated their dead, otherwise have left little evidence of their bodily characteristics. Caught in the fierce heat and swirling ash of a pyroclastic surge, the victims had apparently been asphyxiated while attempting to flee by boat. (An overturned 30-foot wooden vessel was found nearby.) The skeletal remains at Herculaneum are considered invaluable because they encompass individuals of all ages and classes, ranging from a bejeweled Roman matron to a teenaged slave girl to a middle-aged soldier, sword in hand, whom the surge had thrown to the ground face-down. Hundreds more skeletons may still await discovery.

### C. Sequence of Eruptive Events in A.D. 79

The effects of Vesuvius's outburst on the nearby human population are now better understood than those of any other ancient volcanic disaster. Not only did a remarkably observant Roman nobleman, Pliny the Younger, write two letters to the historian Tacitus in which he carefully described Vesuvius's behavior, but modern volcanologists led by Haraldur Sigurdsson have been able to correlate Pliny's account with particular strata deposited by the eruption. The eruptive sequence, and its effects on the human population, is now well understood. After some preliminary activity, which dusted one slope of the volcano with a light tephra fall, the main eruption began about 1 P.M., August 24 with an explosive discharge of pumiceous ash, forming an ash column that, in Pliny's words, resembled a towering pine tree with spreading upper branches. For the next 11 hours, Vesuvius ejected a vertical eruption cloud (called Plinian after the Roman author who first described the phenomenon) that rose approximately 12 miles into the stratosphere. Carried south-southeastward by the prevailing winds, the ash canopy enshrouded Pompeii, extinguishing sunlight

and raining lapilli (the Latin term for small stones) over the city, where pumice accumulated at the rate of 6 inches per hour. Lying four miles upwind from Vesuvius, Herculaneum received only a trace of ash during this phase of the eruption.

Shortly after midnight, however, the character of the eruption abruptly changed. As Vesuvius tapped deeper levels of its magma chamber, the gas-rich volatile mixture that had sustained the Plinian cloud became increasingly depleted, causing the ash column to collapse. Expanding horizontally, the turbulent ash cloud separated into a fast-moving pyroclastic surge that swept through Herculaneum, killing all who remained there, and a somewhat slower-moving pyroclastic flow that enveloped the town, initiating its burial. As the eruption column continued to fluctuate, a second surge and pyroclastic flow were generated an hour later. A third, at 5:30 A.M. on August 25, finished the work of entombing Herculaneum under a hot ash deposit tens of feet thick.

The third pyroclastic flow, which had interred Herculaneum, was deflected from Pompeii by the city's massive walls. The fourth, however, exhibited lethal energy, racing 6 miles from Vesuvius's crater and blasting through the city like an incandescent sandstorm. Rushing across the 7-foot thickness of pumice that had previously fallen, the flow toppled exposed walls, sheared off roofs and upper stories of buildings, and asphyxiated the remaining inhabitants.

Trapped in the fourth pyroclastic flow, thousands of fleeing Pompeians were instantly entombed. When their bodies decayed, they left behind hollow spaces in the ash. Recognizing that these cavities were, in effect, molds of human figures, 19th century archaeologists filled them with liquid plaster, allowed it to solidify, and then removed the surrounding ash. The plaster casts thus formed are astonishingly lifelike, some showing in detail the agonized facial expressions of the volcano's victims.

In 1961, archaeologists unearthed a particularly poignant group in a location called the Fugitives Garden, where casts were made of seven adults and six children. Like many of the 57 people killed in the 1980 pyroclastic surge from Mount St. Helens, the fugitives appeared to have died of suffocation from inhaling the pervasive ash. Estimates of the fatalities in Pompeii—some archaeologists state that about 2000 perished—were based on the number of skeletons found in the lower pumice deposits and the body-shaped cavities formed in the upper pyroclastic flow deposits. With the realization that the pyroclastic surges and flows probably killed simultaneously many of the people who were

TABLE I Some Representative Archaeological Sites Related to Volcanism

<i>Site name and location</i>	<i>Volcano</i>	<i>Date</i>	<i>Significance</i>
Pompeii & Herculaneum, Italy	Vesuvius	79 A.D.	Entire Roman cities preserved
Akrotiri, on Santorini, Greece	Thera	late 17th century B.C.	Minoan-age city; rare murals
Catal Huyuk, central Turkey	Karapinar cinder cone field (?)	6200 B.C.	Earliest known painting of a volcanic eruption
Maya settlements, El Salvador, Central America	Ilopango	Third century A.D.	Massive disruption of Maya population centers
Northwest Costa Rica, Central America	Arenal	c. 1550 B.C. to A.D. 1080	Average of 4 eruptions per century fails to disrupt population
Arizona, U.S.A.	Sunset Crater	c. 1060 A.D.	Causes redistribution of native agricultural sites in vicinity
Washington State, U.S.A.	Rainier	c. 3600 B.C.	Mudflow buries campsite and tools
Washington State, U.S.A.	St. Helens	c. 1500 B.C.	Abandonment of native habitats in southwest Cascade Range
Yukon Territory, Canada	White River Volcano, Alaska	20 A.D. and 720 A.D.	Triggered mass migrations of Athapaskan peoples, northwestern Canada
Aleutian Islands, Alaska	Aleutian Range volcanoes	18th Century A.D.	Probable submarine activity and tsunamis displaces coastal Aleut tribes

fleeing along the roads outside Pompeii's city gates, historians now believe that many more thousands perished in the disaster.

At 8:30 A.M. on August 25, Pliny witnessed the generation of the sixth and largest pyroclastic surge, "a fearful black cloud . . . rent by forked and quivering bursts of flame" that swept across the Bay of Naples toward Misenum, located 20 miles west of Vesuvius. Fleeing the city with hoards of panicked refugees, Pliny noted that "many besought the aid of the gods, but still more imagined there were no gods left, and that the universe was plunged into eternal darkness for evermore."

#### D. Rediscovery and Excavation

Although some survivors later burrowed into the deposits covering Pompeii, retrieving valuable objects and even building materials, the buried cities eventually became almost entirely forgotten until 1709, when laborers digging a well happened upon Herculaneum's theater. Despite being rediscovered first, most of Herculaneum still lies underground, embedded in pyroclastic flow deposits that hardened to the consistency of cement. Besides the enormous difficulty of removing the solidified

ash enshrouding the site, landowners in the modern town of Resina, which sprawls atop the deposits covering Herculaneum, refuse to permit archaeologists to expand the excavations.

Beginning in 1738, excavators bored a network of tunnels through part of the town, haphazardly looting statuary and other portable art and carelessly wrecking any structure considered uninteresting. One of the most promising 18th century finds was an elaborate residence known as the Villa of the Papyri, which sheltered a library of 1800 carbonized scrolls. Hopes that this collection would yield literary masterpieces, such as a lost tragedy by Sophocles, were dashed when most of it turned out to be the work of a minor Epicurean philosopher, Philodemus. The villa's presumed owner, L. Calpurnius Piso, the father-in-law of Julius Caesar, was Philodemus's patron.

Today most of the 18th century tunnels burrowing through underground Herculaneum are closed, and visitors can no longer walk across the theater's ancient stage. Even though most of Pompeii has been opened to light and air, Herculaneum remains largely buried, its mysteries still hidden. The few buildings now exposed, such as the elaborate suburban baths, represent only a fraction of structures waiting to be discovered, along with an unknown number of sculptures, paintings, and scrolls.

### III. AKROTIRI: AN AEGEAN BRONZE AGE CITY

#### A. Relation to Minoan Civilization

A particularly spectacular example of volcanic preservation occurs on the Aegean island of Thera (also called Santorini), about 60 miles north of Crete, where a late Bronze Age city, named for the nearby modern village of Akrotiri, was engulfed during a cataclysmic eruption of the Thera Volcano in the late 17th century B.C. Dubbed the Pompeii of the Aegean, Akrotiri was similarly buried by voluminous tephra falls and pyroclastic flows. By far the best preserved settlement of its era (corresponding to Late Minoan III-A on Crete), Akrotiri was a prosperous sea port, enriched by maritime trade with Crete and other parts of the eastern Mediterranean region. The luxury and opulence of its multistory dwellings (some rose three or even four stories high) is indicated by their technological sophistication (indoor running water and flush toilets) and artistic splendor (some of the most extensive and beautiful wall paintings to have survived from the ancient world).

Although the site of Akrotiri was continuously inhabited since the Neolithic period and hence represented a native Cycladic culture, pre-eruption Akrotiri was profoundly influenced by Minoan civilization. Named by modern archaeologists after Minos, a mythical king of Knossos on Crete, Minoan culture dominated the Aegean region between about 2000 and 1450 B.C. The Akrotiri wall paintings reveal a typically Minoan delight in physical nature and the human form. Most of the human figures, including richly dressed and bejeweled female figures and nude youths carrying fish, probably depict participation in religious processions or other rituals. Other paintings focus on portraying highly stylized flowering plants, soaring birds, or animals, both wild and domestic, including the famous blue monkeys adorning the aptly named House of the Frescoes. Perhaps most important for archaeologists are the lavish wall murals showing a Bronze Age naval fleet and urban waterfront scenes, one of which may represent Akrotiri and its people.

Because the artists made no attempt to keep the plaster they painted on wet and continued to paint over patches that had already dried, the frescoes are unevenly preserved. Generally intact where the paint had permeated wet plaster, the wall paintings quickly flake away from the dry areas, challenging the techniques of Greece's most skilled archaeologist-restorers. Even so, Akrotiri's frescoes survive in larger fragments than the

roughly contemporary murals from other Aegean sites, including Cretan Knossos. Besides their exceptional state of preservation, the paintings are unusual in that they generally remain in their original positions, allowing archaeologists to reconstruct the original decoration of entire rooms and to speculate on the probable relationship between scenes painted on different parts of the same room.

#### B. Architectural Sophistication

At the time of its destruction, Akrotiri was probably one of the Aegean's major ports, with a population of several thousand. Although only a small fraction of the town, which may have covered several tens of acres, has thus far been excavated, it appears that prehistoric Akrotiri closely resembled the general layout of modern villages on the island. Designed for a society functioning without vehicles, its streets were narrow, wide enough only for two loaded donkeys or other pack animals to pass one another. Some archaeologists suggest that the town's zigzag streets and small, irregularly shaped open spaces, such as the aptly named Triangle Square, may have been deliberately planned to block gusty winds and to prevent heavy rains from transforming thoroughfares into stream beds.

Judging from the small portion of the town now exposed—a mere ten houses have been exhumed and most of these have not been fully explored—it seems that the community was highly organized, with special attention given to sanitation. The streets, apparently well maintained, were generally paved with large, relatively flat stones; beneath this flagstone surface ran a carefully constructed sewage system consisting of stone-lined ditches covered with stone slabs. These underground sewers received effluents from neighboring houses via clay pipes incorporated in house walls. The closely packed, multistory domestic edifices and the entire absence of accommodations for livestock or other animals indicates that Akrotiri's inhabitants were thorough-going urbanites.

Individual houses were built of native stone and clay, the masonry walls strengthened against seismic hazards by both horizontal and vertical timber reinforcements. Although no standard house plan exists at Akrotiri, most builders observed some accepted conventions, including the placement of a window next to the main doorway, a practice that may account for the Greek word for "window" (*parathyron*, which literally means beside the door). The same passion for interior light and color that characterize the Minoan palace architects on Crete

appears in Akrotiri's private houses. Virtually every room contains a window, with relatively large ones punctuating upper storeys, and every house uncovered to date boasts vivid wall paintings. It is possible that the presently excavated dwellings represent the home of the town's more affluent residents, but the abundance of these distinctive amenities indicate that at least a significant part of the population enjoyed both a luxurious domestic environment and a strong aesthetic sense.

With some structures rising three stories or higher, staircases are common and are built of both stone and wood. Most stairways rested on piles of rubble enclosed in a solid wood framework set between parallel walls, with stone treads laid atop the rubble. Whereas families had their living quarters on the upper levels, the ground floor was typically devoted to storage of foodstuffs and other supplies. Most houses also had workshops equipped with such stone tools as hammers and anvils, as well as private mills, complete with grindstones and containers to catch the ground flour.

Although no wooden furniture or building materials have survived, the decay of these objects left cavities in the surrounding ash deposit, into which archaeologists poured liquid plaster, resulting in plaster molds of such household items as beds, tables, and even an elaborately carved three-legged stand that may have been used for religious purposes. Besides a plethora of decorated pottery and huge storage jars, some examples of beautifully crafted metalwork have also been found, ranging from bronze awls and daggers to large bronze cooking utensils.

### C. The Thera Eruption

The scarcity of valuable jewelry or metal goods, as well as the total absence of human remains, indicates that Akrotiri's people had ample warning of the disaster that overtook their city. As at Pompeii, the combined efforts of volcanologists and archaeologists have enabled researchers to interpret the stratigraphic record, reconstructing the order of events that doomed Akrotiri. According to recent studies, precursory earthquakes severely damaged buildings throughout the town, perhaps years or even decades before the eruption occurred. The city's high degree of social organization is suggested by major communal program following the tremor to clear debris from the streets, tear down ruined buildings, and repair weakened structures. Extensive reconstruction was still underway when further seismic activity apparently prompted the inhabitants to abandon Akrotiri permanently, taking with them their most valuable possessions. The volcano's interruption of this restora-

tion process is effectively symbolized by the presence of two vessels of dried plaster and a third containing dried paint in a second-story bedroom of the West House, where painters were busily redecorating until forced to lay aside their work.

The climactic eruptive sequence began with phreatic blasts that produced a thin layer of ash, followed by a paroxysmal outburst that ejected between 5 and 7.5 cubic miles of magma, creating approximately 12.5 to 19 cubic miles of pyroclastic material. It was previously assumed that this Plinian event triggered the collapse of Thera's former summit, creating the large caldera, subsequently flooded 1000 feet deep by the invading sea, that occupies most of the island today. Geologists have recently concluded, however, that a caldera already existed on Thera at the time of the "Minoan" eruption, although it was probably enlarged by further subsidence of the volcanic edifice. The island's present crescent shape, deriving from a prehistoric collapse long before the Minoan era, inspired its ancient name *Strongyle*, which means round.

The Thera catastrophe is notable for reputedly spawning two celebrated theories—one ancient and one modern—about the sudden disappearance of a technologically advanced prehistoric civilization. According to one hypothesis, the eruption that buried Akrotiri and other prosperous towns on Thera was the inspiration for Plato's famous myth of Atlantis. In his dialogues, the *Critias* and *Timaeus*, Plato has the Athenian statesman Solon relate a tale he heard from Egyptian priests in the sixth century B.C. concerning a tyrannical island kingdom, supposedly located beyond the Pillars of Hercules (the Straits of Gibralter), that disappeared in a sudden catastrophe. The Atlantis tradition, in this view, was based on the classical Greeks' dim memories of the disaster that overtook Thera and other Minoan sites. Plato's locating the vanished civilization out in the Atlantic was merely an imaginative but inaccurate attempt to place the ancient culture beyond the realm of the known world.

### D. Thera and the Decline of Minoan Political Dominance

A second, contemporary theory links Thera's outburst with the demise of Minoan civilization. In 1939, the Greek archaeologist Spyridon Marinatos suggested that the Thera event was powerful enough to change the course of Mediterranean history, weakening Minoan political dominance of the Aegean and permitting the warlike Mycenaeans of the Greek mainland to invade and

conquer Crete. Tsunamis generated by Thera's collapse, Marinatos suggested, may have overwhelmed Minoan ports, demolishing any fleets harbored there and decimating their maritime empire. Recently revised dating of the Thera eruption, placing it about 1645 B.C. (according to ice core samples) or 1628 B.C. (from tree-ring evidence), however, makes it unlikely to have triggered the final decline of Minoan power, which did not occur until about 1450 B.C. In the absence of a substantial ash layer on Crete or unequivocal evidence of flood damage to its ports, most historians now conclude that Thera's explosions were not responsible for the eclipse of Minoan hegemony in the Aegean. Efforts to connect the eruption with the biblical plagues on Egypt, described in the Book of Exodus, or with the Israelites' miraculous deliverance at the Red Sea, when a pursuing Egyptian army was allegedly overwhelmed by a "wall of water" and drowned, are equally unsubstantiated. The exodus from Egypt, which most scholars place in the 13th century B.C., occurred almost four centuries after the Thera disaster.

---

#### IV. CATAL HUYUK: THE EARLIEST REPRESENTATION OF A VOLCANIC ERUPTION

Although archaeologists have not yet discovered a fresco depicting the Theran volcano, the ruins of Catal Huyuk in central Anatolia (modern Turkey) contain a remarkable Neolithic portrayal of an active volcano, the earliest known visual record of a volcanic eruption. Dating to

about 6200 B.C., the Catal Huyuk mural (Fig. 3) shows a cinder cone, looming steeply above a town nestled at its base, ejecting tephra from the summit vent. More than six millennia older than the fresco at Pompeii that portrays Bacchus (the Roman wine god) presiding over vineyards near Vesuvius, this painting bears witness that human interest in documenting volcanic phenomena began at an extremely early date.

---

#### V. MESOAMERICAN ARCHAEOLOGICAL SITES

##### A. Probable Effects of the Ilopango Eruption on Maya Cultural Development

Volcanic activity has also preserved a number of important archaeological sites in the New World. During the third century A.D., a caldera-forming eruption of the Volcan Ilopango devastated the highlands of El Salvador, Central America, covering a broad area under pyroclastic flows and a much larger region under thick layers of tephra. Whereas land lying within a radius of about 60 miles of the vent was rendered completely uninhabitable, areas lying farther away suffered varying degrees of environmental damage, leaving a large population of survivors with no means of subsistence. Recent studies by Payson Sheets and others suggest that the eruption, occurring at the close of the Protoclassic Maya period (A.D. 200–300), had unusually long-term social and economic effects on the evolution

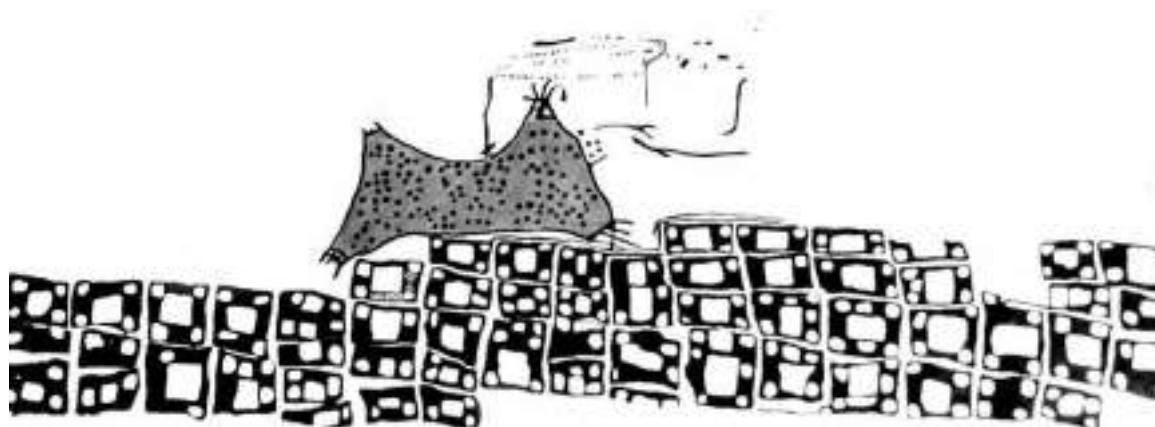

FIGURE 3 Dating from about 6200 B.C., this wall painting from a shrine at Catal Huyuk (central Anatolia, Turkey) is the oldest extant picture of an active volcano, perhaps one of the cinder cones in the Karapınar volcanic field that lies about 30 miles east of Catal Huyuk. Although the volcano is shown exhibiting only mild Strombolian activity, the artist's placement of a Neolithic town in such close proximity to its base suggests some anxiety about its eruptive behavior. (Courtesy of James Mellaart, *Catal Huyuk: A Neolithic Town in Anatolia*, 1967, McGraw-Hill.)

of Maya culture. Besides totally destroying farmlands and villages in the most severely impacted zone around the volcano and disrupting agricultural production over a vast region, the eruption may also have been responsible for a massive redistribution of the Maya population, causing an estimated 320,000 survivors to migrate northward from Salvador to Belize and northern Guatemala. The influx of migrants, displaced by the Ilopango event, may have been a catalyst that helped accelerate the already in-progress development of Classic Maya civilization. Flooding lowland towns and villages north of Ilopango, these tens of thousands of refugees may have stimulated rapid social and political responses by the Maya leadership to accommodate the suddenly increased populations. After the eruption forced abandonment of the major highland trade route, rulers at Tikal gained control of regional commerce.

Excavations at sites scattered over central and western El Salvador which were affected by the Ilopango cataclysm reveal a wealth of Preclassic Maya artifacts. Located about 40 miles from Ilopango, pre-eruption Chalchuapa was a major residential, economic, and ritual center in the southeast Maya highlands, featuring numerous 50 foot high pyramids arranged around open plazas and elaborately sculptured monuments, some of which bore calendric dates. Numerous ceramic vessels, some with polychrome painting, were found under Ilopango's ubiquitous layer of light-colored ash, known locally as the *tierra blanca*. Digs at rural sites have uncovered farms, fields (many apparently irrigated), and villages. The ruins of a farmhouse at the village of Joya de Cerén, buried under 16 feet of ash, disclosed much about the Maya villagers' diet and way of life, indicating that they ate corn, wild and domesticated beans, and squash, liberally spiced with an array of chilies. Enjoying a variety of shellfish, they cooked their food in cottonseed oil and wove cotton cloth that they may have traded for obsidian, a desirable raw material for tools in the New as well as the Old World.

### B. Mount Arenal and the Prehistoric Culture of Costa Rica

In contrast to the long-term effects of the Ilopango disaster, repeated eruptions of the Mount Arenal in the rainforests of northwest Costa Rica do not seem to have had a significantly disruptive impact on the native population. Sheets' investigations around Arenal, one of Central America's most active volcanoes, indicates that village life, established about 2000 B.C., was remarkably

stable. Despite at least nine explosive outbursts during the prehistoric period, villagers were resilient and maintained permanent settlements near the volcano. Whereas the Ilopango paroxysm was large enough to generate massive changes in Mayan society and mark a definable boundary between distinctive phases of Mayan cultural development, the frequent Arenal eruptions—averaging four per century—did not effect a comparable alternation in the culture of prehistoric Costa Rica. Aerial photographic surveys and digital remote sensing devices have detected numerous linear anomalies in the region, many of which have been identified as prehistoric footpaths, representing a long-established system of transportation and communication through the rainforests that persisted in spite of Arenal's many explosive eruptions.

---

## VI. NORTH AMERICAN ARCHAEOLOGICAL SITES

### A. Eruptions at Sunset Crater, Arizona

In the southwestern United States, native peoples pursued a sedentary existence and farmed land near the present site of Flagstaff, Arizona, since at least A.D. 600. Then, during the 1060s, Strombolian eruptions formed Sunset Crater, blanketing the landscape with tephra and emitting a series of lava flows that buried previously arable fields. Until recently, anthropologists believed that tephra ejected during the eruptions greatly enhanced the soil's fertility, causing large number of Native Americans from other territories to flock to the posteruption Sunset area. Reexamination of the archaeological evidence, however, indicates that the presumed population increase is illusory; instead of other cultural groups migrating to cultivate the ash-enriched fields, the indigenous peoples merely transferred their settlements to new locations near the cinder cone, readjusting their practices to cope with the volcanic changes wrought in the physical environment. Unusually heavy rains that characterized the three decades following the ash eruption probably accounted for the Sunset area's posteruption increase in crop productivity, not deposition of the ash itself.

### B. Native American Site Near Mount Rainier, Washington

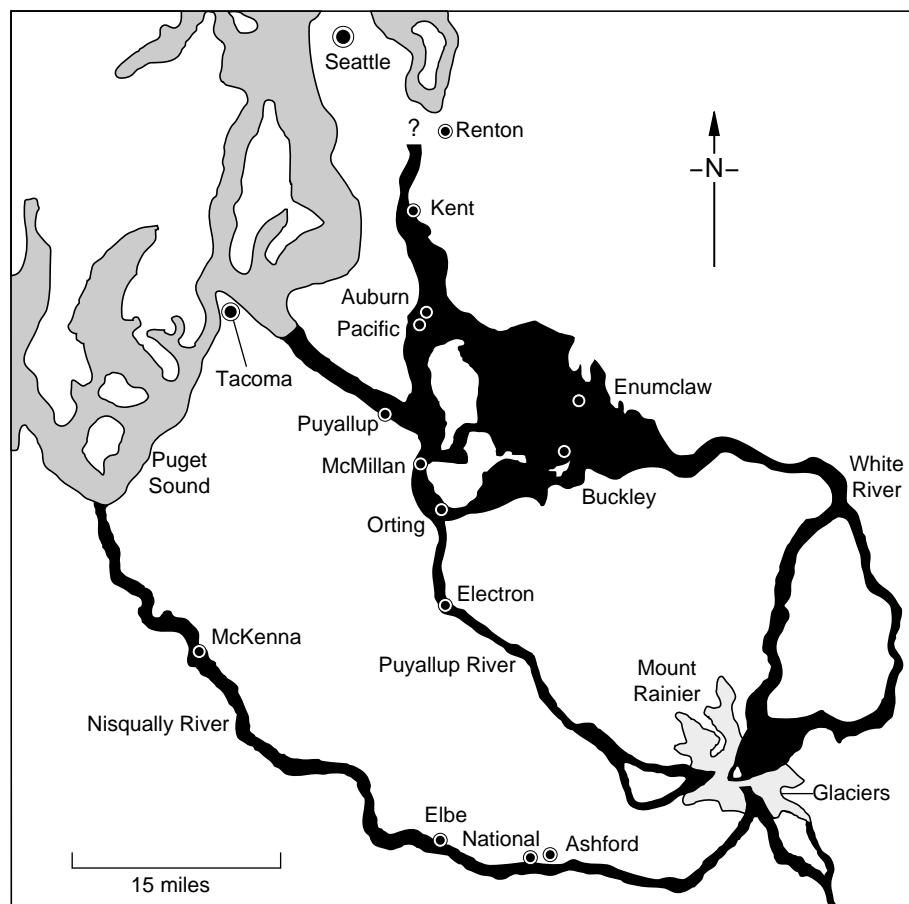

Most of the world's archaeological sites conserved by volcanic activity are those rapidly buried by tephra or

pyroclastic flows. By contrast, lava flows typically crush, pulverize, and/or burn man-made structures in the process of covering them. Similarly, most volcanic debris flows and lahars, which resemble churning wet concrete as they stream downslope, also destroy more than they preserve. A rare exception is a Native American settlement in the Cascade Range foothills of western Washington, near the present towns of Enumclaw and Buckley (Fig. 4). Discovered in 1972, the prehistoric campsite contained numerous stone projectile points, scrapers, and other tools, as well as charcoal that helped to fix the date of its burial. The encampment, located on what was then a hilltop above a valley floor, was engulfed almost instantly by an enormous lahar, the Osceola Mudflow, generated when an explosive eruption caused the former summit of Mount Rainier to collapse (Fig. 5). Almost a cubic mile of rock, much of it hydrothermally altered, avalanched down the volcano's northeast flank

and was transformed into a thick lahar as it traveled more than 65 miles down the White River Valley, beyond the Cascade mountain front, where it easily swept over the hilltop camp, and ultimately into an arm of Puget Sound. Although the Osceola Mudflow had transformed the area beyond recognition and many centuries elapsed before native peoples reoccupied it, a new settlement was eventually established directly above the buried site. Two thousand years older than Akrotiri, this collection of native artifacts is one of the oldest evidences of human culture in the Puget Sound region.

### C. Effects of the Mount St. Helens "Y" Tephra

As the most frequently and violently explosive volcano in the 48 contiguous states, Mount St. Helens in southwest

**FIGURE 4** Map showing hazard zones for mudflows (lahars), lava flows, and pyroclastic flows from Mount Rainier, Washington State. About 5600 years ago, the volcano's former summit collapsed, generating the Osceola Mudflow that buried an Indian encampment near the present town of Buckley, preserving the oldest known human artifacts in the Puget Sound region. More recent mudflows followed the channels of the Puyallup and Nisqually Rivers, inundating areas where tens of thousands of people now live. (From U.S. Geological Survey Open-File Report 98-428).

FIGURE 5 Mantled by a cubic mile of glacial ice, Mount Rainier (14,411 feet) towers above the densely populated Puget Lowland of western Washington State. Considered the most potentially dangerous volcano in the 48 contiguous states, Rainier has repeatedly produced massive debris flows, some of which have inundated areas where hundreds of thousands of people now live. (Photo by Austin Post, U.S. Geological Survey.)

Washington apparently affected the settlement patterns of some Native Americans. About 3600 years ago, St. Helens began a series of intermittent outbursts that produced the "Y" (yellow) tephra sequence, pumiceous deposits mantling much of the Pacific Northwest. Although the degree of environmental degradation to the affected areas is not known, comparisons with similarly voluminous eruptions at other volcanoes indicate that a heavy fall of coarse lapilli typically defoliates trees, smothers vegetation, pollutes water sources, and depletes both animal populations and the human predators who depend on them. Recent studies by the U.S. Forest Service and others indicate a hiatus in settlements throughout the southwest Cascade Range between about 3600 and 1600 years ago. During approximately the same period, there was a coincidental increase of native populations in the Columbia Plateau to the east, a shift perhaps attributable to St. Helens' repeated ejections of tephra.

#### D. Effects of the White River Ash on Native Inhabitants of the Yukon

The White River Volcano, located in southeastern Alaska near the headwaters of the White River, produced two cataclysmic eruptions, about A.D. 20 and A.D.

720, that covered most of the southwestern Yukon Territory with voluminous ashfalls. Anthropological studies indicate that the later and larger of the two outbursts, which deposited the east lobe of the White River Ash, caused profound disruption of the native population, possibly initiating a series of migrations that culminated in the formation of the Pacific Athapaskans in British Columbia and of the Apache and Navajo of the southwestern United States. Athapaskan lore, transmitted orally for more than 1200 years, refers to fiery explosions and a collapsing mountain that caused the people's ancestors to abandon their original homeland and, in small bands, eventually drift westward or southward to their present locations.

One of the world's most active volcanic regions, the Aleutian Range of Alaska hosts at least 45 historically active volcanoes. Studies of peoples inhabiting the Aleutian Islands during the 18th century A.D. indicate that eruptions, including submarine activity, have repeatedly influenced the movements of native inhabitants. Dependent exclusively upon marine fauna for their existence, the Aleuts have apparently been forced to abandon settlements destroyed by tsunamis generated during earthquake-induced underwater landslides or submarine eruptions. In some cases, it appears that the Aleuts have deserted settlements because underwater activity killed the sea life that constitutes their sole food supply.

---

## VII. GEOMYTHOLOGY: VOLCANOES IN PREHISTORIC ORAL TRADITIONS

### A. Greco-Roman Myths

Dealing with the social customs and belief systems of ancient cultures, as well as their tangible remains, archaeology encompasses the relatively new discipline of geomythology, the study of oral traditions that perpetuate memories of prehistoric geologic events, such as earthquakes, floods, and volcanic eruptions. Geomythology provides not only some of humanity's oldest surviving verbal responses to volcanic activity but also some basic terminology for describing volcanic phenomena. The term "volcano" derives from the name of Vulcano, an Aeolian island in which Vulcan, the Roman god of fire and metalcraft, was believed to have set up his blazing smithy. When busy working, Vulcan employed a giant bellows that roared and sent huge sparks rising skyward. Vulcan's earlier Greek counterpart, Hephaestus, similarly a god of fire and the forge, was said to have landed on the volcanic island of Lemnos when Zeus, king of the Olympian gods, threw him from heaven, presumably accounting for the long-lived thermal activity there.

As the tale of Vulcan's noisy workshop implies, the myths of classical Greece and Rome reflect the volcanic nature of the eastern Mediterranean. In his *Theogony*, an epic poem about the origin of the Greek gods, Hesiod (c. 750 B.C.) describes a cosmic battle between Zeus and his giant enemies, the Titans, that depicts the conflict as it were a violently explosive eruption, perhaps a mythic echo of the Thera paroxysm. Hesiod also narrates Zeus's defeat of another fiery opponent, the dragon Typhoeus, using similar volcanic imagery. According to the dramatist Aeschylus in his *Prometheus Bound*, Zeus finally imprisons Typhoeus, an embodiment of primal chaos, under the bulk of Mount Etna, Europe's largest and most active volcano. Aeschylus's etiological account thus explains Etna's outbursts as Typhoeus's struggles to escape his subterranean prison, his fiery breath melting rock to produce outpourings of lava that endanger human settlements.

### B. A North American Myth: The Formation of Crater Lake, Oregon

The largest Holocene eruption in North America, that which decapitated Mount Mazama about 7500 years ago

to form the caldera holding Crater Lake in the Cascade Range of southern Oregon, deposited ash over a half million square miles and, without a doubt, had an impact on the lives of countless prehistoric Native Americans. Although researchers have not yet been able to correlate the physical effects of Mazama's eruption on the flora and fauna of eastern Oregon, native survivors of the volcanic holocaust apparently were so deeply impressed by it that they created an exceptionally long-lived oral tradition about the event. However improbable it seems, oral accounts of the eruption must have been transmitted through approximately 250 generations!

In 1865, Lalek, an aged member of the Klamath tribe, told William M. Colvig, then a young soldier stationed at Fort Klamath, Oregon, the story of a battle between Llao, an underworld deity who inhabited Mount Mazama, and Skell, a sky god who dwelt atop Mount Shasta, 125 miles to the south. Although it ascribes volcanic phenomena to the tempestuous rivalry between two supernatural figures, Lalek's tale includes geologic facts then unknown to white settlers, including the extreme devastation wrought by Llao's flaming mountain and its subsequent collapse to create the basin now occupied by a lake almost 2000 feet deep. The fact that Mazama once towered high above neighboring peaks and that its former summit subsided rather than blew apart was not generally recognized by geologists for many decades after Lalek's time.

### C. The "Bridge of the Gods" and Cascade Volcanism

About 200 miles north of Crater Lake, native tribes living along the Columbia River Gorge of the Pacific Northwest transmitted to early missionaries other ancient myths involving seismic and volcanic events. Perhaps the best known of these concerns the "Bridge of the Gods," a natural formation that reputedly once spanned the Columbia River near the present site of Cascade Locks, Oregon. Although it is probably now impossible to disentangle later embellishment and Caucasian interpretation from the original tradition, a Klickitat account reflects some of the region's actual geologic history. According to Klickitat storytellers, long before white people appeared on the scene, native tribes were able to cross the Columbia via a land "bridge" that was *tomanowos*, a creation sacred to the gods. But when the tribes became greedy and quarrelsome, *Tyee Sahale* (commonly translated the Great Spirit) took steps that eventually led to the bridge's destruction. First, he

caused all the fires in their lodges to go out. Only the fire maintained by Loowit, an aged lady who avoided the violence that divided her people, remained burning, so that all her neighbors had to come to her to reignite their campfires. When *Tyee Sahale* asked Loowit to name a reward for her generosity, she instantly demanded youth and beauty. Transformed into a lovely young woman, Loowit inadvertently rekindled the fires of war, attracting two intensively competitive brothers, Pahto, who ruled over territory north of the Columbia, and Wyeast, who led the Willamette people south of the river.

When Pahto and Wyeast contended furiously for Loowit's favor, hurling red-hot boulders at each other, *Tyee Sahale* separated them by destroying the *tomanowas* bridge linking their two territories, its fragments creating the cataracts for which the neighboring Cascade Range was later named. The Great Spirit also changed the three principals of this love triangle into volcanic mountains: Pahto became the broad-shouldered giant that white settlers called Mount Adams; Wyeast became Mount Hood; and Loowit, Mount St. Helens. Although St. Helens's two alpine suitors repeatedly thundered their passion, the temperamental St. Helens (whom some tribes named *Tabonelatclab*, fire-mountain) remained active longest, her 1980 outburst continuing the lovers' saga into the late 20th century.

An etiological myth explaining the eruptive behavior of three sentinel peaks guarding the lower Columbia, the Bridge of the Gods tradition also evokes memories of an enormous avalanche (the Bonneville Landslide) that completely dammed the river between about A.D. 1100 and 1250, forming a causeway that allowed the Indians to cross the river dry-shod. (Because the local tribes had no word for "bridge," the notion that this formation was a soaring natural arch is a Caucasian invention.) It is possible that some of the large basaltic blocks forming the landslide dam remained in place long after the river cut a new channel through its southern toe. If so, the famed Bridge of the Gods was in fact a chaotic pile of lava slabs (a native leader described the formation to a French missionary as "a long range of towering and projecting rocks") before it collapsed, possibly in the Cascade Subduction Zone earthquake of January of A.D. 1700.

### VIII. SUMMARY

In many important ways, volcanoes have proven a boon to the science of archaeology. Widespread deposits of

ash create valuable time-markers, helping to date artifacts associated with a distinctive ash layer. Unusually large eruptions of tephra that have been dated by radiocarbon or other methods, such as those produced by the Thera volcano (traces of which have been found from eastern Crete and the Aegean sea floor to central Turkey) and Oregon's ancient Mount Mazama (which mantled almost the entire Pacific Northwest and southwestern Canada), can provide even greater precision in dating objects found directly covered by the tephra. Because even exceptionally large explosive eruptions typically last for only a few hours or days, in a single moment of time, they are able to bury nearby cities and other settlements with great rapidity, preserving, as at Pompeii, Herculaneum, and Akrotiri, the whole gamut of a culture's material artifacts. Volcanic outbursts also inspire survivors to create richly imaginative traditions about the supernatural forces that precipitate such terrifying manifestations of power, generating some of the world's most intriguing myths.

## GLOSSARY

**classicism** The type of art that was characteristic of Greek and early Roman culture. It was revived in Florence in the 15th century, when it was often regarded as the highest point that art could reach.

**edo painting** The style of painting typical in Japan up to the mid-19th century, before the arrival of a strong western influence in art.

**genre** A type of painting showing realistically scenes from everyday life; a category or style of art.

**iconography** The study of the symbolic meaning of objects, persons, or events depicted in art.

**impressionism** A type of realism in art, with the aim of showing the immediate impression of the scene on the artist, mainly in terms of the representation of light.

**neoclassicism** An art form that was the result of the revival of interest in Classical forms and values in the 18th century, largely due to the discoveries of ancient Greek and Roman classical art works during the 18th century excavations in Pompeii and Herculaneum.

**picturesque** In the late 18th century, European people began to travel specifically to enjoy the scenery, seeking out spectacular natural scenery, ruined castles, and unusual sights. Picturesque tourism coincided with the rise of landscape painting and a romantic celebration of the landscape in art. It is an art form that is first and foremost an expression of our worship of Nature.

**romanticism** An attitude in art and literature that stems from the 19th century philosopher Rousseau, where moral passion counted for more than intellectual analysis, and where principal values were sincerity, authenticity, and moral exaltation.

**sublime** Nature overwhelming the onlooker and filling him with awe for its unpredictable force. The epitome of the sublime in art is the terrifying spectacle of a volcanic eruption.

**Ukiyoe** Traditional Japanese woodblock color prints, generally portraying the ever-changing world of the city or village. This form of print popularized the landscape in Japanese art in the 18th century.

---

## I. INTRODUCTION

Volcanoes create the most beautiful landscapes in the world. No one who has viewed the symmetry of Fuji volcano in Japan will forget its esthetic profile, defined by a perfect catenary curve. Volcanic mountains are associated with a great geologic process which has resulted in the construction of a fascinating variety of landforms, but the spectacle of volcanoes goes far beyond their pleasing landscape form. Their eruptions are exciting and thrilling because they are dangerous and exceed all natural catastrophes known to man in their explosive release of energy; they are without doubt the most spectacular natural phenomenon witnessed by humans. In terms of the cultural context of the 19th century, volcanic eruptions are sublime, invoking an expression of terror, awe, fascination, and savage beauty. They are also amongst the most stunning of visual phenomena, as they display an overabundance of fire, light, energy, and terror on the grandest scale. It is therefore not surprising that volcanic eruptions have been a subject for landscape artists in the western world from the 16th century to our time. Similarly, because of their purity of form and mythological significance, volcanoes have also featured prominently in Oriental art, particularly in the treatment of Japanese landscape pioneered by Hokusai in the early 19th century. This chapter discusses the artists' vision of volcanic eruptions in painting from the earliest examples to our time. The topic is vast in scope, and only a few examples of the principal and better known works can be given here. Table I lists over 90 artists who have painted volcanic eruptions or related phenomena.

---

## II. THE BEGINNINGS OF LANDSCAPE PAINTING

Artists began to paint volcanoes and other landscape forms in the Renaissance, the period of artistic creativity which began in the 15th century and brought us genius

such as Copernicus and Leonardo da Vinci. In Renaissance culture, art and science were closely associated and were in fact almost interchangeable types of mental activity, as both were stimulated by a new vision of the Earth, humans, and the world as a whole. Through its representation of objects in their true proportions, for example, Renaissance art opened the door for a new methodology in the empirical sciences, whereby scholars could accurately demonstrate their findings in drawing or illustration. The impact of art on anatomy and on the biological sciences is well known. Similarly, in geology, the storing of information and observations through the new dimension in art led to advances in the study of fossils and minerals by simply enabling communication through graphic representation of natural objects.

The study of landscape advanced much more slowly. There are glimpses of natural scenery in some Medieval manuscripts, and, in the Renaissance, admirable landscapes were portrayed by some artists, such as Leonardo da Vinci's graphic panoramic drawing of the Arno Valley in Italy, but on the whole the study of landscape did not captivate artists and scholars until late in the 17th century. By that time, the surveying of the land and the development of geography had opened the realm of landscape to the human mind and made the study of the Earth's wrinkled surface a worthy and manageable topic for art and science. During the age of Romanticism, which began in the late 18th century, admiration for the wilder natural phenomena, such as mountains, storms, and waterfalls, is abundantly expressed in landscape art. Another phenomenon common in Romantic landscapes are volcanic eruptions, which also inspired exhilarating terror and most dramatically expressed the sublimity of nature.

After their common origins in the Renaissance, science and art have steadily and inexorably diverged from one another on their separate cultural paths. This regrettable trend has developed to the point of schism in our modern society, where these two cultural pursuits are in practice often mutually exclusive, in contrast to their unity in the Renaissance age. The gradual parting of the ways was of course an inevitable consequence of the cultural specializations which our structured society imposes on its members, and in our age, the division has reached a level where most artists and scientists are largely illiterate in each other's fields. It is, for example, ironic and symptomatic that Roger Brown's painting of the Mount St. Helens 1980 eruption is styled after an industrial oil refinery fire, displaying surprising ignorance of a volcanic process, and harking back to the Medieval concept that volcanic eruptions were the con-

TABLE I Artists and the Volcanoes They Painted

Artist	Volcano
Cesare Ripa (ca. 1550), Italian	Etna
Pieter Bruegel (1528–1569), Dutch	Vesuvius 1558, 1561, Monte Nuovo
Annibale Carracci (ca. 1594), Italian	Etna
Filippo D'Angeli (1587–1640), Italian	Vesuvius 1631
Didier Barra (1590–c.1650), French	Vesuvius
Guercino (Giovanni Francesco Barbieri (1591–1666)	Vesuvius
Claude Lorrain (1600–1682), French	Vesuvius (1631)
Micco Spadaro (Domenico Gargiulo; 1609–1675), Italian	Vesuvius (1631)
Scipione Compagno (?–c.1670), Italian	Vesuvius (1631)
Salvator Rosa (1615–1673), Italian	Etna (Empedocles)
Thomas Wijck (1616–1677), Dutch	Vesuvius
Johannes Lingelbach (1622–1674), German	Vesuvius 1669
Jan Wyck (17th century), Dutch	Vesuvius 1689
Antonio Joli (1700–1770), Italian	Vesuvius
Claude-Joseph Vernet (1714–1789), French	Vesuvius 1748
Carlo Bonavia (18th century), Italian	Vesuvius (1757)
Katsukawa Shunsho (1726–1793), Japanese	Fuji
Pierre-Jacques Volaire (1729–1802), French	Solfatara, Vesuvius (1777)
Joseph Wright of Derby (1734–1799), English	Vesuvius 1774
Tomasso Ruiz (18th century), Italian	Vesuvius (1737)
Jacob Philipp Hackert (1737–1807), German	Vesuvius 1774, 1779
Michael Wutky (1739–1822), Austrian	Vesuvius
Pietro Antoniani (1740–1781), Italian	Vesuvius 1767
Pietro Fabris (?–1784), Italian	Vesuvius 1776, Solfatara, volcanic rocks
Jacob More (1740–1793), English	Vesuvius 79 A.D.
Angelica Kauffmann (1741–1807), Swiss	Vesuvius 79 A.D.
Jean-Louis Desprez (1743–1804), French	Vesuvius 1779
Alessandro D'Anna (1749–1810), Italian	Vesuvius 1794, Etna (1766)
Xavier Della Gatta (?–1827), Italian	Vesuvius 1794
Jean-Baptiste Genillion (1750–1829), French	Vesuvius
Giovan Battista Lusieri (1755–1821), Italian	Vesuvius 1787, 1794
Saverio Della Gatta (1755–1827), Italian	Vesuvius
Odoardo Fischetti (late 18th century), Italian	Vesuvius (1805)
Camillo De Vito (c.1760–c.1830), Italian	Vesuvius (1794, 1820, 1822, 1828)
John Webber (1751–1793), English	Krakatau
Pierre-Henri de Valenciennes (1750–1819), French	Vesuvius (A.D. 79)
Katsushika Hokusai (1760–1849), Japanese	Fuji
Joseph Franque (1774–1833), French	Vesuvius (A.D. 79)
Joseph Mallord William Turner (1775–1851), English	Vesuvius, Soufriere of St. Vincent
John Vanderlyn (1775–1852), American	Vesuvius (A.D. 79)
Martin Johnson Heade (19th century), American	Omotepe, Nicaragua, 1867
William Hodges, American	Mauna Loa
Jacob Munch (1815), Norwegian	Vesuvius

Francois-Joseph Heim (1787–1865), French	Vesuvius allegorical
Johann Christian Dahl (1788–1857), Norwegian	Vesuvius 1820–1823
John Martin (1789–1854), English	Vesuvius (A.D. 79)
Keisai Eisen (1790–1848), Japanese	Fuji
Sebastian Pether (1790–1844), English	Destruction of Pompeii A.D. 79
Jean-Baptiste Louis Gros (1793–1870), French	Popocatepetl
Utagawa Hiroshige (1797–1858), Japanese	Fuji, Sakurajima
Carl Rottmann (1797–1850), German	Etna, Santorini
Karl P. Briullov (1799–1852), Russian	Vesuvius (Pompeii A.D. 79)
Titian Ramsay Peale (1799–1885), American	Kilauea
James Baker Pyne (1800–1870), English	Vesuvius 1856
Thomas Cole (1801–1848), American	Etna, Vesuvius
Johann Moritz Rugendas (1802–1858), German	Colima
Robert S. Duncanson (1802–1872), Afro-American	Vesuvius and Pompeii
Paul Kane (1810–1871), Canadian	Mount St. Helens
Raden Saleh (1816–1880), Indonesian	Merapi 1865, Vesuvius 1839
James Hamilton (1819–1878) American	Vesuvius (Pompeii A.D. 79)
Frederic Edwin Church (1826–1900), American	Cotopaxi, Sangay, Chimborazo
Louis Remy Mignot (1831–1870), American	Cotopaxi
Archibald D. Willis, New Zealand	Tarawera (1886)
Albert Bierstadt (1830–1902), American	Vesuvius 1868
Degas, Edgar (1834–1917), French	Vesuvius 1890
Charles Furneaux (1835–1913), American	Kilauea, Mauna Loa 1881
Jose Maria Velasco (1840–1912), Mexican	Popocatepetl, Iztaccihuatl, Orizaba
Auguste Renoir (1841–1919), French	Vesuvius
Masayoshi Tokonami (1842–1897), Japanese	Sakurajima 1895
D. Antonio Munoz Degrain (1843–1924), Spanish	Vesuvius
Jules Tavernier (1844–1889), French	Kilauea 1887
D. Howard Hitchcock (1863–1943), American	Kilauea, Mauna Loa 1896
Charles H. Woodbury (1864–1940), American	Montagne Pelee
Seiki Kuroda (1866–1924), Japanese	Sakurajima 1914
Dr. Atl (Geraldo Murillo; 1875–1964), Mexican	Paricutin, Popocateptl
Asgrimur Jonsson (1876–1958), Icelandic	Laki, Grimsvotn
Hiroshi Yoshida (1876–1950), Japanese	Fuji
Kawase Hasui (1883–1957), Japanese	Fuji
Johannes Kjarval (1885–1972), Icelandic	Volcanic landscapes
Diego Rivera (1886–1957), Mexican	Paricutin 1943
Saturnino Herran (20th century), Mexican	Legend of volcanoes
Ruyzaburo Umehara (1888–1986), Japanese	Asama, Sakurajima 1935
David Alfaro Siqueiros (20th century), Mexican	Volcanic eruption
Gudmundur Einarsson (20th century), Icelandic	Grimsvotn 1934
Ichien Somiya (1893–), Japanese	Sakurajima 1957
Alfredo Zalce (1908–), Mexican	Paricutin 1956
Misao Yokoyama (1920–1973), Japanese	Sakurajima 1956

sequence of the combustion of fossil fuels in the Earth. In contrast, many of the 17th century paintings of Vesuvius display details of eruption, pyroclastic surges and lava flows which indicate a high degree of understanding of the volcanological process, based on direct observation by an eyewitness.

The earliest visual representation of volcanic eruption dates to one of the oldest village cultures on Earth, which thrived on the Anatolian plateau in southeastern Turkey more than 8000 years ago. Excavation of this site, known as Çatal Hüyük, revealed a Stone Age town, with a long and rich cultural and artistic history, that flourished between 6500 and 5700 B.C. Numerous shrines found at the site attest to the development of religion and display a wealth of decoration, reliefs, and wall paintings. In their work the early artisans of Çatal Hüyük used rich colors and had a full range of pigments at their disposal, derived from a variety of minerals. They also manufactured fine artifacts of highly polished obsidian. A wall painting of an erupting volcano was found in one of the older shrines at a level carbon-14 dated to 6200 B.C. In the foreground is a group of domino-like rectangular houses, which represents the town, and in the background rises a twin-peaked volcano, ochre in color, and spotted with black dots, with an eruption spewing from the higher cone (see Fig. 3 in "Archaeology and Volcanism"). The eruption is portrayed as curved lines or spray above the crater, and the

dots on the cone and outside its outline may represent falling volcanic "bombs" or large pieces of semiliquid lava. The lines emerging from the base of the volcano may represent lava flows. Today the plain surrounding Çatal Hüyük is indeed dominated by the twin volcanic peaks of Hasan Dag and Karaca Dag, and it is very likely that this ancient painting represents an eruption of Hasan Dag. It has been proposed that the painting had religious meaning, but several factors may have motivated the artist: perhaps it was a response to the threat from the erupting volcano, a work to appease the powers of the underworld? Was it inspired by gratitude to the volcano, the source of valued obsidian? A large number of obsidian spearheads and other implements have been found in the excavations, and it has been suggested that the town derived much of its wealth from the obsidian trade. Or was the painting simply inspired by fear in witnessing Earth's greatest display of power?

Most of the known examples of early Roman landscapes have been unearthed at Pompeii and Herculaneum, the cities buried by eruptions of Mount Vesuvius. These landscapes show a variety of views, natural forms, cultivated lands, wooded groves, streams and harbors, populated by shepherds, farmers, nymphs and other mythological figures. Several Roman wall paintings of Vesuvius have survived in houses excavated from the A.D. 79 volcanic deposits in Herculaneum and Pompeii. A painting from the lararium of the House of the Cente-

FIGURE 1 This is one of the oldest surviving paintings of a volcano, and it was preserved for posterity due to the volcanic burial of a city. Before the eruption of A.D. 79, Vesuvius was covered with forests, vineyards, and other vegetation up to the summit crater, as shown in this Roman wall painting, found in the House of the Centenary in Pompeii. The figure draped in bunches of grapes is the god Dionysus (Bacchus), and the snake represents the household gods. Archaeological Museum of Naples.

nary in Pompeii shows the steep volcanic cone as it appeared before the A.D. 79 eruption (Fig. 1). The mountain is covered in vineyards and other vegetation to the top. In the foreground stands Dionysus (Bacchus) clad in a mantle of grapes. Thus the few images which can be identified as Vesuvius show it as a benign mountain, its slopes covered with an abundance of the vines which thrive in the rich volcanic soil. Of course, these

were painted before A.D. 79, but even after this time there is no evidence of a painter attempting to portray the awesome spectacle of the eruption. A violent eruption or any other catastrophe would be quite unsuitable as a wall decoration! Pliny Younger's vivid and stirring description of Vesuvius erupting would have to wait some 1700 years before its expressive, visual qualities could be appreciated.

During the Middle Ages, the only images associated with volcanoes are vivid, but symbolic pictures of flaming Hell, devils, and burning rocks found in illuminated manuscripts and frescoes. After 1400, with the Renaissance revival of classical culture, a new world view emerged as people began to examine the natural world around them and to consider mankind's place within it, but the first portrayals of a real volcano are not seen until around 1550. In Cesare Ripa's *Iconologia*, a handbook of symbolic personifications used by painters, "Sicily" is described as represented by a seated woman holding attributes that identify her as this particular island. Behind her is a representation of Etna volcano shown simply as a truncated, irregular pyramid topped by flames. This symbolic image does not attempt to show the actual appearance of Etna in particular or any volcanic eruption as observed in nature. A 1541 woodcut of Etna erupting in the *Cosmographia Universa* of Sebastian Münster indeed shows the volcano as icon (Fig. 2). The volcano, with the appearance of a block of wood, emits flames, with rounded boulders flying through the air, threatening the near-by town of Catania.

One of the earliest attempts at showing a more realistic view of Etna erupting was made in 1594 by the two Bolognese painters Annibale and Agostino Carracci, who decorated the Farnese Palace in Rome with fresco

scenes representing moral actions taken from classical literature. In one scene, we see an erupting Etna in the background. In the foreground two young men flee from the flames and smoke, carrying their mother and father on their backs to safety. This story of the legendary Catanian brothers was intended as a moral allegory, for unlike the Catanians who attempted to save material possessions and perished, the brothers showed filial devotion by rescuing their aged parents. The primary subject of the painting is the moral action of the brothers, and the volcano is relegated to the background providing a reason for this heroic deed but stimulating little interest in itself. This portrayal of an eruption is unusual at this time, for neither Etna nor Vesuvius appear in a landscape for another 40 or 50 years.

Volcanic eruptions have been witnessed and described by mankind for thousands of years in many parts of the world, but it is mainly within the past 300 years, since the Renaissance, that the subject has appeared in the visual arts. In fact, most paintings of volcanic activity have been produced only since the latter half of the 18th century when the birth of scientific investigation and systematic observation of the workings of nature stimulated an interest in unusual and marvelous phenomena, which most people would never actually see in their own lives. Before artists could represent volcanic eruptions and the human reaction to them, they had to create a visual vocabulary for such depictions. It was therefore necessary to invent an iconography of volcanoes, which until the 18th century had rarely been seen in painting. Volcanoes were not part of the standard schema for landscape painting, which had developed during the Renaissance. Most European artists would have been totally unfamiliar with the appearance of an eruption. Furthermore, volcanoes had no place in the range of conventional subjects of the arts: Biblical scenes, mythological themes and genre, that is, views of common folk at work or play.

The European exploration of distant lands, such as the East Indies in the 16th century, revealed many new volcanoes, whose topography and eruptions were at times documented in art. Such is the case with the early 17th century eruption of Gunnung Api in the Banda Islands in Indonesia (Fig. 3).

FIGURE 2 An eruption of Etna volcano, shown in a woodcut from the *Cosmographia Universa* of Sebastian Münster, from 1541 (author's collection).

### III. VESUVIUS 1631 ERUPTION

In 1631 Vesuvius erupted with a violence it had not demonstrated since ancient times. This catastrophe

FIGURE 3 Engraving from 1631 of an eruption of Gunung Api volcano in the Banda Islands in the South Moluccas. An early 17th century example of the representation of a volcanic eruption (author's collection).

killed over 4000 people and devastated the population of Naples, as has been recorded in several vivid eyewitness accounts. The event is described not only as frightening but also spectacular to see. By this time, Italian artists had developed a full range of techniques for portraying landscape images with convincing naturalism, and there are several pictorial records of this eruption. As a result of this eruption, a new interest and direction in the

depiction of volcanic eruptions arises in the 17th century. Rather than purely documentary or religious, the volcano itself becomes the focus as a powerful, awe-inspiring phenomenon. A sketch by Filippo D'Angeli shows a view of the 1631 eruption from the harbor, with people fleeing, and a lightly rendered view of Vesuvius with line suggesting flames and lava (Fig. 4). The main focus of the drawing, however, is Saint Gennaro (St.

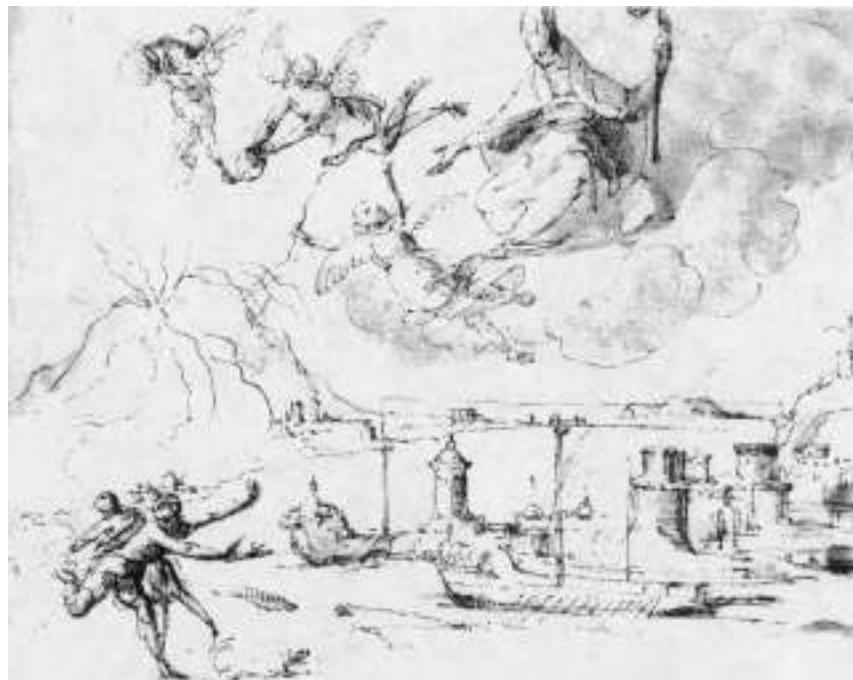

FIGURE 4 As seen by the contemporary Neapolitan artist Filippo D' Angelo, the 1631 Vesuvius eruption brought out Saint Gennaro, the patron saint of Naples, and his helpers, serving as a fire brigade, but the eruption also caused panic among the citizens. Janos Scholz collection, Pierpont Morgan Library, New York.

Januarius), the patron saint of Naples, in the heavens. Januarius gestures toward Vesuvius while three angels pour down water in an attempt to quench the flames. In essence, this is still a symbolic representation expressing the hope of averting the eruption, rather than recording its spectacle. The image of the saint is unremittingly tied to the volcano, and the saint's duty, in the eyes of the populace, is to avert volcanic catastrophe. If the saint fails in his duty, the people may take strong measures, which include attacking the images of the

saint himself. During the unusually violent Vesuvius eruption of 1872, the people of Campania felt totally abandoned by the patron saint, and attacked the statue of Saint Gennaro in anger (Fig. 5). A detailed and finished contemporary view of the 1631 disaster can be seen in a painting by Micco Spadaro, who also witnessed this eruption. A city square is shown from above to display the crowds in a procession, to invoke the protection of St. Januarius whose relics are carried by the clergy. The saint and angels can again be seen hovering in the clouds,

FIGURE 5 The Neapolitan population attacking the statue of Saint Gennaro, patron saint of Naples, when their appeals to the saint failed to stop the April 1872 Vesuvius eruption (*Harper's Weekly*, June 1872).

while in the distance Vesuvius belches forth flows of ash. Another contemporary artist, Scipione Compagno also painted two views of the eruption, which focus more on Vesuvius itself. What is particularly interesting in these paintings is the phenomenon of ground-hugging surge clouds, that sweep down the slopes of Vesuvius—a process that these artists clearly witnessed. If the early 20th century volcanologists had only bothered to look at these paintings, they would have appreciated that the deadly phase of the eruption was associated with surges and pyroclastic flows and not with mud flows.

---

#### IV. EMPEDOCLES LEAPS INTO ETNA

A remarkable volcanic painting by the Neapolitan painter Salvator Rosa also dates from this time. It portrays the Greek philosopher Empedocles hurling himself into the flaming crater of Etna in order to commit suicide (Fig. 6). According to ancient legends he had done this so that the followers of his philosophy would believe he had disappeared from Earth and thus gained godlike immortality. The truth became known when the philosopher's followers found one of his sandals at the crater's edge. Rosa's Empedocles hurtles headlong into the turbulent, steaming crater, his fluttering robes and outflung arms echoing the shapes of the rocks and clouds. He seems to merge with the volcano, a small man lost in the immensity of nature's turbulence. Painting toward the end of his life, in 1666, Rosa, who was something of a poet and philosopher as well as painter, intended the volcano as a metaphor for uncontrolled creative inspiration which can overwhelm the artist. Although he took the idea from a poem by Horace, this is the first time the image appears in painting. The volcano has taken on new meaning, and its violent spectacle, unpredictability, and deadly might are exploited for their aesthetic qualities. The idea that an eruption, even while destroying life, could contain beauty worthy of artful speech or painting was developed by Rosa and others in the 17th century, and it helped to create a taste for the marvelous, unusual, and awesome in nature. The style that captured these qualities was termed the sublime, that which was great and inspired feelings of awe, fear, and amazement in the spectator.

In a treatise on the art of painting published in 1715 by Jonathan Richardson, the superiority of visual expression over verbal description was exemplified by an eruption of Etna. The poets since classical times had de-

FIGURE 6 Empedocles leaping into the crater of Etna. The Greek philosopher Empedocles lived in Sicily and studied the activity of Etna. He had novel ideas about volcanic activity, but legend has it that he took his life by secretly jumping into the crater of Etna, in order to convince his pupils that he had ascended to heaven. Brown ink and chalk drawing by Salvator Rosa, ca. 1666 (Galleria Palatina, Palazzo Pitti, Florence).

scribed eruptions, but how much more effective a picture could be when the whole scene opened up at once! The taste for the sublime became most popular in England after the 1757 publication *A Philosophical Enquiry into the Origin of Our Ideas of the Sublime and the Beautiful* by Edmund Burke. He defined the "beautiful" as something that is well-proportioned, graceful, smooth, clear, quiet, and harmonious, a prospect which elicits an emotional response of calm, security, and joy. In striking contrast Burke's "sublime" contains darkness, noise, overwhelming magnitude, stenches, and sudden danger that evokes emotions of terror, fear, and pain. This notion suggests an earthquake, terrible storm, or a volcanic eruption as an ideal sublime image and experience filled with the sights and sounds of uncontrolled forces, immensity, darkened skies, stinking fumes, harsh lights,

burning, and perhaps death. The sublime is not seen as the opposite of the beautiful, but as an alternative aesthetic taste. This taste soon became widespread among the cultured, art-loving classes, an audience now attuned to seeing the terrifying as pleasing—and for them a volcanic eruption was the ultimate sublime experience.

---

## V. THE NEAPOLITAN SCHOOL

From the middle of the 18th century, the subject of Vesuvius in eruption became increasingly popular in painting, gouache, and prints. These were frequently produced as souvenirs for the English, German, and French gentlemen and ladies who came to Italy on the Grand Tour, a highlight of which was a visit to Naples and Vesuvius. Luckily for the travellers, Vesuvius became very active once again and was in frequent eruption from the 1730s through the end of the century. It was a great tourist attraction for those who could safely view the fiery lava and clouds of smoke from a distance, a scene they would later recall back home in London or Paris—where they could share their sublime experience with friends through these colorful works of art.

Claude-Joseph Vernet arrived in Naples in 1734, where he had a profound and pioneering influence on the painting of Vesuvius, establishing a formula for the representation of its eruptions. In his numerous works, the fiery glow of molten lava is shown silhouetted against the night or ash-darkened sky, with the steely blue cool light of the moon in strong contrast. In the foreground, relatively tiny human figures gesticulate toward the eruption in a mixture of wonder, terror, and admiration. Many contemporary artists adapted this scheme of volcano painting, such as the English Joseph Wright of Derby, the German Jacob Phillip Hackert, the Austrian Michael Wutky, and later the Norwegian Johann Christian Dahl. Vernet's most prominent pupil, Pierre Jacques Volaire, stayed in Naples for 20 years and established himself as Vesuvius' visual biographer. His painting of the *Eruption of Vesuvius in 1771* epitomizes this genre. He plays the burning red against the ice cold blue, a fiery lava fountain illuminates red clouds of steam and a river of molten lava contrasts with the silvery moonlight and the tranquil Bay of Naples on the other side. In earlier times Vesuvius, the powerful, earth-shaking giant, might have been represented as a Cyclops at the forge, a fiery, muscular figure, but now the mountain itself takes on the characteristics of sublime beauty. The dark side of Nature had become worthy of portrayal,

and these artists arranged their compositions and choice of colors to convey both the actual appearance as they observed it and the dramatic artistic effects. No longer does St. Januarius hover protectively over Naples; now the figures are excited spectators who study and enjoy the phenomenon.

Natural catastrophes and landscape were among the subjects which were considered potentially sublime in late 18th century painting in Europe. In no subject matter, however, did the catastrophic possibilities become as manifest as in the painting of volcanic eruptions, as was demonstrated by the paintings by Joseph Wright of Derby of the eruptions of Vesuvius. Wright had climbed the volcano in 1774 and witnessed its eruption, and his pictures of this subject are startling for their vividness of colors and tumultuous movement of the volcanic emissions. His views of the volcano were both at the very edge of the crater, from within the crater, or from a great distance, such as in *Vesuvius from Posillipo*, creating scenes that were almost too intense to be natural. One of the paintings of Vesuvius from this time, and most pleasing to modern taste, is a gouache study of 1774 by Wright of Derby. The reddened mountain and billowing gray smoke are made in a sketchy, soft manner with emphasis on the color and shapes. Here there are no small fleeing figures or scientific observers but simply the volcano in splendid isolation.

The German artist Jacob Philipp Hackert was also attracted to Italy by the strength of the 17th century Roman landscape tradition. He became the court painter for King Ferdinand IV in Naples, where he had ample opportunity to paint Vesuvius in action. Many of his views of Vesuvius erupting are remarkable because of the close-up of the volcano in action and are closer to a geological study than most other paintings of the mountain, in particular his painting of *The Eruption of Vesuvius in 1774* (Fig. 7). This emphasis on scientific process may have been influenced by Hackert's close association with the pioneer volcanologist William Hamilton, also a resident of Naples.

---

## VI. NEOCLASSICISM

When Herculaneum was discovered out of the ashes of Vesuvius in 1709, and Pompeii in 1748, European artists became fascinated by the great eruption of A.D. 79 and by the cities which had been buried in layers of ash, as well as the newly revealed classical culture. The recovered buildings and artifacts quickly promoted a taste for

classical styles in furniture, clothing, and art, and the evidence of the inhabitants's swift deaths, and the immensity of destruction further stimulated fascination with the sublime. Paintings which depicted scenes of this ancient catastrophe were now made, along with the landscapes of Vesuvius as it looked in modern times.

In 1785 the Swiss painter Angelica Kauffman made a painting based on the events of 24 August A.D. 79 as described by Pliny Younger (Fig. 2 in "Introduction"). The young Pliny and his mother are shown in the courtyard of their villa at Misenum where a friend urges them to flee before it is too late. In the distance, framed within the archway of a gate is Vesuvius, an outline on the horizon shooting forth lava, pumice, and ash. The sky is dark and the waves on the usually calm sea are agitated. The only suggestions of sublime emotion here are the expression and gestures of the two frightened women on the steps down to the sea. The painting has the cool, detached crispness and clarity typical of Neoclassicism. The artist has recreated a historical moment in which the human figures dominate, rather than the volcano.

A more emotional version on the subject of the A.D. 79 eruption of Vesuvius can be seen in a spectacular painting by Pierre Henri de Valenciennes in 1813. Now in the Romantic era, the sublime becomes even more powerful through emotional and imaginative imagery to emphasize the horror of the moment in the appearance of the sky, brilliant color, and small-scale figures. Valenciennes also used Pliny's letters as a source, in a scene where his uncle Pliny Elder is carried by two slaves as he succumbs to choking clouds of fumes issuing

**FIGURE 7** *The Eruption of Vesuvius in 1774* by the German artist Jacob Philipp Hackert (1737–1807), the court painter for King Ferdinand IV in Naples. The painting is an unusual close-up view of an erupting volcano, with pioneer volcanologists clambering right up to the vent on the volcano's flank to get a closer look. The Hessen State Collection, Germany. (Also see color insert.)

**FIGURE 8** In 1832 the Russian artist Karl Briullov painted *The Last Day of Pompeii*, a representation of the catastrophic 79 A.D. eruption and its effects on Pompeii. It is the quintessential example of Neoclassicism, with Greek and early Roman architectural and physical forms juxtaposed to the terror of the volcanic eruption. The State Russian Museum, St. Petersburg. (Also see color insert.)

from the volcano. This subject had been painted as early as 1780 by Jacob More in *Mount Vesuvius in Eruption: The Last Days of Pompeii*, but the subject became increasingly popular through the 19th century in many versions that stressed the physical agony, fear, and other sublime emotions in romanticized paintings. This was especially true after the 1834 publication of Bulwer-Lytton's tremendously popular novel *The Last Days of Pompeii*. Vesuvius in eruption was interpreted as divine retribution for wicked mankind; corrupt civilization was contrasted with the purity of nature.

In 1833 the Russian artist Karl Briullov painted a huge composition titled *Last Day of Pompeii*, which was inspired by the opera by Pacini: *Ultimo giorno di Pompeia*, performed in Naples 1827. Briullov had visited the excavations of Pompeii, and the sight of the city buried by layers from the great A.D. 79 eruption astounded the artist. He became captivated by the idea of sudden interruption of life by this great natural catastrophe. Briullov made many sketches of the composition and then began a study of historical documents of the excavations of Pompeii as well as Pliny Younger's description of the A.D. 79 eruption, in order to create authenticity and to follow the Romantic principle of historical truth (Fig. 8).

## VII. TURNER'S FIRE

By far the most notable artist to paint volcanic eruptions was Joseph Mallord William Turner (1775–1851).

Turner was the greatest British painter of his age and probably the greatest painter England has ever produced. He was both by training and inclination a true landscape painter in the tradition of the picturesque sublime, and his choice of subject matter included apocalyptic and catastrophic topics. He had a brilliant gift to translate onto canvas the most fleeting effects of light, such as a passing storm, sunrise, or dissolving mist. In 1817 Turner painted *Vesuvius in Eruption*, creating a work that has a sense of volcanic energy and the spectacle of light that is unique to this artist. However, Turner's basic treatment of the eruption follows the 18th century formula: a white to red-hot fire fountain out of the central cone, reflected on the Bay of Naples, a cool blue-gray sky with a crescent moon in the background, contrasting with the conflagration around the volcano. Lightning and the arched trails of glowing volcanic bombs are shown by generous use of a scraping-out technique.

Turner's earliest painting (1815) of a volcanic eruption is *The Eruption of the Souffrier Mountains, St. Vincent*. In April 1812 the Soufriere volcano on St. Vincent in the Caribbean erupted explosively. The eruption resulted in ash fall on the island of Barbados to the east and produced deadly hot ash flows down the flanks of the volcano. The eruption blasted out a new crater in Soufriere's summit and killed many of the Carib Indians living on the volcano's slopes. News of the eruption spread with the British colonialists to England, and these reports stimulated Turner to put his impression of this volcanic eruption on canvas. Turner wrote these lines in the catalogue published at the first Royal Academy showing in 1815:

Then in stupendous horror grew  
The red volcano to the view.  
And shook in thunders of its own,  
While the blaz'd hill in lightning shone,  
Scattering their arrows round.  
As down its sides of liquid flame  
The devastating cataract came,  
With melting rocks, and crackling woods,  
And mingled roar of boiling floods,  
And roll'd along the ground.

In 1815 another volcanic eruption occurred in far-off Indonesia which may have influenced Turner's art in a fundamental way. The volcano Tambora erupted in 1815, lifting into the atmosphere more ash and volcanic gases than any other eruption in history. The atmospheric effects of the eruption included spectacular twilights of yellow and red skies in the years following the

event. Turner undoubtedly experienced this marvelous coloration of the skies caused by the aerosols or fine particles injected into the atmosphere after the eruption. Is it possible that Turner's fiery skies, for which he is so justly famous, were in this way inspired by the effects of a distant volcanic eruption of which he was unaware and would never hear of in his lifetime?

---

### VIII. HOKUSAI AND THE SPELL OF FUJI

At the time when Turner was executing his rich paintings of Vesuvius, there was at work in Japan an artist gifted with extraordinary powers of draftsmanship and design, who devoted much of his career to the imagery of Fuji volcano near Tokyo. Like Turner, Hokusai was the most eccentric of men and dedicated to his art with the passion and singlemindedness of a saint to his religion. Hokusai, like Minsetsu, Hiroshige, and other Japanese artists, was drawn to Fuji volcano, not because of its spectacular eruptions, but because of the veneration and idolatry for the volcano by the Japanese people. From 1823 to 1829 Hokusai created *Thirty-Six Views of Fuji*, often regarded as among his finest landscapes. The series of landscape colorprints includes the incomparable *Fuji in Clear Weather*. Here the calm selection of lines and graduation in colors bears the imprint of the woodblock printer's art (Fig. 9). In 1834–1835, he published another set of prints entitled *One Hundred Views of Fuji*. The earlier 36 landscapes are dwarfed by the eternal and monumental cone of Fuji, which hints at the transitoriness of human life. Is it the gentle curve of the cone, with its near-perfect geometric form, sweeping the eye to the sky, which has led to Japanese idolatry of this volcano? Or was it based on fear because of the history of Fuji's deadly eruptions? The phenomenon is outside our western experience, and thus we miss some of the special significance that Hokusai's views of Fuji have for his countrymen. Already in the eighth century, Fuji was revered with superstitious awe, as shown for example in Manyoshu, one of the earliest poems of the Japanese language:

No words may tell of it  
No name know I that is fit for it  
But a wondrous deity it surely is!  
It is the peace giver, it is the god, it is the treasure.  
On the peak of Fuji, in the land of the Suruga  
I never weary of gazing.

FIGURE 9 *Fuji in Clear Weather*. Color woodcut by the Japanese artist Katsushika Hokusai (1760–1849). From the series *Thirty-Six Views of Fuji*, ca. 1830.

In the later 100 views, the curious and unexpected glimpses of Fuji, reflected in the sake-cup held by a tippler or seen through a bamboo thicket, transmute the ordinary into the memorable.

To my knowledge, Hokusai only executed one picture featuring a volcanic eruption, which is *The Upthrow of Mount Hoei* in his great book of woodblock prints *One Hundred Views of Fuji* published in 1834. In the winter of 1707, the great volcano exploded in one of the largest eruptions of the historical period. In this flank eruption, Fuji created a new cone or “hump” on the slope of the volcano that was named Hoei. In the woodcut *The Upthrow of Mount Hoei* Hokusai lets his imagination run free in what is an image of the effects of the eruption on the people and an utter demolition of their world (Fig. 10). The plate shows the terror the eruption and its associated earthquake created among the villagers living near the volcano. Rocks and stones are hurled from the new crater and showered down in destructive abundance over the village. Men, women, and children are tossed about the air, together with the debris of their ruined homes. Some villagers try to escape, dragging after them their fainted wives. The terrible eruption has created panic, destruction, and despair among the helpless folks. Fuji itself is not to be seen in this picture of chaos, but its effects are devastating. In the woodcut *Sono ni* in the same volume, Hokusai shows us the quiet volcano after the eruption (Fig. 11). The great eruption

of 1707 did not occur from the central crater but rather from a lateral vent on the southeast slope of the volcano, forming Hoeizan, an unsightly lump on the otherwise perfect profile of Fuji.

Hokusai’s colorprints achieved a compromise between representation of actuality on one hand and creation of an abstract design in color and line. His style of brushwork was consistent with the highest ideals of Japanese calligraphy. Hokusai’s prints lie between two opposing styles—the Japanese ancient Edo school, suggesting a landscape of the imagination, and the school of Western landscape artists, approaching as near as the oil or water color mediums will allow to a realistic representation of a certain place. His work had significant influence upon Western art in the direction of a new formalism and simplification (e.g., in the French Impressionists). Hokusai’s work was, however, most influential in Western book illustration and design.

A large number of other Japanese artists, who had mastered the color woodblock, were captivated by Fuji, including Keisai Eisen (1790–1848), Utagawa Hiroshige (1797–1858), Hiroshi Yoshida (1876–1950), and many others listed in Table I. In addition to Fuji, another volcano has received much attention among Japanese artists, particularly in the 20th century. This is Sakurajima in Kagoshima Prefecture in south Japan. Early studies of this volcano are shown in the oil paintings of Masayoshi Tokonami (1842–1897), who was a pioneer

in making the transition from Edo style painting to a more modern form of Western painting. Seiki Kuroda (1866–1924) also painted a number of works showing the 1914 eruption, which he witnessed. The dramatic Sakurajima landscapes of Ryuzabnuro Umehara (1888–1986) are Impressionistic works, but he studied under Renoir in France and was acquainted with Picasso. He successfully fused the traditions of Japanese and European painting, and his Sakurajima works brought Japanese art into another phase. Ichien Somiya (1893–) painted a close-up of the Sakurajima crater during the 1956 eruption. Perhaps the most striking works of Sakurajima is the 1961 painting *Island of Fire* by Matazo Kayama (1927–), where a modern approach to Japanese painting is combined with a traditional sense of design that turns the volcanic landscape into a fantastically designed fabric screen.

FIGURE 10 *The Upthrow of Hoei*. Woodcut by the Japanese artist Katsushika Hokusai (1760–1849), showing the effects of the 1707 eruption of Fuji on the local people. From the series *One Hundred Views of Fuji*, ca. 1830.

FIGURE 11 In the woodcut *Sono ni* Hokusai shows the changed profile of Fuji after the 1707 eruption, which took place from a lateral vent on the southeast flank of the volcano and created the cone of Hoei.

#### IX. AMERICAN EXPLORATION OF UNKNOWN VOLCANOES

With the opening of the American continent in the 19th century came the discovery of new worlds, which included volcanic mountains greater and more terrifying than any of the European experience. In the 1840s, a young Canadian artist, Paul Kane, was employed by the Hudson Bay Company to aid in the documentation of the Pacific Northwest. During his travels, he stumbled upon Mount St. Helens volcano, which he represented in a series of paintings, mostly in vigorous eruption. In the painting *Mount St. Helens Erupting*, Kane shows a fiery strombolian-like fountain rising out of a crater on the north flank and a dark eruption cloud billows away from the eruption column, watched by awestruck Indians.

ans in a canoe. The eruption site appears to be the Goat Rocks dome, a parasitic vent on the north flank, which was about 2000 feet lower than the summit of Mount St. Helens. Today there is no trace remaining of Goat Rocks: the entire north flank of the volcano was completely obliterated during the explosive eruption on May 18, 1980. Although Kane's view appears to be accurately observed and was intended as a scientific record, it is composed using the conventional formulae for the depiction of volcanoes that had developed during the 18th century in conjunction with Vesuvius. He shows the darkened sky, the silhouetted volcano, the fiery reflection on the water, and the small foreground figures who react with expressive gestures.

The most prominent American artist in the early 19th century belonged to the Hudson River School, which still contained residual elements of European influence. Thomas Cole (1801–1848) was the father of the Hudson River School of painting and one of the leading figures in the development of a national tradition of American art. His work was a mixture of devotion to natural scenery on one hand and illustration of moral truths on the other. Gradually, however his natural landscape themes gave way to the moral and allegorical themes and strong religious influences.

Several American landscape painters of the 19th century chose volcanic eruptions as subjects for painting, and Thomas Cole painted *View of Mt. Aetna* in 1844. The development of tourism as an aspect of leisure and education may have had a profound and stimulating effect on appreciation of landscape painting in America in the early 19th century. The appreciation of the wilderness grew with the developing middle class and urban elite, and people sought pleasure through tourism and developed a demand for views of the familiar and picturesque landscape. Cole, as one of the greatest landscapists in North America, was perfectly suited to meet this new demand, when fine art was becoming popular in the emerging American culture at large. Cole was the first American artist to tackle the wilder and untamed features of the scenery of American mountains. By 1825, his Romantic pictures of the Hudson Highlands and the Catskill Mountains had received attention, particularly because of their sublime representation of American mountain tops and inaccessible peaks.

Cole was a close friend of the geologist Amos Eaton, and Cole was also acquainted with the pioneer American geologist Benjamin Silliman. It is likely that Cole's interest in volcanoes may have been influenced by these friendships. Cole spent several years in Italy, including an extended stay at the foot of Vesuvius volcano in 1832. He ascended Mount Etna volcano in Sicily in 1842, but

the ascent of the volcano took a strong hold of Cole's imagination and formed the subject of four pictures. The famous painting of Mount Etna from Taormina took 5 days to paint. It was then sold for \$500 to the Hartford Lyceum, which was "pretty good for five days work," as Cole stated in a letter to his wife. The painting produces the effect of a huge and lofty mountain, whose summit is white in perpetual snow, while its slopes below are basking in perpetual summer. In this distant view from the northeast, a gentle steam plume rises from the main crater, and the northeast crater is also visible on the upper slopes. The height and steepness of the top cone are exaggerated in this painting to attain the sublime effect.

In the early 19th century, biblical ideas of a volcanic judgment day appear frequently in American poetry and art. In 1828, Cole painted the *Expulsion from the Garden of Eden*, where he introduced the more terrible objects of Nature including a volcano in violent eruption. Here Adam and Eve leave the sunlit paradise, to enter desolation and darkness, with all the elements raging against them—including a volcanic eruption towering overhead. Cole had not yet seen a volcano at this stage but borrowed the image from the conventional view of an eruption of the time.

The work of many early 19th century American artists reflects a viewpoint and a social evolution that has been referred to as Manifest Destiny—the Euro-American dream of discovering, exploring, and conquering an unspoilt and undeveloped terrain, toward creating an authentic American civilization. The works of Cole and his brilliant disciple Frederic Church reflected this spirit. Frederick Edwin Church (1826–1900) was a central figure in 19th century American landscape painting and prominent in the group of artists associated with the Hudson River School. But he was first and foremost an adventurer-explorer artist. As a former pupil of Thomas Cole, Church received the mantle of American landscape painting from the master who had carried it for an entire generation.

Church replaced the subjectivity of his romantic teacher with an objectivity perceived by a mind steeped in geology. He was particularly influenced by the writings of the great German geographer Alexander von Humboldt whose descriptions of South American volcanoes drew Church on his first expedition to Cotopaxi in 1853. Church was, however, primarily a product of the golden era of prosperity and cultural nationalism just before the Civil War, the years of Manifest Destiny, which fostered a New World authentic movement of painting and heroic art. Taken to its extreme, the faith of Manifest Destiny was the faith that natural history had

dictated Anglo-Saxon domination of the great American continent and regeneration of the whole world. Thus Church's art was premised on the Grand Design that the Creation existed for man.

Church's famous volcano painting *Cotopaxi* (1862) was painted early in the Civil War and dramatizes the struggle between the forces of darkness, represented by the belching volcano, and the forces of light. This work resulted from Church's travels to South America in 1857, when he was at the base of Cotopaxi volcano in Ecuador. In his painting *Cotopaxi*, he invokes the moment of creation itself. It is painted with the fidelity of a naturalist, yet the style suggests Earth's terrible power and Mankind's insignificance. His monumental South American scenes started with the *Heart of the Andes* in 1859. They attempt to combine into a single colossal scene the geological, meteorological, and botanical history of the continent, and his volcanic paintings metaphorically suggest a new world in the making. On his second journey to South America in 1857, Church made a trip to Sangay volcano in Ecuador. Traveling in the pathless wilderness of the high Andes mountains, Church ascended a ridge to obtain a view of the volcano, which rewarded him with a series of explosions:

*Above a serated, black, rugged group of peaks which form the crater, the columns arose, one creamy white against an opening of exquisitely blue sky, delicate white, cirrus formed, flakes of vapor hung about the great cumulus column and melted away into the azure. The other, black and sombre, piled up in huge, rounded forms cut sharply against the dazzling white of the column of vapor and piling up higher and higher, gradually was diffused into a yellowish tented smoke through which would burst enormous heads of black smoke which kept expanding, the whole gigantic mass gradually settling down over the observer in a way that was appalling.*

This experience resulted in his painting *Distant View of Sangay Ecuador*.

The great public following and admiration for the landscape works of Church and other American artists went into rapid decline in the late 19th century for reasons that can be attributed to an advance in science. By the 1880s, the Scientific Revolution sparked by Darwin's world-shaking theory of evolution had triumphed in the intellectual world. The concept of the Grand Design was shattered, and man's place in nature shifted from the heroic to the unheroic. Church was one of the victims of this revolution, and by the 1990s his work was all but forgotten.

Albert Bierstadt (1830–1902) was one of the artists

who discovered the grandeur of the American West and was the principal rival of Frederic Church. He became well known for his paintings of the spectacular mountainous vistas of the Rocky Mountains. Bierstadt's interest in volcanoes was kindled when he visited Naples in 1857 and climbed Vesuvius, resulting in the painting *Mount Vesuvius and the Bay of Naples*. His second treatment of the subject was painted in 1868, showing the volcano in full eruption, as seen from the upper slopes of Vesuvius, northwest of the crater, in a gaudy, almost fluorescent view.

---

#### X. HAWAIIAN ERUPTIONS

The painting of Hawaiian volcanoes begins with the visit of Robert Dampier to Hawaii in 1825. Another important interpreter of Hawaii's volcanoes was Titian Ramsay Peale, son of the noted American painter Charles Willson Peale, who painted the famous portrait of George Washington. The younger Peale traveled widely and was selected to participate as an illustrator in the U.S. Exploring Expedition of the South Seas (1838–1842) under the command of Lieutenant Charles Wilkes. On the fleet of six ships were a large number of naturalists and scientists, who collected a wealth of specimens which were returned to Washington, DC, and formed the nucleus of the National Museum of the United States in the Smithsonian Institution. One of the scientists on board was the American geologist James Dwight Dana. In September 1840, the expedition reached Hawaiian waters and remained near the volcanic islands until April 1841. A major eruption of Kilauea volcano had partly filled in the caldera with lava in 1839, which solidified to form the Black Ledge. During their climb on the flanks of Mauna Loa volcano, Peale sketched a view of the distant Kilauea, which he later used for the painting *Volcano Kilauea Pele*. The painting shows Peale's companions hiking across lava formations in the foreground, and in the background is the shield of Kilauea, fuming from the summit region and from the site of a recent eruption on the lower flank. When Peale reached the summit of Kilauea volcano, the Black Ledge was still about 200 m below the caldera rim and there was an inner pit, about 100 m deep below the Black Ledge, with several erupting lava pools on the floor. From this vantage point, he painted West crater "Kilauea Pele" from "Black Ledge," showing the outer caldera wall, inner Black Ledge, and the main firepit (Halemaumau).

Charles Furneaux (1835–1913) became the first of Hawaii's resident volcano painters. He arrived in Hawaii in 1880 with the volcano enthusiast William T. Brigham. At the time, an eruption of Mauna Loa produced a major lava flow, which advanced toward the town of Hilo. Furneaux took advantage of this opportunity to the fullest, and painted over 40 views of the advancing lava and other landscapes in connection with the eruption.

Jules Tavernier arrived in Hawaii in 1884 and can be credited with starting the Hawaiian "volcano school" of painting. He was born in Paris, and traveled widely in Europe and North America as an illustrator and writer. Upon arriving in Hawaii, Tavernier immediately went to view Kilauea, and from that day forward, the volcano became his chief subject, painting about 100 views of it during his stay in Hawaii. At this time, the caldera of Kilauea was flooded by a lava lake, and Tavernier devoted much effort to capturing this spectacle on canvas. Many of these paintings are based, however, on the Italian iconography of Vesuvius painting developed by Vernet in the 18th century, with the caldera shown at night, the glowing lava lake sluggishly rolling and flashing steam, surrounded by massive walls of lava cliffs, and the cold silvery moon emerging from the clouds in the background. One of Jules Tavernier's art students was the Hawaiian-born David Howard Hitchcock, whose output of Hawaiian volcano landscapes was enormous.

---

#### XI. DR. ATL—VOLCANOLOGIST AND ARTIST

In the early 20th century, the visual arts turned away from attempts at rendering the visible world and turned instead toward the representation of abstract forms. This may have been brought about in part by the invention of photography. Thus interest in landscape painting declined, and along with it, volcanoes vanished as part of the painted natural scene. One notable exception is the Mexican artist Dr. Atl, who showed the same devotion to Paricutin volcano that Volaire had shown to Vesuvius in the 18th century. In February 1943, a fissure opened in a farmer's cornfield in the state of Michoacan in western Mexico. A volcanic eruption out of the fissure threw up scoria and lava, which during the following 9 years built up the 410 m high volcanic zone known as Paricutin. In his vibrant, expressionistic paintings, Atl has recorded the actual birth of Paricutin producing a

unique pictorial biography of the volcano. Atl was a representative of Impressionism in Mexican art, but his simplified forms and details and brilliant coloring made his art highly personal and new.

Dr. Atl was one of the outstanding figures in Mexican cultural and political life in the first half of the 20th century. He was one of the original creators of Mexican landscape painting and a leading figure in the revolution in Mexican art. Thus he fought for the identity of national and racial consciousness in his nation's art, against the Spanish colonial past. The modern vision of Mexican landscape created by Dr. Atl is a reflection of the enthusiastic temperament, travels, and explorations of this man of culture and wide artistic experience. He spent whole seasons on the snow-covered peaks of the Mexican volcanoes, which he painted many times.

He made major contributions in art, literature, philosophy, poetry, history, revolutionary politics, and the science of volcanology. Jose Gerardo Francisco Murillo was born in Guadalajara, Mexico, in 1875. When he came of age, he renounced the Spanish name and took an Indian pseudonym, changing his name to *Atl*, meaning *water* in the Aztec language, to declare his separation from the dreary influences of the second-hand European culture into which he was born. He knew instinctively that the arts in Mexico were counterfeit, and he set out to rediscover or create a contemporary native art—striving for a renaissance of Mexican and pagan culture. At the age of 21, he was already noted in Mexico as an outstanding artist and writer. He traveled widely during a 7-year stay in Europe, Egypt, and China, but upon his return to Mexico in 1907, he took up mountaineering, which led to his lifelong affair with the volcanoes of his country. In Mexico City, he set about to revolutionize the Academy of San Carlos, where he lectured about the art of the Impressionists, but he also encouraged his students—including the young Diego Rivera—to paint out of doors and appreciate the drama of the Mexican landscape.

In 1912, he traveled to Italy, where he studied volcanology for a time under the expert guidance of Immanuel Friedlander and Frank A. Perret at the University of Naples—the leading volcanologists of the time. From this period, he began to combine his two primary interests in a unique manner—painting and volcanoes. Prior to the work of Dr. Atl, the only Mexican artist to paint the volcanoes was Jose Maria Velasco, who painted more than 200 Mexican landscapes, noted for their poetic realism and sensibility. He explored Popocatepetl before Dr. Atl's time and published texts and lithographs and engravings of the revered mountain. Several Mexican volcanoes had been painted earlier by European visitors,

such as the French artist Jean-Baptiste Louis Gros whose 1883 work shows in a vivid manner the sulfur encrustation of the interior of the crater of Popocatepetl, and numerous dramatic paintings of Colima volcano were executed by the German artist Johann Moritz Rugendas (1834).

Dr. Atl required a new medium to capture the striking colors of the Mexican volcanoes. He therefore invented the Atl-colors, which were, like pastel, for use on surfaces like wood, paper, plaster, fabric, and board. The colors were composed of wax, dry resins, oil color, and gasoline, manufactured in small bars like the sticks of sealing wax. The color itself is apparently unalterable, although the sticks can be melted like wax or dissolved in gasoline for spreading with a brush or palette knife.

The Mexican revolution at the beginning of the 20th century not only transformed the political and social fabric but also created a new tremendous flowering of artistic and intellectual creative energy that changed the course of Mexican culture. Intense nationalism reacted to the largely European-oriented culture of the regime of the dictator Porfirio Diaz. In 1910, Dr. Atl organized an exhibition of nationalistic paintings in honor of the centenary of Mexican independence, which has often been regarded as the beginning of the revolution in Mexican art. A few months later, the political revolution broke out, and Dr. Atl became a leader of the revolutionary intelligentsia, persuading other artists to devote their energies to journalism and political propaganda in the cause of the revolution. Among his assistants were the young David Alfaro Siqueiros and José Clemente Orozco, who later became Mexico's best known painters. Prior to the Mexican revolution, many artists and writers had felt intellectually oppressed, forced to admire the foreign and to scorn the native and the ordinary. With the revolution, they were able to share these feelings and become fully absorbed in the revolutionary movement—and for many, the volcano was a potent symbol. This sentiment is illustrated in the novel *Los de Abajo* (Those from Below) by Mariano Azuela, when one of the characters states: "You ask me why I am still a rebel? Villa, Obregon, Carranza? What's the difference? I love the revolution like a volcano in eruption; I love the volcano because it is a volcano, the revolution because it's the revolution! What do I care about the stones left above or below after the cataclysm? What are they to me?"

Following the revolution, Dr. Atl spent much time exploring and painting the Mexican volcanoes. His interest in volcanic activity was further aroused when Popocatepetl erupted in 1919. He had earlier written of his beloved volcano:

*For millions of years it slept in the silence of death, for millions of years the wind lashed it, for millions of years the forces of nature have tried to destroy it. They closed its mouth, gnawed at its vertebra, they shook its formidable mass and tore its lips which in other times vibrated from thundering eloquence. But one day in its venerable old age, its entrails stirred and from the decayed lips of the Colossus, fire shot forth again. Oh marvellous teaching of nature! Nothing is old and nothing has died: in the end of the Destruction of Life.*

In 1939 he published a monograph on this volcano, *Volcanes de Mexico: La actividad del Popocatepetl*. In it he put forward the curious view that the eruption of 1919 had "acquired an importance of the first order in the history of geology, because it was the result of purely artificial action." Sulfur deposits around fumaroles in the bottom of the volcano's crater had been mined since the 16th century. When the volcanoeros or sulfur miners blasted the fumarole deposits with dynamite, it was apparently Dr. Atl's belief that the dynamite blasting by the volcanoeros had triggered the 1919 eruption. Popular tradition in Mexico claimed that the by-now legendary Dr. Atl lived in a cave in the side of Popocatepetl volcano, where he sustained himself by eating locusts and honey. Legend also has it that he was erupted out of the volcano into this world:

*Subio al Popocatepetl,  
Bajo del Ixtaccibuatl,  
Y es hombre de gran valer  
el inquieto Doctor Atl.*

Dr. Atl also used to good effect the curvilinear perspective in his landscapes and flew in an airplane over his beloved volcanoes to paint them from a new vantage point; a method he called aeropainting. The finest examples of Dr. Atl's aeropainting give a panoramic view of Mexico's most famous volcano, Popocatepetl. Atl uses this extraterrestrial view repeatedly when painting his favorite volcanoes. In a 1960 painting, Popocatepetl pokes its majestic snow-clad crater above the clouds, framed by the curving horizon and the starlit Milky Way. For all its 20th century realism, Atl retains the romanticized vision with which earlier ages viewed volcanoes. He enhances this mood by juxtaposing the volcanoes to our contemporary sublime, the vastness and mystery of the stars and space. The volcano as part of the Earth has become one of the last natural phenomena that we can still awe. In Atl's paintings, there are no small, frightened figures, no evidence of human devastation, no moralizing overtones, just the volcano itself.

During the 1920s and 1930s, Atl dropped out of the

postrevolutionary government of Mexico and began to wander the world, chiefly in the study of volcanoes. When the volcano Paricutin was born in a corn field in 1943, the aging Dr. Atl disappeared from Mexico City and moved to a shack at the foot of the growing volcano and began to paint. He produced 130 drawings, 11 paintings, and a large book on the activity, documenting all stages of its evolution. Births of new volcanoes is a common experience in the history of the Mexican people. In 470 B.C., the birth of Xitle volcano destroyed the Mexican city of Cuicuilco. Again in 1759 the volcano Jorullo was born in the State of Michoacan.

In 1950, Dr. Atl published his observations of the eruption in a unique volume, including a large number of paintings and sketches of the activity, which document the growth of the volcano, in *Como nace y crece un volcán: El Paricutín*. The illustrations in brilliant color capture and preserve the spectacle of the eruption and the artist's excitement in the presence of this awesome display of nature's force. The text includes a detailed chronological description of the eruption and his conclusions regarding the fundamental mechanisms of volcanic activity. He rejects the ideas that volcanic heat is derived from reactions between iron and sulfur or from the combustion of petroleum or indeed the modern concept of heat generation by the decay of radioactive elements. Instead, he proposes that the volcanic energy is residual heat left over from the primitive globe, and only a small amount of additional heat from chemical reactions or from radioactive decay are needed to trigger an eruption. As a fundamental driving force for volcanism, Dr. Atl embraced Alfred Wegener's theory of continental drift: "It is possible to conclude, as a consequence, that this abundance of volcanic structures is due to innumerable fractures caused by continental drift." Atl was not alone in painting Paricutin; his most illustrious student, the famous Mexican painter Diego Rivera, was also fascinated by the activity and created *Volcano Erupting* in 1943.

In *Cráter en Llamas*, we see a full view of the volcano in the height of activity, with fiery fountains of red scoria mixed with black ash clouds billowing out of the crater, while a lava flow creeps along the ground toward the observer (Fig. 12). In *Paricutín Violeta al Amanecer* (1946), the activity produces mostly ash-fall to one side of the volcano with the entire landscape draped by a uniform layer of gray ash. In *Falda Incendiada del Paricutín* (1948), the lava flow creeps forward, oozing red hot molten lava at its base. The waning phase of the eruption is shown in *Paricutín en Erucción* with a wispy black plume of ash rising from the crater. These paintings dominate the materials, colors, and movements of the volcano, but

FIGURE 12 The painting *Cráter en Llamas* (Crater on Fire) by the Mexican artist and volcanologist Dr. Atl shows the Paricutín volcano in 1943 in the height of activity.

the artist uses the expressive qualities of the paint to render the scene as experienced by human eyes rather than with the objective clarity of the camera.

In *Paricutín en Noche Estrellada*, we see the eruption from a vantage point characteristic of Atl's works. As if gliding by Earth in a spaceship, hundreds of kilometers above the planet's surface, we have a full view of the erupting volcano against the strongly curved horizon of the planet in the background.

## XII. THE MODERN VOLCANO LANDSCAPE

Until Mount St. Helens reminded us of Nature's fury, strength, and indifference in 1980, our modern fears had been those we created ourselves—wars and the horror of nuclear devastation. What most Americans had forgotten was both the power and beauty of natural cataclysm, the coming together of earth and sky, brilliant color contrasted with uniform gray, the sight of all those trees laid flat in parallel lines, and the emotional impact of

lives disrupted or gone. Artists like Dr. Atl had followed earlier painters in giving form to these observations so that we can appreciate and understand volcanoes as both real phenomena and as symbols of our own states of mind and emotions. Toward the end of the 20th century, a new interest is emerging among artists in capturing on canvas the spectacle of volcanic eruption.

In the 1980 painting *First Continental Eruption* by Chicago artist Roger Brown, the residents of two high-rise apartment buildings gaze out their windows at the erupting volcano and its billowing clouds of ash (Fig. 13). The painting cleverly expresses the surprise of the American nation over this volcanic eruption in their own backyard, and the effrontery of Mount St. Helens volcano to intrude into their lives in the spring of 1980. After all, volcanic eruptions belonged to Hawaii and Italy and were definitely not part of the safe continental scene! In this painting, the stylized volcano is erupting a black plume which rises sinuously like smoke toward the sky. The nasty-looking eruption plume spreads horizontally on top, with black to gray mammary-like clouds of ash and steam marching across the sky and fading in the distance. At the tip of the volcano is a red hot flame which feeds the black smoke plume rather like the flame which continuously burns off waste products at an oil refinery. The artist has reached back to the Middle Ages in his interpretation of volcanic activity, when eruptions were thought to be the burning of combustible rocks

in the earth. Roger Brown's paintings have been grouped with the art movement of the 1980s referred to by some as Survival Art. The politics of survival in his paintings address the idea of a definitive upheaval from which none will escape, such as in this volcanic eruption. The gloom is, however, tempered by a jazzy, parodic idiom with a vaudeville touch. In *Mania* (1984), the American artist Robert Hawkins conveys a dark, whimsical view of reality. Hawkins often selects the most menacing gifts of nature and blows them up to a frightening scale. In his aerial view of a volcano, the active crater has an inner pool of glowing, steaming lava, while several rows of volcanoes spew out ashes in the background.

The contemporary American artist Bill Sullivan has the temerity to take on the panoramic tradition of 19th century American art. Like his 19th century predecessors Church and Heade, some of Sullivan's pictures have been inspired by the volcanoes of the Ecuadorian Andes, particularly Cotopaxi. In painting volcanoes, he plays with the theatrical qualities of the subject, heightening it with extravagant color combinations and a sense of elegance that keeps his work from turning into kitsch. In the *Last Refuge*, the painting is of Cotopaxi, the highest active volcano on Earth, and the Lord of Terror of the Incas. The volcano is framed between snow-covered rocks, across a vast gray plain. Cotopaxi is almost completely covered with snow, and a full moon breaks through the clouds, punctuating the majestic stillness.

In 1985, the Museo di Capodimonte in Naples in Italy mounted an exhibition of the work of American artist Andy Warhol, commissioned especially on the theme of *Sterminator Vesuvio* or Vesuvius the exterminator. The hallmark of Andy Warhol's Pop Art was to take a mass-media image out of context, be it a soup can label or a photo of Marilyn Monroe, and to formulate a new meaning for it. An erupting Vesuvius is such a well-known artistic icon that it too approaches a mass-media image. In 1980, Warhol spent some time in Naples and returned in 1985 to work on the image of Vesuvius and transferred it to his realm of fantasy. For Warhol, a Vesuvius "eruption is an overwhelming image, an extraordinary happening and even a great piece of sculpture." His product from the stay in Naples was a great one: 16 hand-painted canvases and 26 silk-screen images of Vesuvius erupting, each one developing a highly distinctive color scheme. The basic image of an eruption is nearly identical, however, with the symmetrical cone of Vesuvius rising out of the ruins of Monte Somma, whose ragged outline is apparent on the left (Fig. 14). Warhol could not witness a Vesuvius eruption—the last one was in 1944—but he has created a very powerful and fiery Plinian eruption, probably based on his impressions

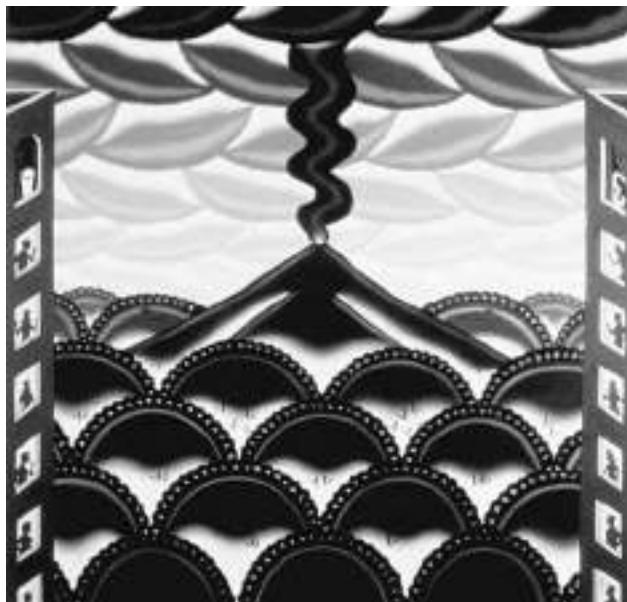

FIGURE 13 The 1980 painting of the *First Continental Eruption* by American artist Roger Brown was inspired by the Mount St. Helens eruption.

from the widely distributed photographs of the great 1980 eruption of Mount St. Helens in the state of Washington, or from the common images of erupting Vesuvius by Pierre Jaques Volaire and his contemporaries in the late 18th century.

### XIII. ARTISTIC ILLUSTRATION

Pictorial representation of volcanoes, eruptions, and other geologic phenomena is found in the domain of the artists and illustrators of books and media as well as among the works of geologists. A spectacular example of an early volcanic illustration is the Japanese color woodcut of the July 1783 eruption of Asama in Japan, which resulted in a large loss of life and was associated with the Ten-meい famine (Fig. 15). Earth science has a visual language, which relates to the communication of ideas and information between geologists by visual materials, especially maps, diagrams, and landscapes. Geologists are not only concerned, however, with the visual representation of topography but also with the penetration of the topography to form a three-dimensional picture of the structure of Earth. The main medium for geologic illustration in the 18th century was the copper engraving, which provided an excellent means of reproducing several hundred copies of the kinds of illustrations presented in early texts on the subject of Earth. The process was, however, very expensive, and only rarely was it used to its full effect. However, the copper engraving was a complex process, consisting of several steps, that could result in a finished product

significantly different than that conceived by the naturalist who commissioned the illustration. Between the naturalist and the reader stood not only the artist but also the engraver and printer. Few scholars who explored volcanoes were in the position of William Hamilton (1776–79), who had at his disposal a fine artist Pietro Fabris. At the request of Hamilton, Fabris lavishly illustrated his volcano monograph *Campi Phlegrei* and showed the volcanic features of Vesuvius and other craters in southern Italy in superb hand-colored engravings (Fig. 16). He is also the only artist who has turned humble rock specimens of obsidian, lava, and sulfur into pure works of art.

In the early part of the 19th century, the invention of lithography had a far-reaching impact on geologic illustration, as it cut out the engraver as a middle man between artist and printer and enabled greater precision, a finer shading, and more subtle expression of detail. Lithography began to be exploited widely for scientific purposes in the 1820s, and it had the great advantage of being much cheaper than copper engraving, and thus allowed authors to illustrate their publications relatively lavishly. In the 18th century, an artistic tradition of realism had developed in the presentation of geologic landscape. In a way, this may be related to the development of Neoclassical movement in art, which encouraged a realistic and clear landscape style, although the Neoclassical artist would be generally scorned for painting an identifiable scene and, therefore, preferred to invent one that suited that overall composition. Similarly, the depiction of wild mountain landscapes was a common theme adopted by the artists of the Romantic movement, but they generally exaggerated the vertical

FIGURE 15 A contemporary Japanese color woodcut showing the great July 1783 Asama eruption, which took many lives, both as a result of pyroclastic flows as well as a famine. (Also see color insert.)

**FIGURE 16** In 1768 the Neapolitan artist Pietro Fabris illustrated the great Italian volcano monograph *Campi Flegrei* for William Hamilton. Among the illustrations is this colored engraving of Stromboli erupting. (Also see color insert.)

scale greatly in order to heighten the Romantic impact of the work, with little regard for realism or accurate representation of the actual landscape. Therefore, the accurate representation of topography or landscape was looked upon with undisguised scorn by the principal spokesmen of 18th century art; consequently, most of the illustrators of geologic and other natural history subjects were from a socially humbler level of documentary topographical drawing and painting. The topographic art or accurate prepresentation of landscape was referred to by Henry Fuseli as "that last branch of uninteresting subjects, that kind of landscape which is entirely occupied with the tame delineation of a given spot." Similarly, Thomas Gainsborough declined to paint "*real Views* from Nature in this country." Thus topography was held in very low esteem by academic artists, and Twyman, for example, argued that "the whole concept of the picturesque is at variance with the needs of topography." Fortunately, this was not the view of all artists, and we are thankful to them for bringing us several wonderful and informative views of the volcanic eruptions of the past.

## I. INTRODUCTION

Volcanoes are terrifying, sublime, and awesome, and their eruptions represent the ultimate exterminator. It is therefore natural that they have been frequently used in literature and film, both as a metaphor and as a plot device. In one of the better if lesser known novels, *Gentlemen in England*, the potency implied by erupting volcanoes allows the Victorian volcanologist to win over the younger woman he is courting. In the most famous volcano film, Rossellini's *Stromboli*, the erupting volcano is used as an image of the despair felt by the young bride, unwelcome and trapped in a foreign society on a tiny island.

This chapter reviews several of the principal works of fiction and film that feature volcanoes and their eruptions. Many of the novels and films are based on or strongly influenced by historical eruptions, whereas others are in the genre of science fiction or fantasy, such

as the pioneering work of Jules Verne in *The Journey to the Center of the Earth*. The various works differ dramatically in how accurately they portray volcanoes and volcanic eruptions. Some novels and films attempt to portray volcanoes in a credible, realistic way. For example, *Juan of Paricutin* was written by a geologist and can be considered a mostly historical account of the eruption. Authors of some other novels have taken considerable care to describe volcanoes in a realistic light. Some authors, such as Jules Verne, present scientific views that are no longer accepted, but their novels reflect the prevailing thinking of their times. Other authors use the power and fury of volcanoes purely for dramatic effect, and their works can only be considered fantasy.

Most films that prominently feature volcanoes unfortunately fall into the fantasy category or, as they are known in the industry, "disaster movies." Yet even these differ in their attempts to present reality; for example, the 1997 film *Dante's Peak* portrayed well the difficult decision of whether or not to evacuate a threatened town—a dilemma that is often faced by volcanologists and public officials, but little known to the general public.

The volcanoes that have most often inspired works of fiction are those that either erupt frequently, such as Kilauea in Hawaii, or those whose eruptions brought tragedy to the people living near them, such as Vesuvius in A.D. 79, Krakatau in 1883, and Mt. Pelee in Martinique in 1902. All these events are major catastrophes that

still capture the imagination of the public and are rich, exciting themes for stories about the interaction between volcanoes and the people who live around them.

The authors acknowledge that the literary works discussed here are predominantly from Western sources and in English, and that the volcano-related literature from the volcanic regions in Russia, Japan, the Philippines, Indonesia, and other parts of Asia, as well as Africa, are as yet largely unexplored.

## II. PRE-20TH CENTURY NOVELS

Probably the earliest Western novel that features volcanic activity is *Montalbert*, a Gothic novel by Charlotte Smith (1795). The heroine Rosalie undertakes a journey from England to Italy, where she witnesses the activity of Etna volcano and is captivated by its sublime beauty and force: We are never surprised at the sight of a small Fire that burns clear, and blazes out on our own private Hearth, but view with Amaze the celestial Fires, tho' they are often obscured by Vapours and Eclipses. Nor do we reckon any thing in nature more wonderful than the boiling Furnaces of Etna, which cast up Stones and sometimes whole Rocks from their labouring Abyss, and pour out whole Rivers of liquid and unmixed Flame.

### A. The Last Days of Pompeii

The first major novel that features a volcano as a central theme is *The Last Days of Pompeii* by the English writer George Bulwer-Lytton (1803–1873). The novel, dealing with the catastrophic eruption of Vesuvius in A.D. 79, was first published in 1834 and became an immediate and spectacular success, with numerous editions published up to our day. It is a work that is based upon substantial research by Bulwer-Lytton in Pompeii and Herculaneum and elsewhere around the volcano. The novel is particularly important because the author attempts to describe the volcanic processes on the basis of the eyewitness report of Pliny Younger, it is thus the earliest recreation of a volcanic eruption.

Bulwer-Lytton's novel coincides with the rise of awareness for volcanoes among the European intellectuals. It is virtually certain that he was aware of the volcanological research of his British contemporaries, such as the experiments of Sir Humphry Davy (who gave frequent popular lectures on volcanoes in London) and the pioneering field work of George Poulett-Scope on

the volcanoes of Central France, as well as the writing of Charles Lyell.

The author with his wife arrived in Naples in 1832 to spend a winter abroad and to write. He explored the ruins of Pompeii and Herculaneum with the guidance of the archaeologist Sir William Gell, whose major work *Pompeiana* (1852) described in great detail the topography, edifices, and ornaments of Pompeii.

Bulwer-Lytton got the idea for the subject matter of the Pompeii novel—and the title—from the painting *The Last Days of Pompeii* that he had seen in the Brera Gallery in Milan. This was the huge 1831 work of the Russian Karl Bryullow. In Italy, Bulwer-Lytton pored over literature sources about Vesuvius volcano, the eruption of A.D. 79 and the Roman cities, reading Vitruvius, Strabo, Livy, Tacitus, Seneca, and Dio Cassius, as well as the letters of Pliny Younger. He returned to England in 1833, after having written most of the novel in Naples.

While exploring Pompeii, Bulwer-Lytton heard a suggestion that during the blackness in the city at the time of the eruption, a blind person would have a better chance of escape than one who had full sight. This remark led to the creation of Bulwer-Lytton's blind flower girl Nydia, the main heroine of the story, who leads her friends to safety in the total darkness beneath the eruption cloud (Fig. 1).

The novel has been justly criticized for turgid oratory and lush style, pseudo-poetical excesses, pretentious striving for wit and profundity, melodrama, ham philosophy, and moralizing. These are said to be features of style that match well Bulwer-Lytton's personality: ostentation, pomposity, and hauteur. Still, *The Last Days of Pompeii* triumphed over all its deficiencies, and made an immediate and spectacular conquest of the readership, becoming by far the most popular of all Bulwer-Lytton's works. His accuracy to history was justly praised, as was his description of Pompeian life and architecture. In this sense, the novel is one of the great recreations of the past. Perhaps the novel's most notable achievement is in the mounting suspense of its plot, beginning as a dark cloud hangs over the summit of Vesuvius. It reaches a climax in the last scenes of the earthquake and the eruption, with terrified crowds, crashing buildings, darkness, the falling of hot rocks and ash over the city, destruction, and chaos.

The threat of Vesuvius is gradually brought into the story and is used effectively to create suspense. Early on in the novel, the young lovers Ione and the Greek Glaucus are discussing the enigmatic Egyptian Arbaces:

*"His calm, his coldness," said Ione, evasively pursuing the subject, "are perhaps but the exhaustion of past*

FIGURE 1 The blind Nydia leading Glaucus and Ione to safety out of Pompeii during the eruption of Vesuvius in A.D. 79 (from the historic novel *The Last Days of Pompeii* by Bulwer-Lytton, 1850 edition).

sufferings; as yonder mountain" (and she pointed to Vesuvius), "which we see dark and tranquil in the distance, once nursed the fires forever quenched." They both gazed at the mountain as Ione said these words; the rest of the sky was bathed in rosy and tender hues, but over that gray summit, rising amidst the woods and vineyards that then climbed half-way up the ascent, there hung a black and ominous cloud, the single frown

of the landscape. A sudden and unaccountable gloom came over each as they thus gazed....

Bulwer-Lytton even makes an attempt at a volcanic hazard assessment when he describes the population sprawl up the slopes of the volcano:

Villas and villages stretched on every side up the ascent of Vesuvius, not nearly then so steep or so lofty as at

*present. For as Rome itself is built on an exhausted volcano, so in similar security the inhabitants of the South tenanted the green and vine-clad places around a volcano whose fires they believed at rest forever. From the gate stretched the long street of tombs, various in size and architecture, by which, on that side, the city is yet approached. Above all, rose the cloud-capped summit of the Dread Mountain, with the shadows, now dark, now light, betraying mossy caverns and ashy rocks, which testified the past conflagrations, and might have prophesied—but man is blind—that which was to come!*

The fact that the residents of Pompeii may have noticed some atypical behavior of the volcano is brought into the lovers' conversation. "Could that mountain have any connection with the last night's earthquake? They say that, ages ago, almost in the earliest era of tradition, it gave forth fires as Etna still. Perhaps the flames yet lurk and dart beneath?" Bad omens continue: "From the summit of Vesuvius, darkly visible at the distance, there shot a pale, meteoric, livid light—it trembled an instant and was gone." An earthquake from Vesuvius later saves the hero Glaucus, as he is about to be killed by the villain Arbaces the Egyptian, who also lusts for Ione: "... at that awful instant, the floor shook under them with a rapid and convulsive throe,—a mightier spirit than that of the Egyptian was abroad!"

The suspense continues as, on the last day of Pompeii, Arbaces is visited by an old hag, a witch, who comes to warn him of the evil that hangs over the city. Living in a cavern under the volcano, she has been able to witness a great change in the nether world, with hissing and roaring and an intensely luminous glowing red stream within the cavern. The witch plans to cross over to safety in the city of Herculaneum, and urges Arbaces to do likewise.

Glaucus is saved once again by the volcano on the city's last day. Arbaces has framed Glaucus for murder, and the Greek hero is sentenced to go before the lions in the Amphitheater that fateful day, armed only with a dagger. In a suspenseful scene, the grating is lifted and the lion jumps into the arena. But miraculously it shows no interest in attacking Glaucus, which the crowd takes as a proof of his innocence. Glaucus is saved by a witness, who pins the crime on the Egyptian. "Arbaces to the lion!" screams the crowd, and rushes in to throw him into the arena. Arbaces has noted, however, that the volcano has become active:

*"Behold!" he shouted with a voice of thunder, which stilled the roar of the crowd; "behold how the gods protect the guiltless! The fires of the avenging Orcus*

*burst forth against the false witness of my accusers!" The eyes of the crowd followed the gesture of the Egyptian, and beheld, with ineffable dismay, a vast vapor shooting from the summit of Vesuvius, in the form of a gigantic pine-tree: the trunk, blackness,—the branches, fire!—a fire that shifted and wavered in its hues with every moment, now fiercely luminous, now a dull and dying red, that again blazed terrifically forth with intolerable glare! "... an instant more and the mountain-cloud seemed to roll toward them, dark and rapid, like a torrent; at the same time it cast forth from its bosom a shower of ashes mixed with vast fragments of burning stone! It was sudden and more ghastly Night rushing upon the realm at Noon!"*

In describing the next stage of the eruption, Bulwer-Lytton takes the common view that mud flows overwhelmed the cities around Vesuvius: "Amidst the other horrors, the mighty mountain now cast up columns of boiling water. Bent and kneaded with the half-burning ashes, the streams fell like seething mud over the streets in frequent intervals."

Bulwer-Lytton describes the climax of the eruption by citing Pliny's Letters in footnotes, in what is perhaps the earliest (1834) volcanological interpretation of the eyewitness account:

*The cloud, which had scattered so deep a murkiness over the day, had now settled into a solid and impenetrable mass. It resembled less even the thickest gloom of night in the open air than the close and blind darkness of some narrow room.... Sometimes the cloud appeared to break from its solid mass, and, by the lightning, to assume quaint and vast mimicries of human or monster shapes, striding across the gloom.... The ashes in many places were already knee-deep; and the boiling showers which came from the steaming breath of the volcano forced their way into the houses, bearing with them a strong and suffocating vapor. In some places, immense fragments of rock, buried upon the house roofs, bore down along the streets masses of confused ruin, which yet more and more, with every hour, obstructed the way....*

Glaucus and Ione escape the horror of the eruption with help from their friend and guide, the blind Nydia, who alone can find the way in the total darkness below the eruption cloud. They reach the shore and find safety on a boat at sea: "Meanwhile the showers of dust and ashes, still borne aloft, fell into the wave, borne by winds, those showers descended upon the remotest climes, startling even the swarthy African; and whirled along the antique soil of Syria and of Egypt." Here Bulwer-Lytton cites, in a footnote, the writings of Dio Cassius as evi-

dence for the ash fallout in Africa and the Levant. At the very end of the novel, Nydia, unable to attain the love of Glaucus, slips out of the boat and into the sea while the lovers sleep, and drowns below the waves.

In a footnote, Bulwer-Lytton discusses the various theories that have been advanced for the mode of destruction of Pompeii. He adopts the one "... which, upon inspecting the strata, appears the only one admissible by common sense; namely, a destruction by showers of ashes, and boiling water, mingled with frequent eruptions of large stones, and aided by partial convulsions of the earth. Herculaneum, on the contrary, appears to have received not only the showers of ashes, but also inundations from molten lava." Where did he get his relatively advanced volcanic ideas? Was he a friend of his geological contemporaries, the pioneer volcanologist George Poulett-Scope and the geologist Charles Lyell? Although he is close to the mark on Pompeii, his assertion that lava flows inundated Herculaneum, on the contrary, is of course wrong and is probably based on the misidentification of the outcrops of consolidated pyroclastic flow deposits in that city as lava flows.

## B. The Crater

The American author James Fenimore Cooper, famous for his *Leatherstocking Tales*, published a novel *The Crater, or Vulcan's Peak*, in 1847. The story begins in the style of Robinson Crusoe, with a shipwreck on a desert island. The hero is Mark Woolston, who becomes a sailor for the East India trade in 1793. Between voyages, he marries his childhood sweetheart and then sails again for the Pacific Ocean, now as first officer on the *Rancocus*. The vessel is shipwrecked, and the only two survivors land on a reef-fringed volcanic island, which Cooper describes in considerable geologic detail. Mark and his companion Bob take advantage of the volcanic formations in many ways, using hollows in the lava as water catchment cisterns, the good soil inside the crater as a natural garden in fertile volcanic ash, and the sheltered crater as their home. Bob is driven off to sea in a small boat during a storm and feared lost, but Mark continues to eke out a living in solitude on the volcanic island for many months.

One day Mark wakes up to terrifying tremors and a violent volcanic eruption, with suffocating gases. Smoke and ashes fill the air. A large part of the surrounding reef and his island has been thrust up above the surrounding sea, by a sudden elevation of the Earth's crust. The volcanic outburst came from a new crater offshore. A new mountain—Vulcan's Peak—has risen overnight

to at least 1000 feet above the ocean. Mark climbs the new mountain and sees other islands in the distance and, much to his joy, a boat approaching, with Bob, a native from a distant island, and a group of new settlers. Bob had returned to America and had told the news of their shipwreck. Then he returned to the Pacific in the company of Mark's wife and several other settlers—the Craterinos. Soon a virtual Utopia is established on the new volcanic island and they begin to multiply, ruled by the author's concept of the ideal government (Scudder 1947). Years later, Vulcan's Peak sinks back into the ocean, and their Utopia is destroyed in a catastrophe, leading to disintegration and physical destruction of the Craterinos.

*The Crater* is a story of survival by courage and ingenuity, with precise description and explanation of many geological phenomena. The central scientific idea of *The Crater* is the Craters of Elevation theory of the German geologist Leopold von Buch (1774–1853). He was probably the most illustrious student of the arch-Neptunist Leopold Werner and one of the most traveled of all field geologists. Von Buch proposed a volcanic origin of oceanic islands from his studies in the Canary Islands in 1815. There he devoted much energy to the study of the form of volcanic mountains and developed his Craters of Elevation theory, which stated that volcanic mountains were thrust up by upheaval of the Earth's crust. Volcanoes, he noted, were generally conical in form, and their strata dipped in all directions away from the central crater at the summit.

Curiously, he did not recognize that this was due to the pouring out of lava and ash from the summit but attributed their form to uplift, accounting for the craters through the bursting and collapse of a bubble-like mass at the summit. In order to support his theory, he proposed cavernous openings beneath the volcanoes, separated by walls or arches, and hypothesized that these caverns were periodically subject to influx of great quantities of gases and lava. Although von Buch abandoned the Neptunist theory, he never abandoned the Craters of Elevation theory. The theory was shattered, however, by a volcanic eruption in the Mediterranean in 1831, creating a new island variously called Graham Island, Isola Julia, Ferdinand, Sciacca, Corrao among others, depending on the nationality of the namegiver. Charles Lyell was quick to point out that the dip of strata on Graham Island was due to deposition, not upheaval. The island has since disappeared beneath the waves—not by subsidence but rather by erosion.

Cooper's contemporary Herman Melville also featured geology in several of his novels, notably in *Mardi* (1849), *Moby Dick* (1851), and *The Encantadas* (1854), a

tale of the Galapagos Islands. Melville was most likely influenced by the popular and widely read writings of the British geologist Charles Lyell, particularly his *Elements of Geology* (1841). In *Mardi*, the philosopher Babalanja offers his theory of volcanism and the evolution of his island:

*The coral wall which circumscribes the isles but continues upward the deep buried crater of the primal chaos. In the first times the crucible was charged with vapours nebulous, boiling over fires volcanic. Age by age, the fluid thickened; dropping, at long intervals, heavy sediment to the bottom; which layer on layer concreted, and at length, in crusts, rose towards the surface. Then, the vast volcano burst; rent the whole mass; upthrew the ancient rocks; which now in diverse mountain tops tell tales of what existed ere mardi was completely fashioned.*

Foster (1945) has proposed that Melville, with the elevation of strata by “volcanic throes,” was here parodying the Plutonian theory, particularly the ideas of Buffon and Hutton.

### C. Journey to the Center of the Earth

The French writer Jules Verne (1828–1905) is the undisputed founder of the genre of science fiction. *Journey to the Center of the Earth* (1864) was the third in his series *Les Voyages Extraordinaires*, where he spins a tale of high adventure around a credible scientific hypothesis—in this case a geological theory about the physical conditions in the interior of the Earth. Verne was clearly very familiar with the conflicting ideas about the origin of heat in the Earth, which basically reflected the debate between the Neptunists and the Volcanists of the later 18th century. One hypothesis centered on primordial heat in the Earth and predicted a gradual increase in temperature with depth, all the way down to the Earth’s core. The competing hypothesis was that heat in the Earth was superficial and caused by combustion at or near the surface, involving heat-giving reactions of the alkali metals on contact with air and water—a hypothesis championed by Sir Humphry Davy. Verne’s German hero, Otto Liedenbrock, is firmly in the Davy camp and insists that there is no proof that heat increases greatly with depth. He is basically a Neptunist at heart—the typical position of German scholars of his time—but he is always on the lookout for evidence that can support his theory.

The professor is therefore ecstatic when he and his nephew Axel discover a soiled slip of ancient parchment with runic lettering, in a volume of the 12th century

chronicle of Heimskringla by the Icelandic scholar Snorri Sturluson. After much effort, they manage to decipher the message: “Descend, bold traveler, into the crater of Snaefellsjokull, which the shadow of Scartaris touches before the kalends of July, and you will attain the center of the Earth; which I have done, Arne Saknussemm.” The professor and his nephew prepare for their journey and take the first ship to Iceland, in order to reach the volcano’s summit before the kalends of July. Upon arriving in Reykjavik, they waste no time in hiring Hans, an Icelandic guide, who is intimately familiar with the terrain and will assist them in carrying their instruments into the bowels of the Earth, including thermometers, aneroid barometer, chronometer, compasses, and Ruhmkorff’s apparatus (based on a Bunsen pile and the bichromate of potash) to give an abundant supply of crucial electric light.

As they approach the glacier-capped volcano, Axel becomes increasingly worried about the prospects of descending into a crater that could erupt at any moment. The professor reassures him and insists that there is no cause for concern, pointing to the widespread fumaroles and jets of hot springs around the volcano: “You see all these volumes of steam, Axel: well, they demonstrate that we have nothing to fear from the fury of a volcanic eruption.” His logic is that:

*At the approach of an eruption these jets would redouble their activity, but disappear altogether during the period of the eruption. For the elastic fluids, being no longer under pressure, go off by way of the crater instead of escaping by their usual passages through the fissures in the soil. Therefore, if these vapours remain in their usual condition, if they display no augmentation of force, and if you add to this the observation that the wind and rain are not ceasing and being replaced by a still and heavy atmosphere, then you may affirm that no eruption is preparing.*

The next day, they climb the volcano and find three chimneys, which are the principal vents of the eruptions of Snaefellsjokull, but the travelers know that only one of these leads down to the center of the Earth. The pointed shadow of the peak Scartaris falls on the middle opening, and they lower themselves into the bottomless pit. The Professor makes geological observations, and after a near-vertical descent of thousands of feet he declares, “The further I go the more confidence I feel. The order of these volcanic formations affords the strongest confirmation to the theory of Davy. We are now among the primitive rocks, upon which the chemical operations took place which are produced by the contact of elementary bases with water. I repudiate the

notion of central heat altogether. We shall see further proof of that very soon."

The travelers are pleased to find that, even at a depth of 1100 feet, the temperature has scarcely increased. They make good progress downward in an inclined lava tube during the next few days, through a succession of fossil-bearing geologic periods. After 20 days, they reach a depth of 16 leagues, at the base of the crust, but the temperature has increased only slightly. Among the wonders conceived by Verne is a subterranean sea in a vast cavern, which the professor promptly names the Liedenbrock Sea. On the shore is a forest of gigantic mushrooms, lycopodium, and other trees from the Carboniferous period. The travelers fashion a raft and set sail across the sea until they are caught in a violent torrent or waterfall that carries their raft instantly to great depths. The torrent reverses direction, and now they are carried upward at even greater speed, and the heat becomes unbearable. The walls of the shaft are burning hot, and the professor concludes that they are being carried up the throat of an erupting volcano! The water column below their raft is replaced by red-hot lava lifting them rapidly up the conduit. Suddenly they are ejected violently from the crater, and, badly shaken but not injured, find themselves lying on the crater rim of an erupting volcano—Stromboli, thousands of miles from Iceland.

---

### III. 20TH CENTURY NOVELS

A large number of 20th century novels feature a volcano, either as a central theme or as a symbol. Perhaps the most famous modern novel that features a volcano in the title is Malcolm Lowry's *Under the Volcano* (1947), which has been referred to as having the best account of a "drunk" in fiction. This modern classic is regarded as one of the major novels of our time, but its relevance to volcanic activity is little or none, except for the memorable title—and perhaps the use of the volcano as a metaphor for the mental and physical hell that the British consul, the novel's main character, descends into. Similarly, don't look for wisdom about eruptions in the massive novel *The Volcano God* by Philip Freund (1959). It is an epic profile of our age and, again, has no relation to volcanism except for the enigmatic title.

Modern novels about volcanoes can be roughly divided into literature and adventure genres, with works in the latter being by far the most numerous. Perhaps the most popular adventure writer of our time, Patrick O'Brian,

puts a volcanic eruption to good use in *The Wine-Dark Sea*. When naval Captain Aubrey is chasing a privateer in the South Pacific Ocean, amazing natural phenomena occur, as the sky turns wine-red, a tidal wave swamps his ship, and violent explosions emerge from the deep. When daylight breaks, they witness the eruption of a new volcanic island, that has devastated their prey with ash fall and bombardment of volcanic ejecta.

The novels in the literary genre often take real volcanoes and their eruptions as a backdrop for the plot but not as the main theme. The 1902 eruption of Montagne Pelee is featured in several of these novels, which is not surprising, considering the strong human appeal of the story. In addition to novels, a few literary accounts of volcanic eruptions have been written. Two very good historical accounts of the catastrophic Pelee eruption are *The Tragedy of Pelee* by George Kennan (1902) and *The Day the World Ended* by Gordon Thomas and Max Witts (1969). Similarly, *Krakatoa* by Rupert Furneaux (1964) is an excellent historical account of the great 1883 eruption. However, in the category of historical accounts of volcanic eruptions, *The Night of Purnama* by Anna Mathews (1965) is unique. Shortly after the author and her husband took up residence in the village of Iseh on the south flank of Mount Agung in Bali, the volcano burst into a furious series of eruptions, producing numerous and deadly pyroclastic flows. Her book is a tense and thrilling account of the impact of the lethal eruption on the Balinese village community, providing much insight on the relationship between the Balinese and their gods—the most powerful of which reside in Agung.

In the theater, a recent work based on the 1902 eruption of Montagne Pelee is the play *The Prisoner of St. Pierre* by Pat Gabridge, which describes the real-life ordeal of the prisoner Ciparis, a black man sentenced to death. When the eruption took place, Ciparis was being held in a dungeon below the city, which protected him from the worst effects of the scalding hot pyroclastic surge. He became the most famous survivor of the catastrophe, and the play describes the hallucinations he experiences while waiting for rescue. Ciparis later made a living by touring in the United States as a member of the Barnum and Bailey Circus. It is perhaps surprising that his fantastic story has not yet been featured as the central theme of a novel or a film.

#### A. The Violins of Saint-Jacques

Patrick Leigh Fermor traveled in the Caribbean after World War II and as a result published *The Violins of*

*Saint-Jacques* in 1953. This beautiful and haunting novel was immediately hailed as a rare and exotic seep of color across the drab monochrome of the postwar years. It is set on a Caribbean island of romantic passion, tropical luxury, and European decadence, and the story captures the delicacy of high society entanglements and the unforeseen drama of the volcanic forces beyond human control.

The narrator first encounters the Caribbean volcanic island in a painting during his visit to the artist Berthe. It is a picture of a colorful town, above which “a tropical forest rises in a cone, hiding to its crater the steep and concave flanks of a volcano from whose blunt apex curled a languid blue-gray banner of smoke.” It is inscribed by the artist and the year 1902. Berthe tells him she had spent 6 years as a governess to the Sheridans, a patrician family on the island of Saint-Jacques, in the shadow of the ever-smoldering Salpetriere volcano.

Every year on the last day of carnival, a great ball was traditionally held in the Count Sheridan household in Saint-Jacques. On this occasion, in the days when preparations were under way for the ball, the Salpetriere had been burning for a week or so with unaccustomed vigor: “Now it hung in the dark like a bright red torch, prompting the island wiseacres, mindful of the terrible eruptions that had coincided over a century ago with the fall of the Bastille, to shake their heads.” The ball is attended by the governor of the island and turns out to be a tremendous success, but it was interrupted by an unexpected event.

*In the middle of a dance, a deep ominous rumble was heard above the notes of the orchestra. A bright flash like lightning drowned the many candle flames for a second with its brighter intensity and a rush of wind filled the curtains in their confining coils of bibiscus and blew them into the ballroom in wavering cylinders. The dancers stopped and looked through the long windows at the top of the Salpetriere where a sparkling fountain of fire had suddenly sprung to a great height in the air; a brilliant red gold needle, whose mounting summit bore all the gazing eyes upwards and then down again as it broadened and lost its shape and subsided. A wide stream of lava burnt its way down from the crater's rim. It looked as if the volcano itself were conspiring with the Count to add lustre to his rout.*

Shortly afterwards, one of the guests remarks: ‘Look, it’s snowing.’ The observation was so unexpected and irrelevant that everybody burst out laughing. And snow was indeed falling. It was that light descent of feather-soft ash that often followed any usual activity of the Salpetriere.

Bethe discovers that the Count’s beautiful daughter, Josephine, has run off with an undesirable suitor, and she suspects they have headed for the harbor, in order to get on the next boat to Paris. She gets a skiff to bring her to the schooner anchored outside the harbor but is disappointed—Josephine is nowhere to be found. While still on the ship, Bethe is startled by

*an incandescent ball of light . . . then two seconds later came a deafening clap of thunder as though the world had been blown in two. The night had vanished. Everything was suddenly brighter than noonday and from the crater of the Salpetriere a broad pillar of red and white flame, thickly streaked with black, was shooting into the sky like the fire from a cannon’s mouth. It climbed higher every second until it had reached a fierce zenith miles up in the air, and the roar that accompanied its journey was interrupted by hoarse thunder claps that almost broke the eardrum. A great wave of heat, as though an oven door had been opened, swept over the watchers on the schooner, and the sea, reflecting the conflagration. Fiery fragments from the centre of the earth were flying through the sky and missiles like jagged lumps of fire, coming apart in their flight as liquidy as sealing wax, fell dripping to the water.*

Bethe sees that in the streets on shore, all is in panic and turmoil, with people leaping onto the water and swarming aboard the boats. A crowd of dancers in flight crowded the terraces around Count Sheridan’s house. After a brief pause, the eruption resumed with a blinding flash,

*followed by something which seemed for a moment, by contrast, pitch darkness. For a black cloud had burst out of the volcano’s flank far below the crater. The fires inside the mountain had blown a new rift which spread upwards towards the steaming chaudières. This jagged, growing tear revealed the inside of the mountain for a blazing fraction of a second before it was obscured by the rapidly swelling volume of a cloud that came rolling and billowing down towards the town, setting fire to everything in its track. At last the entire cloud was growing from the island’s side in a great unfolding rose. It slowly faded again into fire-rimmed blackness and all was opaque and impenetrable. Gently it settled over the town and enfolded the houses and the spires.*

What follows is a scene based entirely on the May 8, 1902, eruption of Montagne Pelee, when ships in the harbor were set afire by fiery hot surges passing over the ocean, while ships further out in the bay were singed,

but limped away to safety. Safe on the schooner outside the harbor, Bethe watches in horror as the citizens are halted in their flight and swept down to the ground by the descending gas cloud that invaded the city when the mountainside opened up. The cloud rolls into the harbor and over the bay, as ships caught on fire. She is terrified that the deadly cloud will reach the schooner, but "The cloud's soft progress over the water halted and its edges began to creep backwards again as though the ghostly mass were drawing in its skirts."

The captain orders all sails set and steers the schooner due west, out of harms way. They look back and see that the island is literally coming apart, with the erupting fissure opening in a fiery yawn. Hills near the coast collapse, sending up a huge tidal wave that wildly tosses the schooner on the sea. Saint-Jacques is sinking into the ocean as the schooner speeds away. Soon only the summit of la Salpetriere remains above the waves, with huge billows of steam around. Then only the crater rim remains visible, with an immense plume of fire, but at last that too subsides into the sea, "and the water flowed in and snuffed it almost in silence."

Bethe goes ashore in the island of Dominica. Soon she finds out that there is not a single other survivor from Saint-Jacques. Ships sailing over the point find not a trace of the island. However, in the following years, the fishermen of Dominica and Guadeloupe claim that they have observed a sign of the vanished town. When they sail over the submerged city at carnival time, they can hear the faint sound of violins coming up through the water. As though a ball were in full swing at the bottom of the sea. They call it "the violins of Saint-Jacques."

### B. The Sleeper of the Moonlit Ranges

In the novel *The Sleeper of the Moonlit Ranges* by Edison Marshall (1925), the native Alaskan Breed Bert from Pavlof village becomes a guide for rich and spoiled Americans in the Alaskan volcanic and rugged wilderness. It is a story that is strongly influenced by the Katmai eruption of 1912 and makes frequent references to the rapidly changing face of the Earth as a result of volcanic activity. Bert and beautiful Grace fall in love, and their journey eventually turns into a deadly love triangle, involving Grace's jealous fiancee Paul. But Pavlof Mountain begins to erupt, at first with a ruddy fountain of lava from the summit crater. The native Alaskans begin a dance to pacify the god of evil in the volcano, and Paul joins them in a frenzied dance. In a trancelike condition, Paul demands that the natives sacrifice both Grace and Bert to the fire god, but they escape—at least

for a while—by running straight up the flank of the volcano. But now they are caught in a vast volcanic outburst, as Pavlof explodes and they loose consciousness in the cataclysm. When they come to, Bert discovers that one side of the volcano has been blown out, the village has been destroyed, and lakes of molten lava are forming in the crater and flowing toward them. The lovers escape miraculously and begin a new life as pioneers of the Alaskan frontier.

Human sacrifices to the volcano gods have been a highly popular topic in a number of other novels, including *The Phantom City* by William Westall (1870), where a young maiden is sacrificed to the fire god in an erupting volcano in the Mayan region of Mexico.

### C. Paricutin

*Paricutin* is a truly historical volcano novel, written by Bernice I. Goodspeed (1945) and published immediately after the birth and growth of Paricutin volcano in Mexico. The central theme of the novel is the mental struggle among the native Tarascan Indians in response to the devastating eruption. It is a struggle over whether to follow the Christian ways and pray or to pay homage to their ancient fire gods and make human sacrifices to appease their wrath. It is thus a story about a people caught at the crossroads of two cultures as they react a natural disaster.

Some of the elders of Paricutin village still secretly worship the fire god Ome Teotl. Thus when Mazatl witnesses an erupting fissure opening up in his field, he

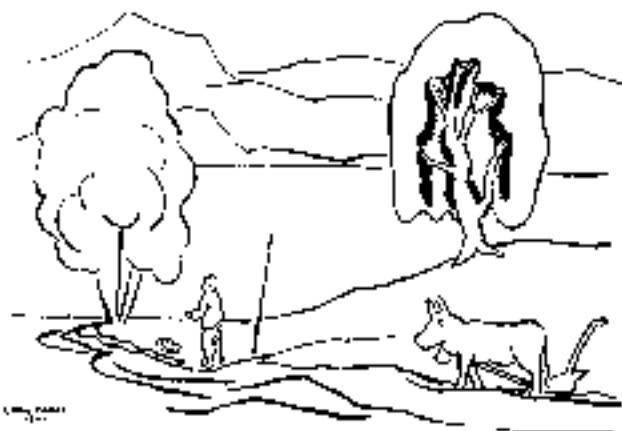

FIGURE 2 When Mazatl plows his field, a fissure opens up in the ground, marking the beginning of a violent eruption and the birth of Paricutin volcano in Mexico. The illustration is from the historic novel *Paricutin* by Bernice I. Goodspeed.

is convinced that someone must have offended Ome Teotl and that more tributes to the god are required (Fig. 2). The priest of their village, however, tries to persuade his people that the eruption is an act of nature, and not due to the actions of the Christian god or of Ome Teotl. But the elders recall the creation of Jorullo volcano nearby, that had severely affected their ancestors. When all prayers had failed at Jorullo, the elders gathered in the temple, and decided that only a human sacrifice would pacify the god of fire. A youth was chosen, and he climbed up the cone to the very brink of the erupting crater, where great tongues of the flames reached out and swept him down into the fiery abyss of Ome Teotl. After a final explosion, the Jorullo crater subsided, and it appeared that their sacrifice had brought them peace.

As the eruption of Paricutin intensifies, the elders become increasingly worried, convinced that the prayers to the Christian god are of little or no value in calming their fire god. Mazatl and his two friends become convinced that only a human sacrifice will save their community from destruction, and select their teenage children, the virgin Zolintzin and young Tochtil, to sacrifice to the flames. They decide, however, that the sacrifice must be made to Popocatepetl—father of all volcanoes—the principal residence of Ome Teotl. The children are convinced that the sacrifice is a necessity and set out on the long journey to Popocatepetl with one of the elders. As they near the crater, the elder is killed in a fall into a canyon, and the frightened youngsters are taken under the protection of an old forester and a Padre in a nearby village. They are torn in a great conflict between the promise they have made to the elders to sacrifice themselves in the volcano crater, and what they hear from the forester and the Padre. Their new guardians gradually convince them that such a sacrifice is not essential for the well-being of their village. The teenagers settle down in the village at the foot of Popocatepetl, marry, and have a child.

Meanwhile, the eruption of Paricutin continues and lavas engulf more fields and villages. Mazatl is now convinced that the sacrifice of his children has been in vain, the ancient god has let him down, and he is heart-broken. The youngsters return to Paricutin one year later, where they are welcomed by all, except Mazatl, the father of Zolintzin, who is furious over the breach of promise of the sacrifice. He then runs up the side of Paricutin's erupting cone to sacrifice himself to Ome Teotl.

#### D. Volcano

As a land where volcanoes are a dominant part of the landscape and often threaten lives and property, Japan

is the source of a number of volcano novels. An excellent example is Shusaku Endo's *Volcano* (1959). In this carefully elaborated Japanese thriller, the aging volcanologist Jinpei Suds and the Catholic priest Dehorned become obsessed by the Akadake volcano. For both, the question whether the volcano is still active or not becomes the overriding concern in their lives. Suds has spent 15 years studying Akadake and is convinced that it is dying. This opinion is very good news to a tycoon who is building a lavish hotel resort on the volcano's slopes. Dehorned is equally certain that the volcano will erupt again, pouring streams of lava down over the religious Christian sanctuary being built at its foot. To Dehorned, the volcano is a symbol of evil and a judgment on the people who cannot understand the significance of sin and redemption: "Akadake is absolutely going to explode. Because evil is a volcano that will never be extinct." To Suds the volcano must remain dormant, or else it will wreck the scientific thesis on which he has spent much of his life and on which the book he is about to publish, *The History of the Eruptions of Akadake*, is based. The book is the result of 15 years of research, with the financial support of the business tycoon.

The novel's volcano has had numerous historical eruptions, the latest at the end of the 19th century, but since Suda's arrival at the observatory, only a plume of thin smoke rises from the crater. Professor Koryama of Kyoto University has declared that this is sign of dormancy; the volcano was stricken with old age: "What a mount of heartache it is. A volcano resembles human life. In youth it gives reign to the passions, and burns with fire. It spurts out lava. But when it grows old, it assumes the burden of past evil deeds, and it turns as quiet as a grave."

Shortly after the ailing Suds is admitted to the hospital, Akadake suddenly explodes:

*It came at high noon, when the people were at lunch. At first they seemed to hear a dull rumble as of distant thunder. Then a sudden ear-splitting detonation. Houses shook, windows rattled. People panicked and ran into the streets, where they beheld a black column of smoke rising into the sky beyond the bay. The top of the column expanded into a shape like the round head on a sprig of cauliflower. They watched the head uncoil.*

The observatory monitoring the volcano stresses that there was no cause for alarm and no imminent danger, even though the eruption was totally unexpected. Investigators report that no tremors of any kind, that might be portents of volcanic activity, have been recorded before the event. They also report that the eruption has not produced any new magma, merely a discharge of gases trapped in the crater mouth. After a few days,

life is back to normal, and it seems as if people have completely forgotten about the event—Akadake appears to have resumed its old forlorn appearance.

Suds had earlier observed that, historically, the volcano has had a peculiar behavior. Successive eruptions always originate at a higher elevation on the flanks than the previous one: It is “an upward moving volcano.” He is relieved when he finds out that the new explosion has taken place from the very top—it is just the last gasp of a dying volcano. This is challenged by a young Tokyo University professor who discovers that the gas emissions include enormous amounts of halogen elements. He predicts the coming of a big eruption at the 900-m level on the volcano’s eastern flank, which would devastate the planned hotel complex. Suds feels humiliated, and his pride is hurt by this novelty hypothesis concocted without evidence by a greenhorn scholar. He reassures the tycoon that all is well; “Everybody wants to publish novel ideas.” “Look it’s safe, I tell you. Akadake is impotent with old age.” When Suds regains some of his strength, he accompanies the tycoon on an excursion to inspect the volcano. They are both pleased to find that the hotel site appears normal and safe—until Suds notices a dead field mouse and withered vegetation. He remains quiet about his find and terminates the investigation, fearing what he might find. A few days later, when he visits the observatory, he discovers to his dismay that ominous tremors have occurred during the night, suggesting an imminent explosion. He returns to the flanks of the volcano, where he finds unmistakable warning signs, such as increased temperature of the ground. Still keeping his findings secret, he returns in silence and in deteriorating health, dying a few days later. His son carries a crock with his ashes to the slopes of the volcano for burial. Shortly afterward, Father De-horned also dies, but a single plume of smoke continues to rise from Akadake. Will it erupt tomorrow, or is it truly dormant? The reader is left to wonder at the novel’s end.

This is a geologist’s novel in many ways. It is full of field observations, historical volcanological data, and lucid descriptions of landscape and Earth Processes. The author Shusaku Endo had great affection for Kyushu Island, the setting for his novel. Thus the city in the novel is based on Kagoshima, and Akadake volcano is inspired by Sakurajima, one of Japan’s most active volcanoes. Sakurajima began as a volcanic island in Kagoshima Bay but joined the mainland in the 1914 eruption. The frequent eruptions have often caused ash fall on the city of Kagoshima, only 8 km from the crater. It is reported that the author’s curiosity about the volcano was so great that he had himself lowered from a helicopter into the Sakurajima crater.

### E. The Volcano Ogre

*The Volcano Ogre* by Lin Carter (1976) is a good example of a bad science fiction/fantasy novel. The action takes place on the slopes of the fictitious Mount Rangatoa volcano on a Polynesian island. In its innards, the volcano harbors a grotesque, humanlike monster, covered with glowing hot lava, who occasionally lumbers out of the crater to threaten the local inhabitants. After the lava devil kills again, the islanders send a plea of assistance to the all-powerful Prince Zarkon and his crime-fighting Omega Crew. The hideous volcano monster, wading through red-hot molten lava as if it were tepid sea water, turns out to be an American geologist, wrapped in protective plastic boron-fiber insulation against the heat of the lava. There is no knowledge of volcanoes to be gained from this novel, although the idea of a geologist as an evil volcano monster is no doubt appealing to some people.

### F. Genesis Rock

In this fantasy novel, Edwin Corley (1980) spins a lively tale about a volcanic eruption in the heart of New York’s Central Park. It is indeed a far-fetched concept but an entertaining story that drops the names of several contemporary volcanologists and makes abundant references to famous eruptions and geological processes. Janet McCoy, a beautiful and brilliant volcanologist who works for the U.S. government, is recalled to New York from Iceland, where she has been studying methods to harness geothermal energy. The reason for Janet’s recall is that she has been picked by NASA for a mission to explore the geothermal energy resources of the planet Mars. Passing through Central Park, she is amazed to come across a chunk of anorthosite lying by the path—a Genesis Rock. In her opinion, it is a very rare rock type that is only found at the surface when hurled out of the Earth by cataclysmic upheavals, such as volcanic explosions. She also finds out that Central Park is riddled with dikes.

A homeless man, who has made shelter in a cave in Central Park, notices hot steam venting out of a fissure in the rock and makes use of it to cook squirrels for lunch. Events unfold as mysterious bubbles of sulfur-rich gases emerge from the lake, and a construction team blasting a subway tunnel through the park encounters steam veins in the solid rock. When a violent steam explosion scalds a worker to death and injures several others, the news spreads rapidly that something very unusual is afoot below Central Park.

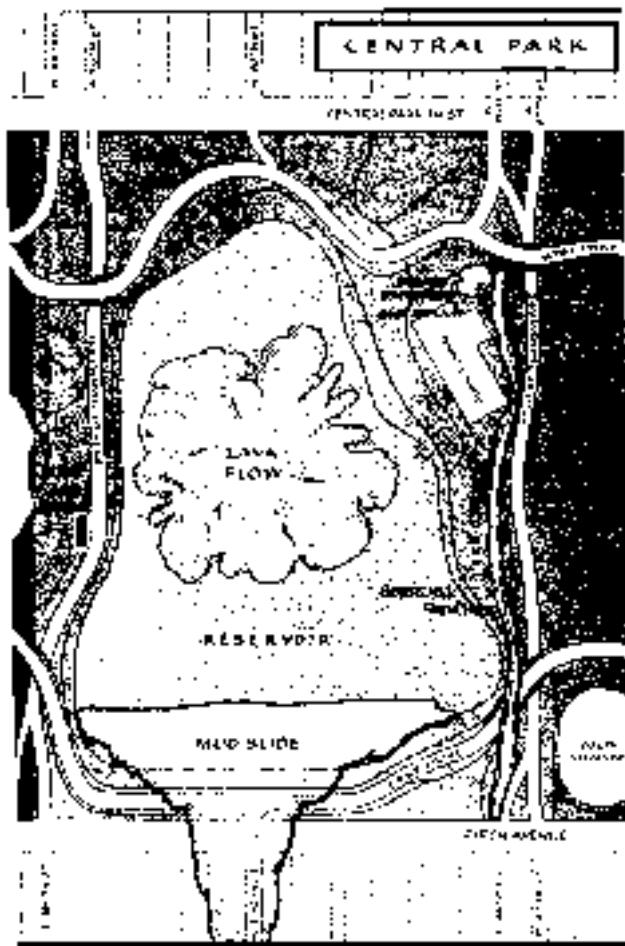

FIGURE 3 In the novel *Genesis Rock*, a new volcano bursts forth in Central Park, New York.

Janet assembles a team of Earth scientists to study this strange phenomenon, and they are startled to find that infrared aerial photos show a "hot" line that strikes from the Baltimore Trench, goes across the continental shelf and terminates near Staten Island. Is this thermal anomaly associated with a magmatic intrusion at depth? Or is it just a stringer from the Gulf Stream? Meanwhile, the fissure erupts again, forming a geyser that shoots up steam to a great height. Janet McCoy informs the mayor that the birth of a new volcano may very well be taking place in Central Park, and that the entire New York region may soon be covered with 4 feet of ash from a Krakatau-size explosion; alternatively, it may result in an Icelandic-type eruption, with widespread lava flows covering the park and large parts of the city. Meanwhile, her geophysicist colleagues are exploring ways to head off a volcanic eruption, possibly with the detonation of a nuclear bomb. They discuss an alterna-

tive scenario of diverting lava flows by pumping water on them, as was done successfully on Heimaey in Iceland in 1973.

The subway tunnel construction crew decides to pump large volumes of water down the fissure to cool things off at depth before they resume drilling—but with disastrous results. "With an incredible belch, the solid rock heaved and began to reject the liquid diet." Several steam explosions occur, ejecting boiling water and superheated steam all over the park and into the city. A thick mudflow rushes down the East Drive and into the East River, resulting in many casualties and destruction of buildings, including the mayor and his residence. Huge fountains of steam and water rise to thousands of feet above the boiling reservoir. When most of the water is dissipated, the top of a glowing lava mass begins to emerge (Fig. 3).

Janet predicts that worse is to come and demands that the city be evacuated before more deaths occur. The president agrees, and, at Janet's suggestion, the Joint Chiefs of Staff plan to bomb the hot vein of magma that runs across the continental shelf to New York with a nuclear device, in order to relieve the pressure below the city. Meanwhile, the reservoir has nearly filled with lava and it is about to burst out of the park. A submarine delivers the nuclear bomb to a spot above the magmatic sill in the ocean floor, and shortly after it is detonated, the magma extrusion rate in the new Central Park volcano slows down to a trickle. Janet McCoy has saved New York City.

The author of this novel came up with an extremely unlikely scenario, but he did some homework, making use of ideas behind the lava diversion in Heimaey in 1973, as well as early bombing of lava flows on Kilauea.

### G. Gentlemen in England

A. N. Wilson (1985) has written a novel of repressed Victorian life and manners, set in London in 1880. *Gentlemen in England* is not a novel about volcanoes, but it features a volcanologist as one of the main characters. The plot centers around young Charlotte, who is courted by the much older Professor Horace Nettleship, an enormously respected volcanologist. She is impressed by the potency that is implied by his fieldwork on volcanoes, and they marry. Soon however, the marriage is in trouble, largely because her husband confines all his passion to the three volumes he is writing about his research. As the plot develops, husband and wife have not spoken privately for 15 years, but keep up the ap-

FIGURE 4 In the novel *Gentlemen in England* (1985) by A. N. Wilson, the volcanologist becomes alienated from his wife and society as his preoccupation with his geologic monographs deepens.

pearance of a happy marriage in public—a caricature of Victorian society. The author makes the perfect statement—indeed the epitaph—of the typical volcanologist: “Volcanoes his expertise, he found out about the world by peering at little pieces of it through a microscope, by hammering little chunks of it, and keeping specimens of it in boxes.” The volcanologist’s alienation from society is also perfectly captured (Fig. 4). The professor is too absorbed in his work: “He has been working on a great book about volcanoes ever since my daughter married him.... All their little holidays as far as I can recollect have been spent in places of particularly volcanic interest.” Soon the professor realizes that his wife does not care for him in the least:

*He toiled at his treatise on volcanoes. In his youth he had explored the earth's surfaces and seen eruptions in Iceland and Mexico. It was the experience of twenty or thirty years which he poured into his three-volume monograph, so there was no temptation of idleness when his study door closed behind him. But the silence had made him into a stranger—not merely to his wife and servant, but also to his children.*

## H. Texaco

Martinican writer Patrick Chamoiseau won the prestigious Prix Goncourt, France’s most celebrated literary award, for *Texaco* (1992), a novel about his French Caribbean island home, written in the French Creole oral storyteller tradition. Like *The Violins of Saint-Jacques*, the deadly 1902 eruption of Montagne Pelee is a subplot within the novel, but here it is seen from the perspective of a former slave. *Texaco* is a mythic history of the rise of the Creole nation in Martinique from its African and French roots. The title refers to a gas station at the outskirts of Fort-de-France, around which a shantytown developed.

Estername Laborieux is born into slavery on a plantation near the city of Saint-Pierre, at the foot of Montagne Pelee. The slaves knew that “... the lumpy mountain overlooking Saint-Pierre was in reality a raging bull.” When slavery is abolished, Estername abandons the plantation and takes up carpentry in Saint-Pierre. Here he meets beautiful Ninon, “with eyes glittering like childhood’s water, eyebrows curving thickly like strange umbrellas, a mouth for smiling, lips more bluish than the skin, and large voracious teeth.” Together, they leave the city and squat on abandoned land in the hills, living the life of subsistence farmers. After a few years, the idyll is shattered when Ninon runs off to Saint-Pierre with a musician. Estername lives on in sadness, and in this daze he did not “see how from time to time the horizon became roaring and how ash from the mountain suddenly floured the land, more and more often, for a longer and longer time.” One morning a huge bang blogodoom shook him into consciousness. He came out of his thousand-year stupor with a ball of hope. His first word upon his return to life was:

*Ninon. Ninon, which he repeated in the general tumult. Manic fleeing shook the Quarter. A fragrance of sulfur, of scorched red-wood, singed life, thickened the air. Each and every one around was screaming, Soufriere has exploded! This rumbling had undone the world. On the horizon, a night that defied the sun was rolling down. Estername went down to City. He wanted to seek, see, save Ninon.*

*On the edge of a hill, my Estername discovered a lump of coal instead of Saint-Pierre. Despite his barbecued heart, it stunned him.... Soon he couldn't take another step forward. His eyes were burning. Even his gray hair burned him. The grass, the trees had withered.... And he moved on and on and on. So that he was the first to enter Saint-Pierre.*

*He walked on like that, not seeing anything any*

*more, so much had he seen. A tide of ash. A deposit of still heat. The stone's red glow. Intact beings stuck to wall corners, going up in strings of smoke. Some were shriveled up like dried grass dolls.*

He went from cadaver to cadaver and examined every blackish thing, but of course he never found Ninon.

The tragedy of Montagne Pelee, so vividly described here, is a recurring theme in novels about the Caribbean. Chamoiseau's later novel, *Solibo Magnificent* (1998), also refers to the eruption, with discussion of Mount Pelee, the ash of Le Precheur, and other geological scenes on Martinique.

### I. The Volcano Lover

In 1992 there appeared a romanticized biography or a historical novel about the life of Sir William Hamilton, by the celebrated American writer Susan Sontag. In this novel, the life of the central character is intertwined intimately with the past and present volcanic activity of Vesuvius. The plot is a well-known tale: Hamilton, an elderly diplomat and nobleman, is the British ambassador to the Kingdom of Naples, where he becomes fascinated by the activity of nearby Vesuvius. His interest in the volcano gradually evolves from amateurish enthusiasm to a fully fledged research project, that culminates in a series of important and lavishly illustrated scientific publications by this first volcanologist. He is tireless in studying the object of his fascination, traversing its lava flows, repeatedly climbing to the fire-spitting summit crater, and facing danger for the sake of more information about the workings of the inner Earth. He collects rock samples and ships them back to England for chemical analysis. When his wife dies, the lonely and aging nobleman begins a relationship with Emma, a young and strikingly beautiful former mistress of his nephew, and soon the unlikely pair weds. The celebrated couple participate in the rediscovery of the cities of Pompeii and Herculaneum, unearthed from the ashes of the A.D. 79 eruption of Vesuvius; the ambassador acquires a fine collection of antiquities, and the wife develops a new performance art form, with her "attitudes" or posing inspired by the recovered Roman paintings. When the great British naval hero Lord Nelson appears in Naples, he is nursed back to health by Emma, and here begins a somewhat scandalous long-term relationship that the ambassador manages to ignore.

*The Volcano Lover* is a formidable romantic biography that is based on meticulous research. All volcanologists are familiar with Hamilton's pioneering work on Vesu-

vius and on the entire volcanic region of Campi Phlegraei in Italy, and it is fascinating to read an account where this historic figure of volcanology is brought back to life in vivid detail.

### J. Swimming in the Volcano

In *Swimming in the Volcano*, a love story and sophisticated political novel by Bob Shacochis (1993), the American economist Mitchell Wilson becomes unwittingly involved in a struggle between two factions of the government of a small Caribbean island, against the backdrop of volcanic activity. The novel's smoldering volcano is Mount Soufriere on the Caribbean island of St. Catherine, and it is of course based on La Soufriere volcano on St. Vincent. The volcano is correctly described as dormant since 1902, with a hot brown lake surrounding a steaming magmatic island in the crater.

In the novel, forest ranger Godfred Ballantyne of the Ministry of Agriculture is dispatched weekly up to the crater to monitor any change in activity. The topographic descriptions of the volcano are excellent, and many details about the monitoring of the Soufriere in the 1970s are brought to life:

*... and then, as though a lid had been pried and removed, the immense bore of the volcano's crater, shattering any sense of human proportion. To Wilson, the scale seemed borrowed from another world—a fantasy land of fire giants, a geography more dreamlike and therefore more threatening than it actually appeared or was. The light spilled into a huge bowl, and they could see across the span of the vent almost a mile to the sheer walls of the opposite side. There was no slope, only a raw precipice of rock that dropped straight for hundreds of feet to the surface of the doomed lake. The interior island appeared incongruous, inappropriate, and trashy, as if somehow and old coal barge had been abandoned here in the eye of disaster, the cargo still smoldering in the hold...*

*Ballantyne checked the water level. Despite a constant replenishment by storms, the level had been receding at the rate of two inches per week for several months, which Ballantyne took for a sign that the core was heating up.*

Because of Mitchell's liberal, leftist leanings and a nonconformist lifestyle, he is viewed with suspicion by the authorities and politicians on both sides. Some suspect that he may have connections with a group of guerrillas that are operating from camps on the remote

flanks of La Soufriere. When Mitchell leads a group of friends on an ill-fated climb of the volcano, they are intercepted by a group of policemen. During the questioning, Mitchell's girlfriend is shot by an unknown assailant—a guerrilla or a government agent? The victim, a Peace Core worker, dies shortly afterward. Mitchell is jailed without trial, but then he is released after the next election.

Although this is not primarily a novel about a volcano or an eruption, the author did his homework on Soufriere, and his descriptions of the volcano and its monitoring are excellent.

---

#### IV. JUVENILE FICTION AND COMICS

Volcanoes are a favorite topic with children and many authors of children and teen-age fiction bring in volcanoes and their eruptions as a subtopic, but rarely are volcanoes featured as a central theme. Probably the best known children's novel to feature volcanoes is *The Little Prince*, written and illustrated by Antoine de Saint-

FIGURE 5 In *The Little Prince* (Antoine de Saint-Exupéry, 1943) the prince is careful to clean out his volcanoes regularly, so that they burn slowly and steadily, without violent eruptions.

Exupéry. First published in 1943, it quickly became one of the world's favorite books. Although written as a story for children, it contains an urgent humanitarian message for people of all ages. Volcanoes are brought into the story as the prince describes his home, the asteroid B-612, to his newly found terrestrial friend. There are two active volcanoes on the asteroid, and the prince finds them convenient for heating up his breakfast in the morning (Fig. 5). He is careful to clean the volcanoes out regularly.

*He also had one volcano that was extinct. But, as he said, 'One never knows!' So he cleaned out the extinct volcano too. If they are well cleaned out, volcanoes burn slowly and steadily, without any eruptions. Volcanic eruptions are like fires in a chimney. On our Earth we are obviously much too small to clean out our volcanoes. That is why they bring no end of trouble upon us.*

The illustration of the Prince, straddling his tiny planet and cleaning out a volcano with a long poker, is an unforgettable image for children and adults alike.

#### A. The Twenty-One Balloons

*The Twenty-One Balloons*, a humorous story by William Pene du Bois (1947), tells of a fabulous voyage around the world in a balloon, undertaken by Professor Sherman from San Francisco in August 15, 1883. The date is important, because his only stop on the journey is on the island of Krakatau. The cataclysmic eruption of Krakatau actually occurred on August 26, 1883. In the story, the professor makes an emergency landing on a small volcanic island, after his balloon is punctured by seagulls. He soon finds out that this is Krakatau, and that it is inhabited by a handful of highly sophisticated American settlers, wealthy beyond belief because they have discovered a fabulous diamond mine under the volcano. The island is ruled by the Gourmet Government, whose motto is "Not new things, but new ways." The only major drawback of the island are the frequent earthquakes and rumblings of the volcano. To avoid earthquake damage, the Krakatoans build their houses on foundations of solid diamond boulders.

The professor settles into a life on the island and joins the Krakatoans in short trips in their own balloon. One trip takes them directly over the crater, where the professor notes that a lake of molten lava seethes in the bottom, emitting clouds of sulfur. The islanders are acutely aware of the danger of living on Krakatau: "This whole island is like a turkey stuffed with nitroglycerin."

**FIGURE 6** In *The Twenty-one Balloons*, by William Pene du Bois (1947), the Krakatoans escape their island in a balloon when the volcano erupts.

As an escape mode for a fast getaway in case of a violent eruption, they have constructed a flying platform to carry the 20 families to safety, lifted by 21 balloons (Fig. 6).

On August 26, during the professor's lecture, a violent earthquake strikes the island, cracking walls and breaking windows. The order is given to all to dash to the balloon platform for evacuation. They take off, but unfortunately the wind carries them directly toward the volcano and over the crater. Here they "were greeted by a roaring swift upward blast of hot air which catapulted the balloon far up into the sky." Trapped above the fiery red crater, they bob up and down on top of the eruption column for the entire night, in hot sulfurous fumes. Fortunately, they eventually drift off the eruption column, toward Java, just before the entire island of Krakatau blows up in a tremendous explosion. A thick blanket of ash settles on the balloon, and the Krakatoans

are deadly afraid that diamonds from the mine will fall and puncture their balloons. They drift away, over the Indian Ocean, the Mediterranean, and Europe. Finally the professor makes a controlled crash of the balloon into the North Atlantic Ocean. This is an unusual novel because it uses a major volcanic eruption as the central theme for a lighthearted story, with delightful illustrations of the volcanic activity.

### B. Juan of Paricutin

The children's novel *Juan of Paricutin* (1953) is unusual in that it was written by a geologist—Marion Isabelle Whitney, who witnessed the eruption and spent considerable time with the local people. Her book can thus be properly regarded as a historical novel. It is a tender and sympathetic story of the hardships that a family in the village of Paricutin experiences as a result of the eruption.

When Juan and his grandparents visit a nearby village, a strong earthquake strikes, swaying the church tower and toppling another tower into the plaza. Rumblings from the Earth and quakes are common during the next few weeks. One day Juan and his family accompany his uncle Dionisio to help him prepare a field. While they get ready, Paricutin village is struck by the strongest earthquake yet. When they arrive in the field, they hear loud rumbling and tremors underground and see a pit opening in the cornfield right before their eyes! A part of the field appears to sink into the Earth, as trails of white smoke curl out of the fissure. A column of black dust rises from the center of the pit, and stones are ejected, as the deep rumble changes to a loud roar. They rush back to the village, where others have seen the activity from afar. An incessant roar comes from uncle Dionisio's cornfield during the night, and a fountain of brilliant red stones plays above the fissure, higher and higher. When morning comes, Dionisio and Juan return to the cornfield and find a terrible sight. A huge cone of rock and black ash had formed around the pit, and the cornfield was ruined. Back in the village, black ash spreads over everything, killing crops and making life nearly unbearable. The volcano grows in height and is up to 450 feet high after 12 days, and it is 1000 feet high after 2 months, still showering the countryside with rocks and dusty ash. Leaves wither on the trees and corn and all other plants die. Their livestock also die in the fields.

Tourists of all nations are now flocking into Paricutin to see the new volcano. Juan's father sets up a stand to sell soft drinks to the thirsty visitors, and the family

manages to eke out an existence on this trade. The roof of their house falls in due to the thick ashfall, and eventually they are forced outdoors to set up tents. Most other villagers flee the area. One day a violent explosion blows the top off the cone, and a new vent opens up on its side, sending out a river of red-hot lava. After the initial fright, Juan begins to marvel at the fascinating spectacle and even at the beauty of sparkling crystals in the cooling lava. Gradually the river of hot lava begins to cover some of the houses of Paricutin village. But the American tourists keep coming, and the demand for bottled drinks is high. Juan's father gets the bright idea of selling the tourists donkey rides to the volcano, which enables his family to survive in the face of the disaster.

One day when young Juan is guiding American visitors, he witnesses a great outbreak of lava which threatens to engulf the rest of the village. Soon the village is totally covered by thick lava, and not even the church is spared—only the church tower stands, sticking out of the black flow. One of Juan's customers, Bill, is a knowledgeable American volcanologist who teaches Juan many things about the workings of the volcano and the nature of the rocks they produce. In turn, Juan tells Bill about the sequence of events during the first day of activity—the birth of a new volcano.

There are some excellent passages in the book that are highly educational for young readers interested in volcanoes. Juan cries over the loss of his village, but he can also see another side of his situation: "I don't like that old volcano. He makes me very unhappy. But he is beautiful."

### C. The Comics

The beauty and excitement of volcanic eruptions make them excellent material for comics. Two notable examples are *The Volcano With Hiccups*, one of the Flintstones stories, and *Donald Duck in Volcano Valley*. *The Volcano With Hiccups* (Horace J. Elias, 1982) is Mount Firepot, about 10 miles outside of Bedrock. It has not erupted for a long time but huffs and puffs a little once in a while. A couple of visitors, masquerading as the Flintstones' "lost cousins" show up in Bedrock for a few days, and, coincidentally, the very day they leave town, the banks are robbed. Fred Flintstone suspects that the robbers have sought refuge and a hiding place for the loot in the crater of Mount Firepot. When he and the police approach the volcano, it huffs and puffs, and spews out rocks, brushes, and 50 suitcases of money!

In *Donald Duck in Volcano Valley* (1973), Donald and

his three nephews acquire a government-surplus airplane for 3. Major Mañana, a stranger from the Latin American republic of Volcanovia, offers Donald 300,000 pezozes for the plane. The major takes them for a test flight to Volcanovia, where they narrowly avoid crashing into several erupting and fire-spitting volcanoes. When attempting to land, however, they end up crashing on the summit of one of the active volcanoes. The situation turns serious when that volcano, Old Ferocio, gets ready to explode. Donald and his nephews get the bright idea to fill the crater with corn in order to stop an eruption. This results, however, in an explosion that spreads a thick layer of popcorn over the entire country of Volcanovia.

---

## V. VOLCANO FILMS

### A. Early Films and Movie "Classics"

It is appropriate that the first volcano film was *The Last Days of Pompeii* (1897), a British silent film inspired by Bulwer-Lytton's novel. Another black-and-white film of the same title but with a different plot was made in 1935, starring Basil Rathbone. This version is notable for its special effects, which are considered remarkable for its time. Italian filmmakers have also worked on this theme, first in the silent film *Gli Ultimi Giorni di Pompeii* (1913) and again in 1960, when writer Sergio Leone and director Mario Bonnard made an Italian-Spanish film with this title, featuring Steve Reeves and Fernando Rey. The theme's appeal is lasting; in 1984 Bulwer's novel was the basis of a television miniseries, starring Ernest Borgnine and Laurence Olivier.

The most important film that relates to a volcano is the American-Italian production *Stromboli* (1950). The film is remembered in part for its artistic merit and in part because of the American establishment's fervently puritanical reaction to the love affair between the actress, Ingrid Bergman, and the film's Italian director and producer, Roberto Rossellini (Fig. 7).

Rossellini wrote the script for *Stromboli*. In 1948, he wrote a personal letter to Ingrid Bergman, then a major Hollywood movie star, about the plot he had conceived: A young and beautiful Latvian woman, victim of the horrors of war, seeks freedom by marrying an Italian soldier. Her simple husband takes her to his home on the volcanic island of Stromboli. Rossellini explains in his letter to Bergman that the Lipari islands consist of seven volcanoes in the Tyrrhenian Sea, with Stromboli

FIGURE 7 A poster advertising *Stromboli*, the movie about a beautiful foreign woman who settles with her fisherman husband on his remote, isolated, and active volcanic island.

continuously active. The islands “earned sad fame during fascism, because it is there that the enemies of the Fascist Government were confined.” On this island, Rossellini wishes Bergman to act out “the life of the Latvian girl, so tall, so fair, in this island of fire and ashes, amidst fishermen, small and swarthy, amongst the women with the glowing eyes, pale and deformed by childbirth, with no means to communicate with these people of Phoenician habits, who speak a rough dialect.” The girl “is stranded in this savage island, all shaken up by the vomiting volcano, and where the earth is so dark and the sea looks like mud saturated with sulfur.”

In April 1949 Bergman, Rossellini, and their film crew boarded a fishing schooner from Sicily to Stromboli. They sailed past Volcano Island, where Anna Magnani, Rossellini’s former mistress, was starring with Rossano Brazzi in the film *Volcano* (1953).

*They crossed the open sea for two more hours before the high cone of Stromboli, smeared with white smoke, rose against the horizon. As the San Lorenzo drew closer, they could stare two thousand feet upward to the black gullet of the live volcano. A semicircle of crimson*

*lava curled like a bloody lip around the smoking cone, and a vast chute of recently spewed pitch-black rock spilled downwards at a steep angle to plunge directly into the bright seas below.*

The crew settled in the small village clinging to the side of the volcano and began shooting a movie. It was not without incident, however. One crew member was overcome by the volcanic fumes and died of a heart attack (Miss Bergman paid the 60,000 lira funeral expenses and set up a 600,000 lira fund for his family).

In her autobiography, Bergman said of Stromboli: “And the volcano . . . the volcano! The first time I had to try to climb it, we slogged for four hours upward. After I climbed for two hours, I just sat down, gasped and said, ‘I’m sorry, I can’t make it.’ But after a rest I did make it, and at the top I could have just lain down and died.” During the filming on the island, a full-scale and highly publicized love affair blossomed between the married star and Rossellini. Puritan America was not yet ready for this display of free love, however, and the establishment attacked the famous actress publicly. On March 14, 1950, the Honorable Edwin C. Johnson of Colorado stood up in the U.S. Senate to introduce a new censorship bill, and began: “Mr. President, now that the stupid film about a pregnant woman and a volcano has exploited America with the usual finesse, to the mutual delight of RKO and the debased Rossellini, are we merely to yawn wearily, greatly relieved that this hideous thing is finished and then forget it? I hope not. A way must be found to protect the people in the future against that sort of gyp . . .”

*Stromboli* may be the only volcano film that can be considered a classic in movie history. However, a recent film that has attained high praise is *Joe Versus the Volcano* (1990), described as a “story of love, lava, and burning desire.” In this light-hearted story by John Patrick Shanley, Joe (played by Tom Hanks) is diagnosed with a destructive brain disease—a brain cloud—and given 6 months to live. A business tycoon makes Joe a peculiar offer: he can have an unlimited expense account, if he agrees to jump into the smoldering volcano of Big Woo on the South Pacific island of Wapuni Woo. The local Waponis believe that there is an angry fire god in the volcano that will destroy their island home in a violent eruption unless they toss a human into the smoldering crater, a sacrifice that must be carried out every 100 years. In return for a volunteer, the Waponis offer the American tycoon exclusive rights to mine bubureau, a mineral that is only found on Wapuni Woo and is essential for the manufacture of superconductors.

Joe agrees to the “bargain,” not realizing that he has

been fooled into believing he will die. He sails off on a private luxury yacht across the Pacific Ocean, with the tycoon's beautiful daughter, Patricia (played by Meg Ryan), as an escort. On the way, the two develop a friendship, are shipwrecked, drift for days atop Joe's expensive luggage, and eventually are washed up on the beaches of Waponi Woo. Patricia declares her love to Joe and pleads with him not to jump into the crater. However, the volcano is showing increasing unrest, and Joe insists on keeping his part of the bargain. Patricia decides to die with him but, as they jump into the crater, a violent eruption ejects them off the island and into the ocean—not only miraculously alive, but again able to use Joe's expensive luggage as a raft. As the lovers float away, they see the island explode and subside into the ocean—and they live happily ever after. *Joe* has become something of a "cult" movie, probably because of its zany plot and dialogue. The theme of a volcano in the South Pacific and of natives who believe in human sacrifice to appease their volcano god has appeared in several other films.

An unusual type of volcano film is Akira Kurosawa's *Dreams*. In 1990 Japan's most celebrated film director, Akira Kurosawa, made a film consisting of a number of short stories, based on the director's dreams. The film was produced by Steven Spielberg, with special effects by George Lucas. Two of the short stories involve volcanoes. *Mount Fuji in Red* is a nightmare about the future, where the meltdown of a nuclear plant causes Fuji to erupt. Six nuclear reactors explode in succession as fireballs rise from the volcano, and a panicked crowd swamps the roads. The "hero" watches Mount Fuji turn incandescent, while multicolored smoke drifts down its slopes. The colored smoke symbolizes different types of radioactive gas. People all around commit suicide by throwing themselves off a cliff. This is followed by a dialogue between the hero, a woman, and an older man about the lies about nuclear plants and their safety. The older man turns out to be one of the plant's engineers, excuses himself politely, and also jumps off the cliff. The hero stands alone, trying to protect the woman and her baby from the radioactive fumes, in vain, as they become surrounded by the colored gas.

In *Demons* the same hero meets tortured souls on the flanks of a volcano. These are men who have survived the nuclear holocaust and are condemned to everlasting pain—they have become grotesque-looking "demons"—and they try to eke out an existence as they regret their past greed and the stupidity that wrecked the planet. There is no direct mention of volcanoes in this short story, but the landscape is clearly volcanic. Monstruous, degenerate plants are growing out of the

ash. Moaning demons roll around in the dirt inside a crater.

## B. Science Fiction and Disaster Movies

Jules Verne's classic science fiction novel, *Journey to the Center of the Earth*, was made into a major Hollywood production in 1959, starring Pat Boone, James Mason, and Arlene Dahl. The novel was the subject of two other films, in 1976 and in 1989, and of a television movie in 1993. None of the versions has been rated particularly highly by critics, although the special effects of the 1959 film were considered impressive for its time. Another volcano film that can be considered a science fiction thriller is *Crack in the World* (1965). The plot centers around a terminally ill villain, played by Dana Andrews, who is tapping geothermal energy from the Earth's interior by detonating a thermonuclear device at great depth. The explosion causes a crack to form that spreads through the Earth's crust and threatens to split the planet in two if not stopped in time. The film's slogan was, appropriately, "Thank God it's only a movie!"

Most other volcano films fall squarely into the disaster movie category. *Volcano* (1942) is a Superman animation movie, where a lethal eruption is predicted on the island of Monokoa. *The Daily Planet* reporters Clark Kent and Lois Lane rush to the scene, and immediately Lois is threatened by hot lava. In *The Devil at 4 O'Clock* (1961), a priest, played by Spencer Tracy, and three convicts land on a South Sea island where a volcanic eruption threatens the inhabitants. The priest and the convicts, one of whom is played by Frank Sinatra, rescue the situation. The epitome of a volcano disaster movie is *Krakatoa East of Java* (1969). The all-star cast, including Maximillian Schell, Rossano Brazzi, and Diane Baker, battle the elements at sea and on land during the Krakatau eruption of 1883. For some reason, the producers could not figure out on which side of Java the volcano sits. The 1980 production *When Time Run Out*, also known as "Earth's Final Fury" is another mediocre disaster movie featuring famous stars, including Paul Newman, Jacqueline Bissett, and William Holden. The theme is a tired one, also seen in *Jaws* and ultimately based on Ibson's *Enemy of the People*: A volcano in a tropical island becomes active, and evil resort developers insist there is no danger. The resort's architect, played by Newman, leads a small party across the island to safety and the resort is eventually destroyed by the volcanic eruption.

The most recent major volcano movies are the 1997

productions *Dante's Peak* and *Volcano*. The two films differ substantially in terms of plot and in how they portray a volcanic crisis. In *Dante's Peak*, a volcano in the Cascades threatens to wake up. The movie producers used three volcanologists from the U.S. Geological Survey as consultants, and the result is a disaster movie that is more true to life than most, although it still uses abundant artistic license. The plot centers around a dashing but brooding volcanologist (Harry Dalton, played by Pierce Brosnan), who believes the volcano is about to blow up; his boss from the Geological Survey, who sees no concrete evidence for an impending disaster; and the town's mayor, an embattled single mother whose kids eventually need to be rescued by the hero. One of the movies' major accomplishments is the portrayal of the difficult decision of whether or not to evacuate a town when the signs of an impending eruption are dubious. Harry's boss points out that evacuation of the town will lead to economic disaster for the residents—even if there is no eruption.

*Dante's Peak* eventually erupts and the usual disaster movie ingredients are brought in. The volcano gives out the widest possible range of products, from Hawaiian-type lavas to an acid lake to a pyroclastic flow. The pyroclastic flow simulation near the end of the movie is very impressive, and several real-life volcanologists have pointed out that it is highly educational. Relatively few people are aware that this type of flow exists and how totally deadly it is.

*Dante's Peak* provoked something of a flurry in the volcanological community, probably because it can be considered the least inaccurate of all volcano disaster movies. It was generally well received by scientists and even reviewed in the scientific periodical *Nature* (Fink 1997). The Harry Dalton character is credible as a volcanologist and will probably be remembered by professionals for his line, "I move around a lot, wherever there is a volcano with an attitude."

The second volcano disaster movie of 1997 was *Volcano* ("the Coast is toast"), a film written by Jerome Armstrong, directed by Mick Jackson (1997). The story seems to be loosely based on the plot from the *Genesis Rock* novel, but transferred from New York to Los Angeles. Like *Genesis Rock*, the principal character is a female volcanologist, and an eruption in the city leads to the growth of a volcano on the streets and brings about a terrifying catastrophe. The main characters, Mike Roark (Tommy Lee Jones) of the Office of Emergency Management and geologist Amy Barnes (Anne Heche), team up to save the city. The plot unfolds as seven men perish in a hot cloud of yellowish sulfur-bearing gas in the manholes below the street. The La

Brea tar pits begin to steam and bubble like a pot on the stove. Mike Roark, investigating the deaths in the manhole, just manages to escape before a hot yellow gas cloud explodes through the tunnel system. "We'd better call a geologist," he says. Here enters Dr. Amy Barnes, driving a Humvee that is a science lab on wheels. She concludes that magma is moving below the city, but the Office of Emergency Management is highly skeptical—until manhole covers start rocketing into the sky, borne on top of columns of white steam, and a huge ball of a fiery explosion from the La Brea tar pits sends white ash fall over the city. A violent volcanic eruption has begun in the heart of Los Angeles. Magma breaks up to the surface, and a thick river of lava flows along the streets, setting fires, choking off traffic, and hindering evacuation. The volcano (later named Mount Wiltshire) quickly grows to 200 feet in height, threatening large parts of the city. Emergency workers build up barricades of cars and earth to try to contain the lava, which begins to form a huge pool. Suddenly Amy has an idea: bring in all available fire trucks, tankers, and helicopters to dump water on the lava pool. It works! A brittle crust begins to form on the lava. The lava diversion idea is used again—this time by the explosive demolition of a large new building. The city is saved as the lava flows harmlessly into the Pacific Ocean.

The lava diversion concept is probably the only credible idea in this movie. Explosives have been used to breach and divert lava on Mount Etna, and the cooling of lava using water hoses was successful in Heimaey, Iceland. Real-life volcanologists were quick to point out that the only real-eruption footage used in the movie was in the final scene, when lava pours into the sea.

The two 1997 movies were welcomed, by the professional community because, despite their artistic license, they succeeded in bringing the potential threats of volcanoes to the attention of the public and, perhaps more importantly, because scientists were portrayed as heroes in both movies. *Dante's Peak* can even be considered generally educational. These and many of the earlier movies contain special effects that are difficult to create—an article in the *New York Times* (1997) discusses how "flowing lava is one of the most difficult illusions to pull off in special effects." Even though the work in creating these effects has to be commended, it is disappointing that the large resources and tremendous creativity available in the movie industry have been limited to making disaster-type films about volcanoes. The fantastic real-life stories of human endurance, courage, and tragedy during volcanic eruptions have not yet been seen in the movies.

## APPENDIX 1: COMMON UNITS AND CONVERSION FACTORS

---

### 1. MATHEMATICAL PREFIXES OF UNITS:

---

<i>Prefix</i>	<i>Symbol</i>	<i>Multiple</i>
tera-	T	$10^{12}$
giga-	G	$10^9$
mega-	M	$10^6$
kilo-	k	$10^3$
hecto-	h	$10^2$
deka-	da	10
deci	d	$10^{-1}$
centi-	c	$10^{-2}$
milli-	m	$10^{-3}$
micro-	$\mu$	$10^{-6}$
nano-	n	$10^{-9}$
pico-	p	$10^{-12}$
femto-	f	$10^{-15}$
atto-	a	$10^{-18}$

---

---

### 2. MEASUREMENT UNITS AND CONVERSION FACTORS:

---

<i>Unit</i>	<i>Conversion factor</i>
<i>Length Units:</i>	
Ångstrom	$1 \text{ \AA} = 0.1 \text{ nm} = 10^{-8} \text{ cm} = 10^{-10} \text{ m}$
nanometer	$1 \text{ nm} = 10 \text{ \AA} = 10^{-7} \text{ cm} = 10^{-9} \text{ m}$
micron (micrometer)	$1 \text{ \mu m} = 10^{-6} \text{ m} = 0.00003937 \text{ in}$
millimeter	$1 \text{ mm} = 1000 \text{ \mu m} = 0.1 \text{ cm} = 0.03937 \text{ in}$
centimeter	$1 \text{ cm} = 10,000 \text{ \mu m} = 10 \text{ mm} = 0.3937 \text{ in}$
meter	$1 \text{ m} = 100 \text{ cm} = 39.37 \text{ in} = 3.2808 \text{ ft} = 1.0936 \text{ yd}$
kilometer	$1 \text{ km} = 3280.8399 \text{ ft} = 1000 \text{ m} = 10^5 \text{ cm} = 0.6214 \text{ mi}$
inch	$1 \text{ in} = 2.54 \text{ cm} = 0.0833 \text{ ft}$
foot	$1 \text{ ft} = 30.48 \text{ cm} = 12 \text{ in} = 0.3048 \text{ m}$

## APPENDIX 2: CATALOG OF HISTORICALLY ACTIVE VOLCANOES ON EARTH

TOM SIMKIN AND LEE SIEBERT  
Smithsonian Institution

This appendix consists of two parts. The first is an alphabetical listing of all historically active volcanoes. Each name is followed by the volcano's catalog number, to facilitate its rapid location in the catalog forming the second and main part.

The catalog is a condensed and updated version of the 129-page "Directory" table in *Volcanoes of the World*, 1994 (see "Earth's Volcanoes and Eruptions: An Overview"; this volume), to which the reader is referred for more information. It is restricted to historical activity (to the start of 1999), and does not include month/day dates, exact vent locations, eruptive characteristics, or precise durations. Sequence is regional, following the numbering system established decades ago by IAVCEI and modified in *Volcanoes of the World*: after a 4-digit subregion number, sequential individual numbers proceed along generally linear volcanic belts. Gaps in the numbering shown here indicate non-historical, Holocene volcanoes numbered in *Volcanoes of the World* but not included in this catalog. Regional sequencing starts in Europe, then moves south and east to New Zealand, generally clockwise around the Pacific, then down the Atlantic from Iceland to Antarctica. A geographic sequence allows the perspective of viewing a wide region's volcano data at once, but readers interested in finding a single, unfamiliar volcano may do so through the alphabetic name index. Noteworthy volcanoes meeting criteria of eruption size, frequency, or fatalities are highlighted in **boldfaced** type (and these are the volcanoes named on the world map making up the inside back cover).

Coordinates (in *italics*) are given in decimal degrees, and elevations in meters above/below sea level. Volcano edifice type follows *Volcanoes of the World* (and "Earth's Volcanoes and Eruptions: An Overview") and subsidiary morphologic features are not included. Unusually large

eruptions, as measured by the Volcanic Explosivity Index, or VEI (see "Sizes of Volcanic Eruptions"; this volume), are highlighted by typography (see header) allowing swift location of these larger events. However, the historical record generally becomes less reliable as one goes further into the past, and many early eruptions are missing from the known record (see "Earth's Volcanoes and Eruptions: An Overview").

Uncertainty is unavoidable in the historical record, and the following conventions are used to display this aspect of eruptive histories. A question mark (?) before a year indicates that the eruption itself is uncertain, while a commercial "at" sign (@) before a year indicates that the location of the eruption is uncertain (it may have been a neighboring volcano). A question mark after a year indicates that the date is uncertain, but if the size of that uncertainty is known it is expressed by a letter code immediately after the year (**a** = ±1 year, **j** = ±10 years, **p** = ±20 years, **t** = ±50, etc). When an eruption is known to have begun sometime prior to a particular year, the "less than" symbol (<) appears after that date. If an eruption was continuing when last observed, but the actual stop date is unknown, then the "greater than" symbol (>) follows the observation date. Volcanoes for which the only historical eruptions are questionable are included in the catalog but appear on the map as the smallest red symbol. Long-running eruptions are shown by a range of years, and when two separate eruptions occur in a single year, that year is listed twice.

The historical volcanic record, in contrast to the instrumentally determined seismic record, is based on human observation. Readers may well know of eruptions that we have missed, so we urge you to contact us with any additions or corrections to the catalog that follows. Such feedback helps us build the more accurate record that will benefit us all.

## VOLCANO INDEX: name with regionally sequenced volcano number

### A

Aa lava flow  
breaching, 297  
channeling and tubing, 297  
definition, 285, 291  
diagnostic features, 295  
energy supply in formation, 299  
evolution, 295–297  
forecasting of behavior  
maximum potential length,  
301–302  
time until front solidification,  
302–303  
topographical control, 303  
interior solidification, 300  
reversibility of formation, 299  
Absorbent, definition, 1271  
Abyssal hill, definition, 383–384  
Accessory mineral, definition, 115  
Accretionary lapilli, *see* Lapilli  
Achnelith, definition, 683  
Acid rain  
biotic extinction role, 1089  
definition, 1035  
volcanic agents, 1041  
Active volcano  
definition, 254

number, 254  
Acute respiratory distress syndrome,  
definition, 1035  
Adakite, definition, 104  
Adiabatic process  
decompression melting, 52, 56,  
135–136, 138  
definition, 55, 133  
Advanced very high-resolution radiometer (AVHRR)  
ash cloud tracking, 1157  
Mount Etna monitoring,  
1178–1179  
Advection  
chaotic, 527  
definition, 527, 835  
Aerial plankton  
colonization of new volcanic habitats, 1063  
definition, 1057  
Aerosol, *see also specific aerosols*  
climate effects, *see also* Climate  
radiation deflection, 939  
stratospheric warming, 939–940  
tropospheric cooling, 940–941  
definition, 2, 931, 997  
direct effects, 931  
global distribution, 937  
indirect effects, 931  
microphysics, 936  
optical depth, 932, 937  
ozone depletion  
Antarctic ozone hole, 941–942  
midlatitude depletions, 942  
overview, 938–939  
Pinatubo eruption effects, 942  
stratosphere, 934, 937–939  
sulfuric acid aerosols in climate cooling, 1086–1088  
volcanic components, 934–936  
Agglutination  
definition, 321  
lava fountains, 324–327  
pyroclastic fall deposits, 566  
spatter, 321  
yield stress in preservation of piles,  
325–326, 329  
Aggregate  
cinder, 1278–1279  
definition, 1271, 1277  
perlite, 1278  
refractory materials, 1279  
A horizon, definition, 1259  
Aircraft, *see* Aviation hazards  
Akrotiri  
architectural sophistication,  
1306–1307  
Minoan civilization

Akrotiri (*continued*)  
 decline following eruption, 1307–1308  
 overview, 1301, 1306  
 Thera eruption reconstruction, 1307  
 tourism, 1295  
 ALARP, *see As low as reasonably practicable*  
 Albedo, definition, 697, 785, 931  
 Alert code, *see Alert level*  
 Alert level, volcano warnings, 1189, 1194, 1196, 1199, 1205  
 Alfisol, definition, 1259  
 Allophane, definition, 1259  
 Amazonian epoch, Mars, 771, 773, 781–782  
 Amphibole, definition, 133  
 Amphitheater, *see Debris avalanche*  
 Anak Krakatau, *see Krakatau*  
 Andesite  
   definition, 219, 463  
   formation, 121  
   magma transport, 229–231  
   volatiles, abundance, 161–162  
 Andisol, *see also Soil*, volcanic classification, 1262–1263  
 definition, 1259–1261  
 Andosol  
   definition, 1259  
   physical properties, 1268  
 Annular flow  
   definition, 237, 447  
   magma ascent at shallow levels, 231  
 Anomaly, definition, 1095  
 Anorthosite, definition, 697  
 Antarctic ozone hole, *see Ozone*  
 Arachnoids  
   definition, 727, 753  
   Venus, 762  
 Arc, *see also Island arc*  
   backarc basins, 105–106, 362  
   continental margin arcs, 103  
   definition, 89, 102–103, 271–272  
   episodicity of volcanism, 277–279  
   extensional versus compressional arcs, 104–105  
   magma production estimation, 276–277  
   mineral deposition processes, 899–900  
   ocean crust creation, 362  
   segmentation, 103  
 Archaeology, *see also Akrotiri; Vesuvius*  
   Catal Huyuk mural, 1308, 1319  
   definition, 1301  
   Ilopango eruption and Maya cultural development, 1308–1309

Mount Arenal, 1309  
 Mount Ranier, 1309–1310  
 Mount St. Helens, Y tephra in archaeology, 1310–1311  
 site preservation by volcanoes, 1302  
 Sunset Crater, 1296, 1309  
 tourism draw to volcanoes, 1294–1296  
 White River ash effects, 1311  
 Arenal  
   archeology, 1309  
   seismic activity in eruption of 1968, 1031–1032  
   tourism, 1289  
 Aridisol, definition, 1259  
 Aristotle, views on volcanoes, 19–20  
 Armalcolite, definition, 697, 700  
 Armored lapilli, *see Lapilli*  
 Arthropod  
   colonization of new volcanic habitats, 1063–1066  
   definition, 1057  
 Artists, volcanoes and related phenomena, 1316–1319  
 Asama, paintings, 1336  
 Ash, *see also Aerosol; Tephra*  
   aggregation, 513, 520–521  
   aircraft hazards, *see Aviation hazards*  
   characteristics, 916–917  
   components, 1155  
   definition, 321, 697  
   monitoring  
    juvenile glass shard morphology, 1155–1156  
    principles, 1153–1155  
    satellite remote sensing, 1157  
    soluble components, 1156–1157  
 Ash-flow deposit, *see also Block-and-ash-flow deposit*  
   definition, 581  
   tuff, *see Ignimbrite*  
 As low as reasonably practicable (ALARP), definition, 1215  
 Aspect ratio, definition, 957, 960  
 Asphyxia, traumatic asphyxia, 1035  
 Assimilation, magma  
   definition, 133  
   oceanic magma, 142  
   subduction zone magmas, 146–147  
 Asthenosphere  
   characteristics, 90  
   definition, 89, 133, 345  
 Atl, paintings, 1332–1334  
 Atoll  
   definition, 383  
   formation, 395

AVHRR, *see Advanced very high-resolution radiometer*  
 Aviation hazards  
   ash damage characteristics, 917–919  
   case examples, 920–921  
   economic impact, 915, 920  
   history, 919–920  
   incidence, 922–923, 929  
   mitigation  
    advisory centers, 928, 930  
    communication, 927, 929  
    monitoring, 925–927, 929  
   overview, 528, 544, 915–917  
   risk areas, 925  
   severity factors, 923  
   size of ash clouds, 923–925  
   trends, 920, 929  
   types of hazards, 919  
 Axial graben, definition, 89  
 Aztecs, volcano mythology, 18–19

**B**

Backarc basin, *see Arc*  
 Basalt, *see also Basaltic magma; Basaltic volcanic field; Flood basalt; Midocean ridge basalt*  
 backarc basins, 106  
 composition and formation  
   continental basalts, 122–123, 125  
   elements, 117, 119  
   island arc basalts, 121–122  
   ocean floor basalts, 115, 119–120  
   ocean island basalts, 120–121, 123–125  
   trace elements, 123–125  
 definition, 41, 219, 345, 697, 1271  
 discovery of volcanic origin, 25  
 melting, 46  
 moon, *see Moon*  
 radiogenic isotope analysis, 128–129  
 Basaltic magma  
   definition, 171  
   definition, 321  
   pressure gradients for flow, 228–229  
   subglacial eruption, *see Subglacial eruption*  
   volatiles, abundance in magma  
   backarc basin basalts, 161  
   continental margin basalts, 160–161  
   flood basalts, 161  
   island arc basalts, 160–161

## INDEX

- midocean ridge basalts, 158–159  
ocean island basalts, 159–160
- Basaltic volcanic field**  
faults, occurrence of vents, 340–341  
origins, 342  
overview of features, 331, 333  
petrogenesis, 341–342  
physical characteristics of selected fields, 332–333  
probability estimation for future eruptions, 337–338  
rationale for study, 332  
spatial patterns in vent distribution, 336–337  
temporal recurrence rates, 333–336  
vent alignment, 339–340
- Base surge**, *see also* Pyroclastic surge  
definition, 945  
volcanic lake hazard, 890
- Batholith**  
definition, 191  
plutons, 192
- Beach**, volcano tourism, 1293–1294
- Bentonite**  
commercial uses, 1277, 1281  
definition, 1271  
deposits, 1277  
properties, 1276–1277
- B horizon**, definition, 1259
- Bimodal volcanism**, definition, 111
- Biota**  
definition, 1057  
volcanic hazards, *see specific hazards*
- Birds**, colonization of new volcanic habitats, 1065–1066, 1069–1071, 1073, 1075, 1078–1079
- Black smoker**, definition, 857, 873
- Blast**, *see* Pyroclastic surge
- Block**  
debris avalanche, 617, 620  
definition, 463  
vulcanian eruptions, 471
- Block-and-ash-flow deposit**  
composition, 592–593  
distribution, 592  
facies associations, 592
- Blocky lava flow**  
breaching, 297  
channeling and tubing, 297  
definition, 291  
diagnostic features, 295  
energy supply in formation, 299  
evolution, 295–297  
forecasting of behavior, 304  
reversibility of formation, 299
- Bomb**, definition, 321, 463
- Bombardment**, definition, 697
- Bore**, definition, 1005
- Bowen**, Norman, petrology contributions, 34
- Breadcrust texture**, definition, 403
- Breccia**, *see* Hyoclastite; Ignimbrite; Pillow lava
- Bridge of the Gods**, geomythology, 1312–1313
- Brinkman number**  
definition, 219  
viscous dissipation effects on magma flow, 225
- Brittle failure**, melt localization and flow focusing, 84–85
- Bromo**, religious significance, 1296
- Bronze age**, definition, 1301
- Bubble**  
definition, 421  
growth, 323–324, 424–425  
magma storage regions, 422–423  
nucleation, 423–424  
volatile loss, 426
- Bubbly flow**  
definition, 237  
magma ascent at shallow levels, 241
- Bulking**  
apparent bulking factor estimation, 613–614  
definition, 601  
lahar transformation, 609–610
- Bunsen**, Robert  
decompression melting contributions, 30  
petrology contributions, 33–34
- Buoyancy**, definition, 835
- 
- C**
- Calalkaline differentiation trend**, subduction zone magmas, 145
- Caldera**  
classification, 653, 658  
climate impact, 659, 661  
definition, 219, 643, 697, 771  
earthquakes, 1024, 1027, 1032  
eruptive processes, 644  
examples  
extraterrestrial, 644  
Fernandina, 646  
Katmai, 646  
Kilauea, 646–647  
Krakatau, 646, 661  
Pinatubo, 646, 661  
Santorini, 645
- table**, 645’  
**Taupo**, 647
- freshwater lakes**, 887–888
- hazard potential**, 658–659, 661
- history of study**, 644–645
- hydrothermal activity and mineralization**, 653
- Io**, 713
- Mars**, 775
- microgravity monitoring**, 1133–1134
- monitoring**, 1173
- postcollapse magmatism and resurgence**, 652–653
- precollapse volcanism**, 647
- size**, 643
- structure and morphology**  
bounding faults, 649–650  
collapse collar, 649  
floor, 650–651  
inner topographic wall, 649  
intracaldera fill, 650  
overview, 647  
subcaldera magma chamber, 651–652  
topographic rim, 649
- subsidence processes**  
chaotic subsidence, 656  
downsag subsidence, 654–655  
funnel calderas, 656–657  
ignimbrite shields, 657  
overview, 653–654, 658  
piecemeal disruption, 655–656  
plate subsidence, 654  
trapdoor subsidence, 655  
volcano-tectonic depressions, 657–658
- Venus**, 757–758
- Campi Flegrei**, gravity monitoring, 1133–1134
- Canali**, *see also* Lava channel  
definition, 727  
**Venus**, 759–760
- Capture front**, definition, 191, 194
- Carbon cycle**  
modeling for volcanic emission variation, 1052–1054  
preindustrial geochemical cycle, 1048–1049  
total carbon on Earth, 1046
- Carbon dioxide**  
annual emission estimates, 1047–1048  
degassing and isotopes, 168–169  
diffuse flank degassing, 813–814  
emission concentration changes over time, 1146–1147

- Carbon dioxide (*continued*)  
 fumarole emission monitoring, 1146–1147, 1149  
 greenhouse warming, 1088  
 hazards, 998–999  
 historic outgassing rates, 1053  
 isotopic analysis, 807, 1047  
 large igneous province outgassing, 1054  
 measurement of outgassing, 1046–1047  
 outgassing rate, 1046  
 pressure-dependent solubility in magma, 169  
 recycling, 1052  
 silicate melts, effects  
   density, 166  
   viscosity, 167  
 solubility in silicate melts, 151–152  
 toxicity, 998, 1000, 1042  
 volcanic lakes  
   artificial degassing, 894  
   content, 887–889  
   release hazard, 891
- Carbon sulfide, stratospheric layer, 934
- Carnivore, definition, 1057
- Catal Huyuk, archeology, 1308, 1319
- Catastrophist, definition, 271–272
- C-band radar, ash cloud tracking, 1157
- Central volcano  
 definition, 283, 771  
 features, 288–289
- Chaotic subsidence, 656
- Chasma, definition, 727
- Chimney, definition, 857
- Chlorine, *see also* Magnesium/chlorine ratio  
 ash components, 1156–1157  
 hydrothermal systems, 869, 871  
 solubility in silicate melts, 153–154  
 subduction, 169
- Chlorofluorocarbons, ozone depletion, 941
- Chondritic rock, definition, 41
- C horizon, definition, 1259
- Church, Frederic, volcano paintings, 1330–1331
- Cinder  
 blocks, 1271, 1280  
 commercial uses, 1278–1279  
 cone, 697  
 properties, 1278
- Classicism, definition, 1315
- Clastogenic lava, definition, 321
- Clathrate, definition, 785
- Clausius-Clapeyron equation, decompression melting, 29–30, 60
- Clay, definition, 1259
- Climate, volcano effects  
 Andisol formation role, 1263–1264  
 atmospheric moisture and plume dispersal, 541  
 caldera impact, 659, 661  
 Etna eruption of 44 B.C. effects, 932  
 flood basalt provinces, 358–359  
 Kuwae eruption of 1453 effects, 932–933  
 mass extinctions, 348  
 Santorini eruption of 1620 B.C. effects, 932  
 sulfuric acid aerosols in cooling, 1086–1088  
 Tambora eruption of 1815, 10–12, 933, 1090–1091
- Clinopyroxene (CPX)  
 definition, 133  
 pressure in formation, 139
- Coagulation, definition, 931
- Coalescence, definition, 321–322
- Cocks tail jet, *see* Tephra jet
- Coextrusion  
 definition, 219  
 magma flow, 230–231, 234
- Cole, Thomas, volcano paintings, 1330
- Colima, ground deformation monitoring, 1128
- Collapse pit, definition, 697
- Collembolan, definition, 1057
- Colles, definition, 727
- Comics, volcano depiction in literature, 1355
- Community, definition, 1057
- Compaction  
 definition, 69  
 magma chamber differentiation, 200  
 melt migration, 70
- Compaction length  
 calculation, 79  
 composition dependence, 72  
 definition, 69  
 melt migration, 71
